HARMSWORTH SELF-EDUCATOR

1906

Vol. V. Pages 3505—4368

A KEY TO THE HARMSWORTH SELF-EDUCATOR

At the heading of each article in the Self-Educator is the number of the group to which the article belongs, and a reference to this key indicates precisely the place of the article in the scheme of the book. This key, therefore, enables the student at any time to understand what has preceded and what is to follow any part of the work to which he may happen to turn.

Group 1.
Agriculture. Beekeeping. Gardening.
Farming. In all its Branches. Dairying. Poultry.
Beekeeping. A Practical and Commercial Course.
Gardening. How to Get the Most out of a Minimum of Land. Gardening for Pleasure and Profit. Market Gardening.

Group 2.
Art. Architecture. Glass. Earthenware. Carving.
Art. Theory and Training. Painting. Sculpture. Architecture (Theory. Styles. Practical Training). History and Ideals of Art.
Glass and Earthenware. Including Pottery.
Carving. Wood. Bone. Ivory. Horn Tortoiseshell.

Group 3.
Biology. Psychology. Sociology. Logic. Philosophy. Religion.
Biology. Including Evolution, Palæontology, Heredity, Anthropology, Ethnology.
Psychology. Including Psychical Research.
Sociology. Including Political Economy.
Logic. The Science of Reasoning.
Philosophy. Systems of Thought.
Religion. History and Systems. Christianity.

Group 4.
Building. Cabinet Making. Upholstering. Fire.
Building. Excavating. Drainage. Manufacture of Bricks, Limes, and Cements. Bricklaying. Clay Wares. Reinforced Concrete. Masonry. Carpentry. Slates and Tiles. Plumbing. Joinery. Foundry and Smiths' Work. Painting, Paperhanging and Glazing, Heating, Lighting, and Ventilation. Building Regulations. Quantity Surveying. Building Abroad. In Business as a Builder.
Cabinet Making and Upholstering. A Practical Course.
Fire. Fireproof Materials. Fire Prevention. Fire Extinction.

Group 5.
Chemistry and Applied Chemistry.
Chemistry. Inorganic and Organic. Chemistry of the Stars.
Applied Chemistry. Acids and Alkalies. Oils (Fixed Oils and Fats; Waxes; Essential Oils and Perfumes; Paints and Polishes). Candles. Soaps. Glycerine. Glues and Adhesives. Starches. Inks. Tar and Wood Distillation. Matches. Celluloid. Manure. Waste Products. Petroleum. Paper Making (including Paper Staining and Uses of Paper). Photography.

Group 6.
Civil Service. Army and Navy.
Civil Service. Municipal. National. Imperial.
Army and Navy. How to Enter Them.

Group 7.
Clerkship and the Professions.
Clerkship and Accountancy. Complete Training. Bookkeeping.
Banking. The Whole Practice of Banking.
Insurance. Life, Fire, Accident, Marine.
Auctioneering and Valuing. Practical Training.
Estate Agency. Departments and Officials of a Great Estate. Training a Land Agent.
Medicine. Training of a Doctor. Specialists. Veterinary Surgeons. Chemists and Druggists. Dentistry: The Dental Mechanic. Home and Professional Nursing.
Church. How to Enter the Ministry of all Denominations.
Scholastic. Teachers. Professorships. Governesses. Coaches Tutors.
Secretaries, etc. Institution Officials. Political Organisations. Lecturers.
Law. Solicitors and Barristers. Personal and Commercial Law. Copyright.

Group 8.
Drawing and Design.
Drawing. Freehand. Object. Geometrical. Brush. Memory. Light and Shade.
Technical Drawing. For Engineers; Coppersmiths, Tinmen, Boilermakers; Architects; Stonemasons; Carpenters and Joiners; Plumbers
Design. Book Decoration. Illumination. Textiles. Wall Papers. Metal Work.

Group 9.
Dress.
Dress. Dressmaking. Underclothing. Children's Clothing. Tailoring. Millinery. Men's Hats. Furs and Furriers. Feathers. Shirts and Collars.

Group 10.
Electricity.
Electricity. Electrical Engineering. Telegraphs and Telephones (including operation of). Cables and Insulated Wire. In Business as an Electrical Engineer.

Group 11.
Civil Engineering.
Civil Engineering. Surveying. Varieties of Construction. Machines Employed. Roads. Bridges. Railways and Tramways. Water Supply. Sewerage. Refuse. Hydraulics. Pumps. Harbours. Docks. Lighthouses. Foreign Work. In Business as a Civil Engineer.

Group 12.
Mechanical Engineering. Military Engineering. Arms & Ammunition.
Mechanical Engineering. Applied Mechanics. Workshop Practice. Tools (Hand and Miscellaneous. Machine Tools. Portable Machine Tools). Machines and Appliances (A General Guide to Construction. Clocks and Watches. Scientific Instruments).
Military Engineering. Pontoons. Bridges. Fortifications. Rafts. Trenches. Passing Rivers. Conditions in Peace and War.
Arms and Ammunition. Manufacture of Arms and Explosives.

Group 13.
Geography. Astronomy.
Geography Physical. Political. Human. Commercial.
Astronomy. A Survey of the Solar System.

Group 14.
Geology. Mining. Metals and Minerals. Gas.
Geology. The Making of the Earth.
Mining. The Practice of Mining: Coal, Gold, Diamonds, Tin, etc.
Metals. Metallurgy. Iron and Steel. Iron and Steel Manufactures Metal Work. Cutlery.
Minerals. Mineralogy. Properties of Minerals.
Gas. Manufacture of Gas.

Group 15.
History.
A Short History of the World from the Beginning.

Group 16.
Housekeeping and Food Supply.
Servants. Qualifications and Duties of Every Kind of Servant.
Cookery. A Practical Course, with Recipes.
Laundry Work. Washing. The Laundry as a Business.
Foods and Beverages. Milling. Bread-making. Biscuits and Confectionery. Sugar. Condiments. Fruit. Fisheries. Food Preservation. Catering. Brewing. Wines and Ciders. Mineral Waters. Tea. Coffee. Chocolate. Cocoa.

Group 17.
Ideas. Patents. Applied Education.
Ideas. The Power of Ideas in Life. Brains in Business.
Patents and Inventions. How to Protect an Idea.
Applied Education. Application of Education in Daily Life. Finance.

Group 18.
Languages.
How to Study a Language. Courses in Latin, English, French, German, Spanish, Italian, Esperanto, Greek. A Table of Root Words.

Group 19.
Literature. Journalism. Printing. Publishing. Libraries.
Literature. A Survey of the World's Great Books and their Writers. Poetry. Classics. Fiction. Miscellaneous. How to Read and Write.
Journalism. A Guide to Newspaper Work, with Practical Training.
Printing. Composing by Hand and Machine. Type Cutting and Founding. Engraving and Blocks. Bookbinding and Publishing.
Libraries. Officials and Management of Libraries.

Group 20
Materials and Structures. Leather. Wood Working.
Materials. The Characteristics and Strength of Materials.
Structures. The Stability of Structures.
Leather. Leather Industry. Leather Belts. Boots and Shoes. Saddlery and Harness. Gloves. Sundry Leather Goods
Wood Working. Design and Operation of Wood Working Machinery. Wood Turning. Miscellaneous Woodwork.

Group 21.
Mathematics.
Mathematics. Arithmetic. Algebra. Geometry. Plane Trigonometry. Conic Sections.

Group 22
Music. Singing. Amusement.
Music. Musical Theory. Tonic Solfa. Tuition in all Instruments. Orchestration. Conducting. Bell Ringing. Manufacture of Musical Instruments.
Singing. The Voice and Its Treatment.
Amusement. Drama and Stage, including Elocution. Business side of Amusement. Sports Officials.

Group 23.
Natural History. Applied Botany. Bacteriology. Natural Products.
Natural History. Botany: Kingdom of Nature—its Marvels, Mechanism, and Romance; Flowers, Plants, Seeds, Trees, Ferns, Mosses, etc. Zoology Animals, Birds, Fishes, Reptiles, Insects.
Applied Botany. Tobacco & Tobacco Pipes. Forestry. Rubber and Gutta Percha. Basket and Brush Making. Cane Work. Barks (Cork, Wattle).
Bacteriology. Pathological and Economic.
Natural Products. Sources. Values. Cultivation.

Group 24.
Physics. Power. Prime Movers.
Physics. A Complete Course in the Science of Matter and Motion.
Power. A General Survey of Power. Natural Sources. Liquid and Compressed Air.
Prime Movers. Engines. Steam. Gas. Heat. Turbines. Windmills.

Group 25.
Physiology. Health. Ill-health.
Physiology. Plan of the Body. Digestive. Circulatory. Respiratory, Locomotor and Nervous Systems. The Senses.
Health. The Five Laws of Health. Personal Hygiene. Environment. State Medicine and the Public Health.
Ill-health. General Ill-health. Its Special Forms. Common Ailments and Domestic Remedies.

Group 26.
Shopkeeping. Business Management. Publicity.
Shopkeeping. A Practical Guide to the Keeping of all Kinds of Shops.
Business Management. The Application of System in Business.
Publicity. Advertising from all Points of View As a Business

Group 27.
Shorthand and Typewriting.
Shorthand. Taught by Pitmans. **Typewriting.** Working and Management of all Machines.

Group 28.
Textiles and Dyeing.
Textiles. The Textile Trades from Beginning to End.
Dyeing. Dyes and Their Application.

Group 29.
Travel and Transit.
Travel. How to See the World. The Business Side of Travel.
Transit. A General Survey of Means of Communication.
Vehicles. Construction of Air, Land and Sea Vehicles. Business of a Liveryman, Carrier, etc. Driving.
Railways. The Management and Control of Railways.
Ships. Shipbuilding. Shipping. Management of Ships.

THE STATE LADDER OF LEARNING

Opportunities for Girls in the British Isles 3505

THE STATE LADDER OF LEARNING

III.* OPPORTUNITIES FOR GIRLS IN THE BRITISH ISLES

By W. H. Stuart Garnett

IT has only of late years been fully appreciated by the British nation that the education of women is a matter of no less importance to the public than that of men. England has, perhaps, taken a longer time to realise this truth than have the sister kingdoms, and it was not until State provision had been made—by the Act of 1870—for the elementary education of children of both sexes on equal terms that any really serious attention was devoted to the secondary education of the daughters even of those parents who spent large sums to secure a public school education for their sons.

The somewhat tardy recognition of the need was, however, followed by strenuous endeavours for its relief, and the outburst of energy in the matter of providing schools for girls which marked the latter half of the nineteenth century has made it possible to say that an excellent elementary and secondary education is now within the reach of every girl in the United Kingdom, and that a university career is open to all girls of talent and determination. The conditions governing the education of girls in the countries of the United Kingdom vary considerably, on account both of the diverse legislative enactments on the subject now in force, or recently abrogated, and of the variations of the social conditions in the different districts.

The Mediæval System. In England, more than in the sister kingdoms, the conditions of education of boys and girls are markedly differentiated by reason of the disparity in the endowments devoted to the support of educational institutions for the youth of either sex. This disparity is no doubt due to the tradition that girls should be trained at home, a tradition dating back to the fourteenth century, when the girl plied her distaff under her mother's eye, while her brother studied the courtly virtues in the castle of his lord, until in due time his master conferred on him the knightly accolade instead of the more modern diploma or degree.

The tradition has come down to modern times, and the girl of to-day suffers from the prejudice of pious founders of the Middle Ages, and their ungallant devotion of their funds to the exclusive use and maintenance of the youth of their own sex. On the other hand, the girls' school is free from the mediæval traditions which bind the public schools of Great Britain. The far smaller expenditure of the girls' school on games and playgrounds and the lower salary required by the schoolmistress than by the schoolmaster combine to reduce the cost of female education, and to compensate the disabilities of girl students arising from lack of educational endowments. The paucity of endowed schools has itself, to some extent, furthered the cause of education. It has been impossible for boys' schools, when the property of a private company or individual owner, to compete with the large and wealthy institutions with which England abounds. The private school has nearly always succumbed, and the consequent absence of serious competition has made possible the survival, in public schools, of mediæval and unsatisfactory methods of education. It may therefore be said that, so far at least as scientific and methodical teaching is concerned, the education in the first grade girls' schools of England is at least as good as that obtainable in the venerable institutions where the boys of the country are trained in the way they should go.

The State School System. In Scotland and in Wales, secondary education has been for some time, as it now is in England, the duty of the local education authorities. Secondary schools are conducted in Wales by the county councils, and in Scotland by the school boards, and conducted with excellent results. We have not, in the appended tables, mentioned any but the largest of the Welsh mixed county schools, and of the high schools in Scotland. All of these may, however, be trusted to furnish an exceedingly good education at a low cost to the parent. The county schools now being started in various parts of England have not been included, partly for the reason that it is difficult to estimate fairly the merits of institutions so new as to be almost experimental, and partly because the numerous and excellent girls' schools established in England, before the Education Act of 1903 enabled the county councils to build and maintain the present county schools, render the latter a much less essential part of the scheme of national education in England than of the Welsh or Scottish scholastic system.

Education of Girls in Ireland. The conditions of education in Ireland are very much the same for girls and for boys. State aid is granted to all efficient secondary schools, largely on the results of examination of the scholars. The principal Protestant secondary schools are the property of companies or of private individuals, very much as in England. On the other hand, the education of girls belonging to the Catholic Church, like that of the boys, is principally in the hands of religious societies. The Ursuline order deserves special credit for its excellent educational work.

The teaching of children by members of a sisterhood, who work without remuneration, makes it possible to obtain an excellent education at a cost phenomenally low. There is probably no part of the British Isles where so good an education is within the reach of the very poor as in the south of Ireland. On the other hand, while the merits of the system are worthy of attention, it must be recognised that it has the effect of inducing a number of the pupils—and these commonly the ablest and best girls in the school—to take the vows of celibacy, a condition

---

which can only be deplored in the interests of the nation.

The universities of Scotland, Ireland and Wales now place women students on the same footing as men, so that it is unnecessary to add anything here to what we have already said on the subject of university institutions in these parts of the Kingdom [see page 1782]. The same course is adopted by the more recently constituted universities of England, but the older universities still decline to admit women to membership, or to confer degrees upon them. Oxford and Cambridge have, however, so far moved with the times as to permit women students of the neighbouring

colleges and halls, here set out, to sit for the university examinations, and to appear side by side with the graduates in the resulting lists.

It will be noticed that, in spite of the endowments of the men's colleges, it has been found possible to provide university education for women at a lower cost than that at which it is available to men. Holloway College for women is richer in scholarships in proportion to the number of the students than are any of the ladies' colleges at Oxford and Cambridge, and compares very favourably with the older institutions of these universities. On the whole, although the smaller number of institutions open to women makes it a little harder for them to procure a free university education than it is for men, still the competition is less—a university career is attractive only to the minority, and for the majority ample provision is made in the domestic economy schools set out in the table—so that it is fair to say that such a career is now open to every girl who is willing to make some effort for the realisation of her ambition.

BEETLES, MOTHS, & BUTTERFLIES

The Life Histories of Insects—continued. Beetles, Butterflies and Moths. Protective and Warning Colouration. Mimicry. Courtship Dress. Caterpillars

By Professor J. R. AINSWORTH DAVIS

Insects—continued

6. Beetles. [See Plate facing page 3361.] These include an enormous host of insects, something like 150,000 species having been described. Their horny investment is particularly thick, and they possess strong biting jaws, though these differ in some respects from those described for the cockroach and its allies. The third pair, for instance, are much more intimately fused together into a lower lip. The fore-wings are modified into hard wing-covers, while the hind-wings are membranous, as in straight-winged insects (cockroaches, grasshoppers, etc.). But there is one marked difference between the two orders in regard to these organs. The hind-wings of the latter fold up along a set of longitudinal pleats when they are tucked away under their covers, but in a beetle they are relatively long, and require a transverse fold as well

The life history of beetles exhibits a well-marked metamorphosis. From the egg a grub hatches out, which, after a time, passes into a motionless pupa stage, and ultimately the investment of this splits open so that the perfect insect may emerge [431].

Stag Beetles. Stag beetles [Plate facing page 3361] are so named from the antler-like appearance of the huge mandibles in the male, though these formidable-looking structures do not appear to be used as weapons. Perhaps they are courtship ornaments. The family includes our largest native species. *Lucanus cervus*, the larva of which lives for some four years in rotten wood or among the roots of trees before becoming a pupa.

Chafers. Chafers include dung-beetles, cockchafers, hercules beetles, and rosechafers. Perhaps the most interesting dung-beetles are the scarabs (*Scarabæus*), of which one species was sacred in Egypt. Their fore-legs are broadened into powerful digging organs [435], with which they excavate subterranean chambers that serve as larders for the storage of balls of dung, and also as nurseries, the eggs being laid in masses of the same unsavoury material. Among cockchafers, the common species, *Melolontha vulgaris* [431], greatly damages the leaves of trees during its adult stage, while the larva devours roots during its underground life, which lasts from three to five years in different localities under varying circumstances. The hercules beetles and their allies are remarkable as being among the largest insects, and also on account of the curious horn-like projections on the body of the male. Rosechafers are beautiful insects of a metallic green colour [Plate facing page 3361].

431. LIFE HISTORY OF A COCKCHAFER
a. Grubs b. Pupa
(Photograph by Prof. B. H. Bentley)

Tiger Beetles. These are highly predaceous forms, most of which live in the warmer parts of the world. The larvæ dig vertical burrows and patiently lie in wait for prey, with only the front part of the body projecting [432]. Ground beetles make up an extremely large family of mainly predaceous species, which mostly live on the ground and fly reluctantly. In some tropical forest-regions however — *e.g.*, parts of South America— they have taken to an arboreal life, probably in the endeavour to escape the ravages of ants. Others, again, are blind cave dwellers. The little bombardier beetle (*Brachinus crepitans*) is so named because, when chased by an enemy, it can eject a volatile fluid of acrid nature, which evaporates so as to look like a little puff of smoke [437]. A slight explosive sound is heard at the same time.

Some Water Beetles. Water-beetles [Plate facing page 3361] are carnivorous types which have become adapted to life in fresh water, although the adults have not lost the power of flight. In our native great water-beetle (*Dytiscus marginalis*) the large hind-legs are fringed with bristles and serve as oars, while air can be stored under the wing-covers. The unattractive-looking larvæ [434] both pierce and suck their prey by means of the large first jaws (mandibles), which are traversed by canals. Whirligig beetles are also aquatic, spinning round and round by means of their second and third pairs of legs, which are broadened into beautifully-constructed paddles. Some of the water-lovers (*Hydrophilidæ*) are also aquatic, the best known being the great black water-beetle (*Hydrophilus piceus*), our largest native fresh-water form, which surrounds its eggs with a pear-shaped silken cocoon [**433**]. The adult is not a particularly good swimmer, and carries the air necessary for breathing partly under the wing-covers and partly sticking to the hairy under-surface of the body.

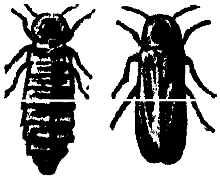
434. LARVA OF WATER-BEETLE

435. SCARAB

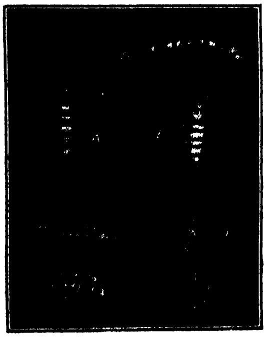
437. BOMBARDIER BEETLE



Female Male
436. GLOW-WORM

Carrion Beetles. Among the carrion beetles, the eggs are deposited in the dead bodies of various small animals. Burying beetles (*Necrophorus*) dig away the earth from under carcases used for this purpose, and ultimately succeed in entirely removing them from sight. Many members of the family are blind cave-dwellers. The rove-beetles possess very short wing-covers, and usually an elongated abdomen, which can be turned up like the tail of a scorpion in the familiar devil's coach horse (*Ocypus olens*), and is used for folding the hind-wings. Many species of the family live in ants' nests, and more will be said about them elsewhere.

Ladybirds. The pretty little ladybirds, red in colour with black spots, lay their eggs on various plants, and the larvæ which hatch out devour plant-lice, scale insects, and other pests, in a wholesale manner. The adults are unusually free from the attacks of insectivorous animals, probably owing to their unpleasant odour and taste, properties which are correlated with the conspicuous "warning" colouration.



438. LIFE HISTORY OF SITARIS
a. Larva *b.* Floating stage *c.* Resting stage *d.* Second larva *e.* Pupa *f.* Adult

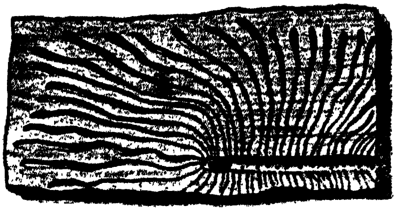
While the members of the last family are friends to the human species, exactly the opposite is true of the small beetles called *Dermestidæ*, widely distributed forms, of which the voracious larvæ devour articles of food, clothing, etc., as in the fur beetle (*Dermestes vulpinus*), bacon beetle (*Dermestes lardarius*), and horsehair beetle (*Anthrenus fasciatus*).

The greater death-watches (species of *Anobium*) appear to make some, at least, of the mysterious tickings often heard in old houses, and the holes in worm-eaten wood are due to their ravages. One species (*Anobium paniceum*) is the insect found in weevily biscuits, but is somewhat catholic in its tastes, and in the larval stage is credited with being the "book-worm" that does so much damage in libraries.

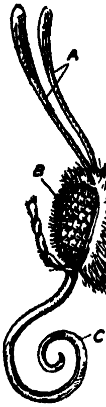
Fireflies and Glow-worms. Fireflies and glow-worms have long attracted attention on account of the light they emit. In the Italian firefly (*Luciola italica*), the males are by far the most brilliant, and fly about together in the evening in large numbers, scintillating like so many tiny lamps. In this case there is some doubt as to the use of the illumination. The source of light in our native glow-worm (*Lampyris noctiluca*) [**436**], on the other hand, is the wingless female, which doubtless attracts a mate thereby. Probably the same is true of the railway beetle of South America, which is so called because there is a red light at each end of the body and a series of smaller green ones along each side.

The click-beetles are able to spring in a somewhat curious way if they happen to fall on their backs, by suddenly bending the body, when a curious peg-and-catch mechanism is brought into play. The larvæ do much damage to the roots of various crops, and are known as "wire-worms" [see pages 1666–7]. Some American forms (*Pyrophorus*) give out a strong light, and are used by the natives for practical and ornamental purposes.

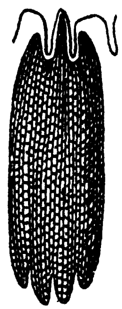
Buprestids are chiefly remarkable for the great beauty of some of the tropical species, of which the thick investments shine with a metallic lustre. Some of the bright green Indian kinds (*Sternocera*) are largely employed for decorative purposes, the wing-covers in particular being arranged in patterns on various fabrics. Quite different from these are the blackish flour-beetles, of which there is one pretty common British species (*Tenebrio molitor*), its grub being known as a "meal-worm."



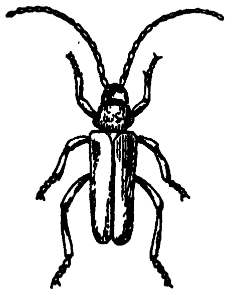
439. GALLERIES OF BARK-BEETLE



440. HEAD OF BUTTERFLY
a. Antennæ b. Eye c. Proboscis

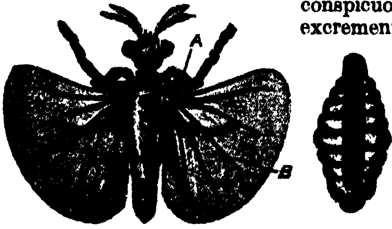


441. SCALE FROM BUTTERFLY'S WING



442. MUSK-BEETLE

Blister Beetles. These are so named because a highly-irritant substance can be extracted from their bodies—as in the typical case of Spanish fly (*Cantharis vesicatoria*), the source of cantharides. The life-history of some members of this family is extremely interesting and complex, as, for example, in one particular species (*Sitaris humeralis*) [438], which provides for its offspring at the expense of certain earth-dwelling bees (*Anthophora*). These construct a series of cells, store them with honey, deposit an egg in each, and then cover them up. Late in August the mother beetle lays her 2,000 or more eggs near the openings of the bees' nests, and some four weeks later these hatch out into little black larvæ (*a*) of peculiar appearance, which remain in a sort of winter sleep till the following April or May. They then wake up, and hold on to any hairy insects that come within their reach, most of them no doubt going fatally astray; hence the necessity for so many eggs. Let us follow the fortunes of a successful larva which has climbed on to the body of a female bee of the right species. After a time the bee will lay a floating egg in a cell previously stored with honey, and the larva seizes the opportunity to slide down on to the edible raft, which serves as a source of food for about a week.



Male Female

443. STYLOPS
a. Fore-wing *b*. Hind-wing

When the egg diet is exhausted, the larva sheds its skin and becomes a sort of bag (*b*) which floats about in and absorbs the honey, which provides rations for some forty days. Next follows a resting stage (*c*), which generally lasts till June of the next year, when a second larval stage (*d*) ensues, which after two days passes into a second resting stage, the true pupa (*e*). From this the perfect insect (*f*) emerges in about a month. Some individuals hurry up their development so as to become adult a year earlier.

Agricultural Pests. The seed-beetles are small inconspicuous forms, of which the larvæ live in peas and beans, often damaging these crops considerably. Leaf-beetles are still more notorious agricultural pests, of which the Colorado potato beetle (*Doryphora decemlineata*) has caused more than one scare in this country, while the greedy little turnip flea-beetle (*Phyllotreta nemorum*)—so named on account of its springing powers—is constantly with us (see page 1667). Here, too, are included the small flat tortoise-beetles (*Cassis*, etc.), the larvæ of which render themselves inconspicuous by heaping up their own excrements on their backs by means of a bifurcated tail acting as a dung-fork.

The long-horned beetles make up a very large family of attractive-looking insects distinguished by the length of their antennæ, and include some tropical species of comparatively gigantic size. The pale grubs possess very powerful jaws, and chiefly feed on wood. Some of them have been known to live in wooden furniture for over a quarter of a century before passing into the winged adult form. One of our most elegant native species is the musk beetle (*Aromia moschata*) [442], with a metallic sheen, and with an odour which has been variously compared to roses, musk, and sweet-brier. Its larvæ live in the wood of willows.

The long-snouted vegetarian weevils include a host of small beetles, the ravages of which are only too familiar. Our native nut-weevil

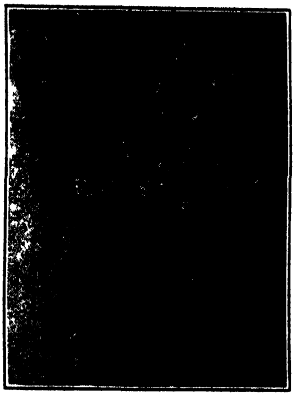
447. EGGS OF VAPOURER-MOTH

(Magnified eight times)

(*Balaninus glandium*), for example, deposits its eggs in hazel nuts and acorns, within which the larvæ find an abundance of nourishing food; while the larvæ of grain-weevils (species of *Calandra*) [**444**] are extremely destructive in granaries (see page 1668). The female of the birch-weevil (*Rhynchites betulæ*) is remarkable for the artistic way in which she cuts and rolls up birch leaves into elegant cases, wherein to deposit her eggs.

Bark-beetles are very destructive to the bark and wood of dead or unhealthy trees, the tunnels driven in which are arranged in characteristic ways according to the species. In a well-known British form (*Scolytus destructor*) the female bores a passage into a tree, and there lays her eggs. The larva which hatches out from each of these makes its own branch tunnel [**439**] and ultimately passes into the pupa stage, from which a perfect insect emerges. In some of these forms the food consists not so much of wood as of a sort of mould ("ambrosia"), which is said to be actually cultivated somewhat after the fashion of the mushroom-growing ants. For other insects of this nature reference should be made to the course on Forestry.



Tonge

448. COCOON CONTAINING CHRYSALIS OF PUSS-MOTH
(Natural size)

Among the beetles we may perhaps include, though they are often regarded as making up a distinct order (*Strepsiptera*), the minute bee-lice (*Stylops*, etc.), which also infest wasps [**443**]. The female is simply a wingless egg-bag protruding from the abdomen of a bee or wasp, within which she is parasitic, but the male possesses well-developed hind-wings, though the front ones are reduced to mere vestiges. He leads a grown-up life of fifteen or twenty minutes, devoting it entirely to wife-hunting, courtship and mating.

7. **Butterflies and Moths.** For beauty and variety of colouration these insects are quite unrivalled, and their attractive appearance is primarily due to the fact that the four wings are covered with overlapping scales of different kinds [**441**]. The mouth parts are specialised to constitute a suctorial organ, made up of the second jaws (first maxillæ), while the first and third jaws are greatly reduced. Each second jaw has become a half-tube, and the two are hooked together to make up a proboscis, sometimes of great length, which can be separated into its halves for cleaning purposes [**440, 455**].

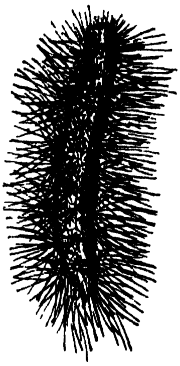
451. MALE PUSS-MOTH
(Natural size)

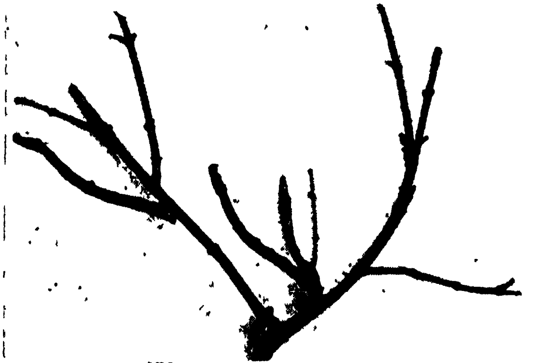
The life-history exhibits a very typical and familiar metamorphosis. From the egg [446, 447], which is often beautifully sculptured, a larva known as a caterpillar [450] hatches out possessing not only the three pairs of jointed legs characteristic of the class, but also a varying number of unjointed pro-legs terminating in suckers. After feeding voraciously for some time by means of its powerful biting first jaws, and undergoing a number of moults, the caterpillar passes into the motionless pupa stage [445, 448], here called a chrysalis, which may or may not be invested in a protective cocoon. The skin of the chrysalis ultimately splits and the perfect insect makes its way out [449, 451].



452 GIPSY-MOTH CATERPILLAR

Butterflies [see Plate facing page 3505] are typically distinguished from moths by the club-shaped thickenings at the ends of their antennæ, and by the fact that when settling the wings are folded together over the back. In moths the antennæ may be of various form, but very rarely club-shaped, and the rest-position of the wings is horizontal [449] or sloping downwards, while in some instances they may be more or less wrapped round the body.

Egg-Laying Habits. The eggs are deposited on various plants, singly or in small batches, as a rule, though exceptions to this are afforded by some species, such as the tortoiseshell butterflies [446], where a large number of larvæ live together in a sort of colony. It is an extraordinary example of instinct that the mother butterfly or moth should invariably lay her eggs on plants suitable for food for the caterpillars, as her own feeding habits are entirely different. There is no maternal solicitude, except perhaps in the egger-moths and some other kinds which cover their eggs with hairs detached from their own bodies.



453. STICK-CATERPILLARS
(Photograph by Prof. B. H. Bentley)

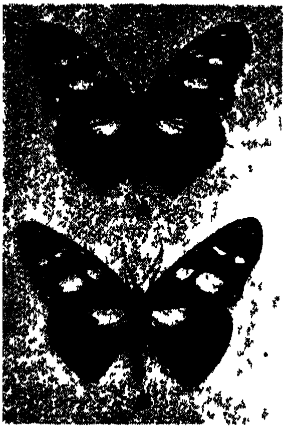
Caterpillars. Caterpillars make a very interesting study, their varying forms and characters being largely of protective nature; such are the numerous stiff bristles covering many of them [452], which can sometimes inflict painful or even poisoned wounds. These kinds are generally treated with respect by insectivorous birds, but cuckoos seem proof against indigestion, and eagerly snap up caterpillars which other species reject. In many instances, their colour and shading are such as to harmonise with surroundings, and make them inconspicuous, while different tints may be assumed by the same kind of caterpillar when feeding on the different food-plants which form its diet.

Very extraordinary are the larvæ of the loopers or geometers, so called from the looping nature of their progression, due to the absence of limbs, except near the two ends of the body. They are often known as "stick-caterpillars," and when alarmed commonly hold on to twigs by means of the last pair of pro-legs (claspers), and bend out their body obliquely, so as to look like branches [453], a delusion favoured by their colour. The muscular exertion involved is in many instances relieved by the spinning of an almost invisible girdle of silk.

Warning by Colour. Some of the caterpillars which possess an unpleasant taste are extremely conspicuous, their warning colouration securing a large share of immunity from attack. A good example is afforded by the larvæ of the cinnabar-moth (*Callimorpha Jacobeæ*), which are marked with alternate black and yellow rings. It has been shown by experiment, for instance, that newly-hatched chicks reject them after the first trial, which is followed by obvious marks of distaste. After having learnt this lesson, a chick will avoid meal placed on a glass slide, to the under side of which is pasted a strip of paper painted with the cinnabar-caterpillar's coat-of-arms.

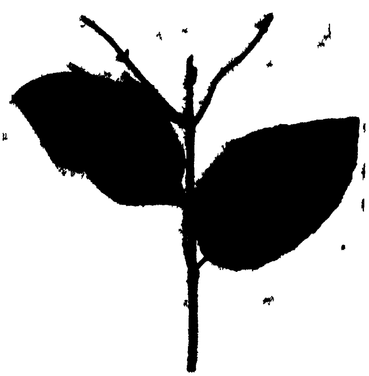
Curious warning attitudes are assumed by some caterpillars when alarmed, one of the most remarkable cases being that of the puss-moth (*Cerura vinula*) [458], which contracts its front end to look like a grotesque mask, and shoots out a pair of whip-like pink threads from the tip of its tail. It can also squirt out a highly irritant fluid from a pore below the mouth. The caterpillar of the lobster-moth (*Stauropus fagi*) is also a weird-looking creature, which, in its warning attitude, looks like a combination of a spider and an earwig.

The Caterpillar at Home. Some caterpillars escape a good many enemies by the sheltered nature of their homes, as, for example, wood-boring forms, such as those belonging to the goat-moth (*Cossus ligniperda*), which tunnel the trunks of willow and elm, and remain for four years in the larval stage. In other instances, protective cases or shields are constructed as a means of protection. The caterpillar of one species of clothes-moth (*Tinea pellionella*), for example, moves about in a tube constructed of fragments of cloth cemented together.



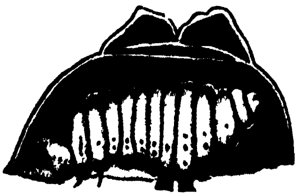
454 PROTECTIVE MIMICRY
a Model *b* Mimic
(Photo by Prof B H Bentley)

A similar habit has earned the name of "basket-worms" for the larvæ of certain small moths (*Psychidæ*), the homes of which are generally cylindrical cases made up of bits of wood or similar substances, and look very much like some of the tubes made by caddis-worms One basket worm constructs a spiral dwelling, looking exactly like a snail shell, and entirely made up of closely compacted silk A somewhat different arrangement is found in the rather short caterpillar of a kind of moth (*Erastria scitula*) which creeps about with a dish-cover shaped shield upon its back [**457**], made out of the coverings of scale insects which have fallen victims to its voracity, for this is an exception to the general rule that caterpillars are vegetarians In some species—*e g*, the peacock butterfly (*Vanessa io*)—the larvæ are associated together in considerable numbers, at least when young, and spin a sort of protective web for mutual benefit

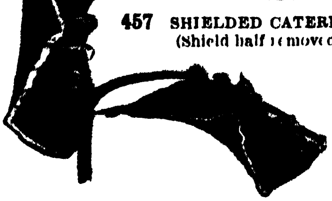


456 LEAF BUTTERFLY
(Photograph by Prof B H Bentley)

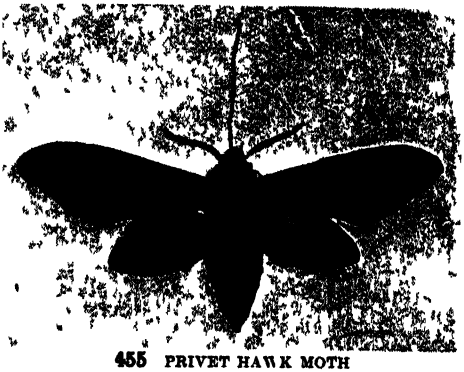
The Chrysalis. Sooner or later, a caterpillar becomes a hard shelled, motionless chrysalis, and there are many ways in which this may be protected Very often, before pupation begins, a thick cocoon of silk is spun, of which the most familiar instance is afforded by the larva ("silkworm") of the silk-moth (*Bombyx mori*) Sometimes cocoons are so tough that provision must be made for the escape of the perfect insect In the emperor moth (*Saturnia carpini*) it is left open at one end, save for the presence of a ring of stiff, closely set bristles, so arranged that they easily permit exit but forbid the intrusion of an enemy A still more curious method is adopted in the puss moth, the cocoon of which is very thick and tough [**446**] When the perfect insect escapes from the chrysalis, it excretes a corrosive fluid containing caustic potash, by which a part of the cocoon is dissolved During this process the head of the insect is protected by a fragment of the chrysalis skin



457 SHIELDED CATERPILLAR
(Shield half removed)



458 CATERPILLARS OF PUSS MOTH



455 PRIVET HAWK MOTH
(Photograph by Prof B H Bentley)

Sometimes protection is gained by the assumption of the chrysalis stage underground, in which case there may either be a cocoon or not The privet hawk moth [**445**] illustrates the latter state of things The caterpillar of one of the British owlet moths (*Brephos notha*) bores into a tree trunk before pupating, first taking care to close the hole by spinning one or two silken screens to keep out foes An exposed cocoon commonly resembles its surroundings, and is thus likely to escape notice A good instance is afforded by the wood eating caterpillar of the goat moth, which at the end of its larval life bores its way to the sur [illegible] ing a cocoon which, though mainly of silk, is covered by chips of wood

A great many chrysalides are neither hidden away from sight nor invested in cocoons, and may be found in all sorts of places, either hanging head downwards or disposed in the opposite way In the former case, attachment is by means of a pad of hardened silk, and the tip of the tail is sometimes provided with a pair of hooks fixed into this When the tail is below it is similarly fixed by a pad, while a girdle of silk often encircles the upper part of the body and holds it to the support Colour is in all these cases a matter of great importance Warning black and yellow tints are displayed in the case of the magpie moth (*Abraxas grossu-*

lariata)—which wears the same livery in all three stages of its existence—and in some other species, but the general rule is for exposed chrysalides to be protectively coloured.

Very remarkable is the case of some forms in which the chrysalis is of different colour, according to the prevailing hue of the surroundings. This is markedly so in the small tortoiseshell butterfly (*Vanessa urticæ*), light, dark, or even golden hues being assumed, according to circumstances.

The Adult Stage. Coming now to the adult, or imago stage of butterflies and moths, there is an enormous amount of variety as regards size, shape, and colour, of which but a faint idea can be given here. On the one hand, we have the great atlas-moth (*Attacus atlas*) with a 12-in. spread of wing, while some tropical butterflies (*Ornithoptera*) may attain to 7 in. or more; and, on the other hand, we have such insignificant little beings as the larch-moth (*Coleophora laricinella*), which can scarcely span three-eighths of an inch with fully expanded wings.

We have already had occasion to notice the mutual adaptation that exists between flowers and the members of the present order. The proboscis of a moth or butterfly is eminently adapted for sucking up the sweet nectar which so many blossoms afford, and its length in a particular species is proportionate to the depth at which the coveted treasure is hidden. Among our native species the hawk-moth is best endowed in this respect [455], and in some tropical forms it is even said to attain the length of 10 in when extended. When not in use this organ is rolled up into a spiral under the head [440].

Colours of Butterflies. The colours of butterflies and moths in their adult condition are even more significant than those of caterpillars and chrysalides. Perhaps in the majority of cases they are of a protective nature, which accounts for the sober tints, specklings and mottlings which distinguish the bulk of our native moths. When most common butterflies settle and fold their wings over the back, only the underside of these is visible. and its tints are not of a conspicuous nature If, as often happens, the two sexes are differently dressed, the female is more inconspicuous than her mate, an obvious advantage to the species. She may even be wingless, or practically so, as in the vapourer-moth (*Orgyia antiqua*), and is discovered by her ardent admirers by the sense of smell, their large feathery antennæ indicating unusual endowment in this direction.

But colour, aided by shape, is capable not merely of bringing about a general harmonising with surroundings, but also a resemblance to specific objects on the lines noticed for stick-caterpillars. An exceedingly pretty example of this is afforded by our common little buff-tip moth (*Pygæra bucephala*). When this settles, the wings are wrapped round the body, and the insect strikingly resembles a little piece of broken stick, even the paler tint of the fractured end being accurately copied. The tropical leaf-butterflies (*Kallima*) go much further. They settle on twigs [456], fold up their wings, and then look precisely like withered leaves. Two little tails on the hind-wings come together to represent a stalk, mid-rib and branch-veins are perfectly simulated, and the apposition of two transparent spots near the tips of the fore-wings even bring about the semblance of a hole drilled by some larva. There are also discoloured patches closely resembling the fungi so commonly found on decaying leaves.

Patterns and Designs in Colour. Warning colouration is abundantly illustrated among adult butterflies and moths. The glaring black-and-yellow livery of the magpie-caterpillar is retained by the adult, while the striped yellow-and-black blazer of the cinnabar-caterpillar gives place to scarlet and dark brown. The pretty little six-spotted burnet-moth (*Zygæna filipendulæ*) is made conspicuous by contrast between scarlet, very dark green, and some black. In all these cases the effect is heightened by pattern as well as actual colour. Spots and bands are characteristic A bold design in black upon a paler background is often very effectively employed [454]. It may also be noted that in warningly coloured species both sides of the wings are much alike, and that the flight is deliberate.

A number of species quite devoid of noxious properties and perfectly edible mimic more or less closely their warningly coloured neighbours, and in this way enjoy a certain amount of peace and quietness A typical instance is figured in **454**. Remarkable cases have been described where the female only is a mimic, and is to be found in as many as three different garbs, simulating the same number of warningly coloured forms. Clear-wing moths (*Sesiidæ*) have come to resemble wasps and bees, and are thus undoubtedly in some measure protected. Their wings have lost most of the scales, so as to be transparent, and the body is banded with black and yellow or black and red, as the case may be

Colour and Courtship. The most beautiful and artistic combinations of tints on the wings of butterflies are generally explained as being examples of courtship colouration, a view which is rendered probable by the fact that they are often best seen in the male. A beautiful native example is afforded by the orange-tip butterfly (*Anthocharis cardamines*), which has received its name from the pretty marking of the fore-wings in the male; and in most of the elegant little blues (*Lycænidæ*) the female is brownish with a bluish tinge, while her mate is of the most glorious azure. It must also be added that some of the colours and patterns of butterflies and moths may perhaps be explained as recognition markings, by means of which members of the same species are spared mistakes in identification of their kind.

DAWN OF THE RENAISSANCE

Gothic Art—continued. A Period of Naturalism. Ivory Carving. Some Great Painters. The Dawn of the Art of "Free Expression"

By P. G. KONODY

We have exclusively dealt with the structural principles of Gothic architecture and the far-reaching changes brought about by the general adoption of the pointed arch. It is only natural that the sister arts of sculpture and painting, which were then completely in the service of, and subordinated to, architecture, should have had to undergo corresponding modifications. With the reduction of solid masonry to a minimum, the demand for extensive wall paintings had practically ceased to exist. Their place in the new order of things was taken by huge stained-glass windows, and the painters had to express themselves in small panel pictures for altar-pieces, which could no longer be monumental in character, but forced the artists from hierarchic dignity and lifelessness to the search for human emotions and movement. This signified the inauguration of a return from the traditional convention to the study of Nature.

Gothic Sculpture. In sculpture, even more than in painting, naturalism triumphed over formalism. Romanesque sculpture had been derived entirely from Roman and Byzantine sources. It was impressive at times and dignified, and well suited to the architecture by which it was set off. But the Gothic style of building, with its upward tendency and graceful slenderness, necessitated a different treatment of the human figure, which, in the hands of the mediæval sculptor, became more flexible, slender, elegant, and expressive—in short, more human. As in the preceding epoch, the representation of the nude remained beyond the pale of art, but, nevertheless, the form of the limbs was better understood, and the drapery treated in gently-flowing lines and ample folds. At the same time the features lost their stony impassiveness, in the place of which we find serenity and even emotional expression.

Giraudon

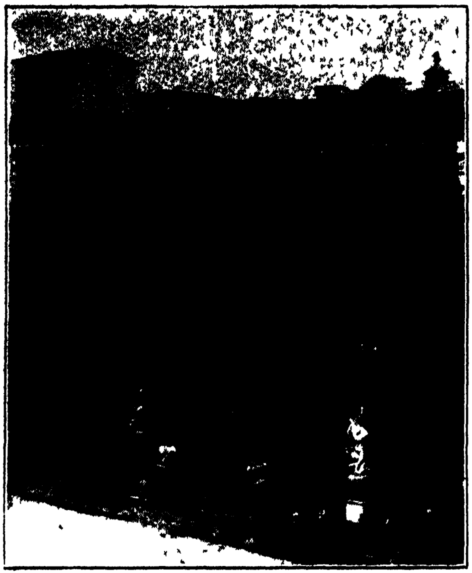
61. GOTHIC CAPITAL IN ROUEN CATHEDRAL

A Period of Naturalism. More marked even than in sculpture, properly speaking, is the naturalistic tendency in Gothic stone carving, where the forms of the local flora are repeated with astounding faithfulness, and with an appreciation of the beauty of Nature's handicraft that has never been equalled at any other period. Some of the Gothic cathedrals present in the stone carvings of the capitals, porches, and niches a perfect course of natural history—an encyclopædia of the knowledge of the time, comprising scriptural history, legend, contemporary life in all its phases, the sciences and trades and crafts, animal and plant forms, allegorical representations of the forces and phenomena of Nature, and many other themes. This applies with particular force to the cathedrals of France [61]; but even in Italy, where the alien Gothic style never became properly naturalised, we find a similar intention in the decorative adjuncts to architecture. Thus the relief panels of the Florence Campanile deal with the creation of Adam and Eve, "Jabal—the father of such as have cattle," "Jubal—the father of all who handle harps and organ," Tubal Cain, the metal-worker; Noah, the vine-grower; astronomy, arithmetic, geometry, grammar, logic, rhetoric, music, building, pottery, wool weaving, law, the three elements personified by a horseman, Dædalus, and a ship with its crew; ploughing, transport, painting and sculpture. This Campanile has not inaptly been called a "Gospel of Intelligent Labour."

Brogi

60. SCULPTURE FROM THE CAMPANILE OF GIOTTO, FLORENCE

The Gothic craftsmen of France and Germany attained great skill in the polychromatic treatment of stone carving, and more particularly of figures and reliefs carved in wood, for altars and church decoration in general. That a period with a distinct leaning towards realism should not have neglected portraiture is only natural. The beginnings of Gothic portrait sculpture must be searched for in the cathedrals, among the tomb slabs showing the figure of the dead carved in low relief. Then came the recumbent figure modelled in the round, and finally the kneeling figure in the attitude of prayer, in all of which the sculptors endeavoured to reproduce as faithfully as possible the features of the dead.



62. ORCAGNA'S LOGGIA DE' LANZI, FLORENCE

Ivory carving, too, was widely practised during the Gothic period, and no doubt exercised a great influence on the plastic art of that time. The shape of the tusk necessitated the adaptation of the pose of the figure to the curve. Perhaps the more flowing line and increased movement of Gothic sculpture, as compared to Romanesque, may to a certain extent be due to the artist's endeavour to fit his figures into a given shape, or indirectly to the accidental form of the elephant's tusk. It is at any rate undeniable that many of the statues carved in stone or wood during the fifteenth century follow the swinging line of the ivory's natural growth

Italian Gothic Art. In Italy, painting and sculpture had never lost their independent existence as completely as in the North, where the Gothic architectural system exercised tyrannical sway over the sister arts. The smouldering fire that burnt under the cold Byzantine tradition broke forth in brilliant flame in the middle of the thirteenth century in the person of Niccola Pisano, the creator of the famous pulpit in Pisa [63], who, inspired by the antique, revived for a short time the noble grandeur of classic form. But Niccola was an isolated phenomenon, and his son, Giovanni, abandoning the direction indicated by his father, succumbed to the influence of the Northern Gothic, and gave his compositions dramatic intensity and emotional life in the place of antique impassiveness. His masterpiece is the pulpit of St. Andrea at Pistoja.

Whilst plastic art thus received a new impulse from Pisa, Florence and Siena were the centres where painting first broke the fetters of Byzantine formalism and achieved individual freedom. Cimabue, a thirteenth-century Florentine, has for centuries been held to be the father of modern painting and the teacher of Giotto. Modern research has, however, deprived him one by one of all the existing works that had been placed to his credit, and has made of him an almost legendary figure. It is now generally held that Cimabue was a mosaic worker trained by Byzantines in the accepted tradition—an excellent artist, no doubt, who perhaps infused a little life into the stiff manner of his precursors, but by no means the epoch-making reformer of Vasari's pretty tale. The famous Rucellai Madonna in Florence, and other panel pictures formerly attributed to Cimabue, are in all probability the works of Duccio of Siena and other painters of the Sienese school.

The "First Modern Painter." Whether Giotto was actually a pupil of Cimabue or no, one thing is certain, that his art has far more in common with that of the sculptor Giovanni Pisano than with that of his supposed master. Giotto (1266-1337) may be called the first modern painter. He was the first to paint objects and figures in a manner to make us realise without mental effort the plastic reality of his painted subject. Measured by the modern standard, his drawing is faulty, the figures clumsy and heavy, the perspective wrong; but his was the first step towards freedom of composition, dramatic life and movement, towards the realisation of an artistic ideal beyond the merely formal beauty of harmoniously arranged line and colour. To appreciate his work fully, one has to study his glorious frescoes in the Arena Chapel in Padua, at St Croce in Florence, and at St. Francis in Assisi. Like most of the early Italian masters, Giotto was well versed in many arts. His combined achievement as architect and sculptor can be admired in the Florence Campanile [60].

63. PULPIT, PISA, BY NICCOLA PISANO

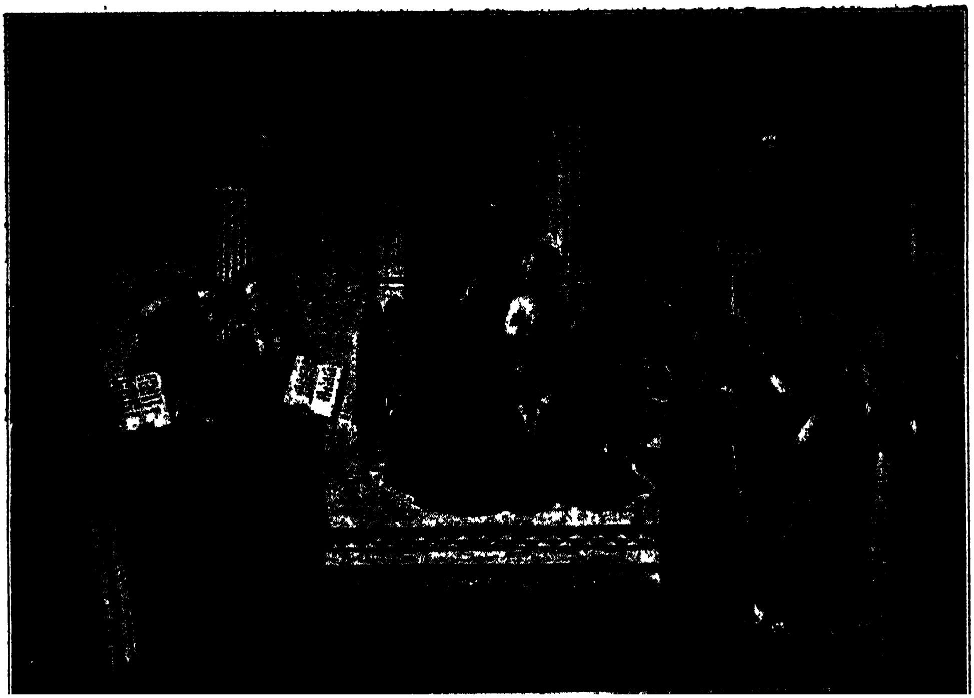
In his painting, as in his sculpture, he, like all the leaders in art, drew his inspiration direct from Nature. And like all those who turn away from Nature to imitate consciously the work of a master, the followers of Giotto—the "Giottesques"—lost sight of the real significance of things, copied the weaknesses and the mere outer form of the admired models without grasping the spirit, and delayed the progress of painting by a full half century. Giotto the painter had logically transferred to another sphere, and developed the principles underlying the work of the sculptor Giovanni Pisano. It was a sculptor again, Andrea Pisano, who was Giotto's legitimate successor; and whilst painting was under a temporary eclipse, Andrea and his pupils infused vigorous life into the art of relief sculpture. With the seriousness and sincerity of Giotto, and with that master's disregard of conventional form, he combines an increased sense of pure beauty. His bronze gates of the Florence baptistery represent him at his best.

The greatest of the "Giottesques" is Andrea del Cione, called Orcagna, Andrea Pisano's pupil, and equally famed as painter, sculptor, goldsmith and architect. The Loggia de' Lanzi [62] in Florence is said to be built from his plans; the solemn, splendid fresco of the Last Judgment in S. Maria Novella, and the richly sculptured Gothic tabernacle at Or San Michele in Florence, are wrought by his hand, though the famous, naïvely realistic "Triumph of Death" fresco at the Campo Santo in Pisa, which was formerly attributed to his brush, is now held to be the work of the Sienese Lorenzetti [64].

64. PART OF THE PAINTING OF THE TRIUMPH OF DEATH, PISA, BY LORENZETTI

What Cimabue was believed to have done for painting in Florence, Duccio di Buoninsegna certainly did for Siena. He, too, broke away from Byzantium, gave life to his figures, suggested the human form under the nobly-arranged drapery, and humanised the expression of the faces, though he did not go far in giving individual character and emotion to each figure. His successors, among whom Simone Martini, Taddeo Gaddi, and the Lorenzetti were the most prominent, continued in the same direction. The Sienese were ever more concerned with expressing the inner life of the soul than the physical life of the body. It was a natural consequence that they excelled more in the small panel picture than in the large fresco. The Sienese School did not have the vitality of the School of Florence, and fell into decay when the art of the rival city achieved its greatest triumphs.

A Great Florentine Painter. Fra Giovanni Angelico da Fiesole (1387-1455), a Dominican monk, is the last great Florentine painter of the Gothic period, and the first of the Early Renaissance. In his art, pure, spiritual, ardent, and sincere, he proves himself a follower of Giotto in the dramatic conception of the subjects and in the freedom of his grouping, whilst the soulful, emotional depth of his sentiment and the celestial beauty and purity of expression are derived from Sienese sources. He is the most lovable painter of all times, the painter of heavenly bliss, of pure Christianity, of angelic beauty. The spirituality and saintliness of his art is so striking, and has been laid so much stress on, that many critics have overlooked another and scarcely less important side of his character, his systematic study of the antique, of the human form and of Nature in general. He was the first painter who represented the Christ-child entirely naked, and drew the nude forms, not from imagination, but from the living model; the first Italian who painted an actual landscape from Nature; one of the first to study aerial perspective, to introduce actual portraiture into his frescoes, and classical forms



65. A FRESCO BY FRA ANGELICO, IN THE MUSEUM OF ST. MARK, FLORENCE *Anderson*

into his architectural backgrounds. For all these reasons Fra Angelico must be accorded a position, and no mean position, among the painters of the Italian Renaissance. To appreciate Fra Angelico's position in the art of his time, it is necessary to study his wonderful frescoes in the cells of S. Marco in Florence and in the chapel of Nicholas V. in the Vatican [65].

The Renaissance. The great movement in art and letters, known as the Renaissance, had its beginning in Italy in the early part of the fifteenth century. In the Gothic period art had been almost entirely at the service of the Church. Fostered by the spread of humanism, which, under the rule of the Medici family in Florence, led to the establishment of a Platonic Academy, the dormant love of the Italians for the forms of classic art, which are so closely connected with paganism, was given a new powerful impetus. Scientists and men of letters, architects, painters and sculptors devoted themselves to the study of classic literature and antique art, the writings of Greek and Roman poets and philosophers were popularised, the fragments of antique sculpture unearthed, the ruins of classic buildings investigated, and the lessons derived from them applied to the creation of new monumental buildings. At the same time, and as a result of the "renaissance" or "rebirth" of classic knowledge, art became to a great extent secularised, and its patronage passed from the Church to the Courts of the Princes and to the wealthy citizens. In the North, the Reformation, coincides with the Renaissance, and even in Italy, where the Church enlisted the service of the masters that had arisen under the influence of the humanists, new fields were opened to the activity of architects, painters and sculptors. Mythology, classic literature and portraiture, entered into the range of subjects, and though some of the greatest churches and monastic buildings belong to this period, the great architects of the Renaissance found their chief employment in the building of palaces.

"An Art of Free Expression." Nothing could be more erroneous, however, than to think that the principles of Renaissance architecture were a mere repetition of the rediscovered classic forms. The style is based on the revival of the classic orders, but these are applied in an entirely new manner, suitable to the modern requirements. As Professor Banister Fletcher has tersely put it, "Architecture ceased to a certain extent to be subject to the considerations of use, becoming largely independent of constructive exigencies, and to a greater extent an art of free expression in which beauty of design was sought for. Speaking generally, there was an endeavour to reconcile the Gothic and the Roman method of construction—*i.e.*, the body and the dress were the same thing constructively, because the architects of the period, attracted by the mere external appearance of ancient Roman art, but perceiving that this form was merely an envelope, continued in the matter of construction to a large extent to follow the traditions of the Middle Ages, which did not separate the structure from the decoration."

ALGEBRAIC SURDS

Simple Surds. Surds of the Same Order. Compound Surds. Rationalisation. Square Root of a Binomial Surd. Equations Involving Surds

Group 21
MATHEMATICS
25
ALGEBRA

continued from page 3415

By HERBERT J. ALLPORT, M.A.

SURDS

119. In Article **143** of Arithmetic [page 1440] a *surd* was defined as a root of a number which cannot be determined exactly. Thus $\sqrt{7}$ and $\sqrt[3]{5}$ are surds. In Algebra, such expressions as $\sqrt[3]{x^2}$ and $\sqrt{y}$ are called surds, although if x and y have particular values, the resulting expression may not really be an arithmetical surd. For example, if $y = 25$, then $\sqrt{y}$ is not really a surd, since its value is $\sqrt{25}$, or 5.

120. Surds are really cases of fractional indices, and therefore are subject to the laws of combination established in Article **117**.

Thus, we know that

$$\sqrt[3]{a^2} = a^{\frac{2}{3}} \text{ [Art. } \mathbf{114}\text{]},$$

and that

$$\sqrt[12]{a} = a^{\frac{1}{12}}.$$

Hence,

$$\sqrt[3]{a^2} \times \sqrt[12]{a} = a^{\frac{2}{3}+\frac{1}{12}} \text{ [Art. } \mathbf{117}\text{]}$$

$$= a^{\frac{3}{4}} = \sqrt[4]{a^3}$$

121. Surds are said to be of the same *order* when they have the same root index.

Thus $\sqrt{7}$ and $\sqrt{a+b}$ are surds of the *second* order, or *quadratic surds*

$\sqrt[3]{x}$, $\sqrt[3]{x^2 + y^2}$, are surds of the *third* order; and, generally, $\sqrt[n]{x}$ is a surd of the nth order.

122. Any rational quantity can be expressed as a surd. For example, to write 4 as a surd of the third order, we have

$$4 = \sqrt[3]{4^3}.$$

Again, a surd of any order can be converted into a surd of a different order. For instance, to transform $\sqrt[3]{5}$ into a surd of the 9th order,

$$\sqrt[3]{5} = 5^{\frac{1}{3}} = 5^{\frac{3}{9}} = \sqrt[9]{5^3}.$$

123. Any two surds can be transformed to surds of the same order. This order will be some common multiple of the given orders. For convenience, we generally choose the *lowest* common multiple.

Example **1**. Reduce $\sqrt[3]{4}$ and $\sqrt[5]{3}$ to surds of the same order.

The L.C.M. of 3 and 5 is 15. Hence,

$$\sqrt[3]{4} = 4^{\frac{1}{3}} = 4^{\frac{5}{15}} = \sqrt[15]{4^5},$$

and

$$\sqrt[5]{3} = 3^{\frac{1}{5}} = 3^{\frac{3}{15}} = \sqrt[15]{3^3};$$

so that the given surds are now expressed as surds of the 15th order.

We are thus able to compare the magnitudes of two or more surds.

Example **2**. Which is the greater $\sqrt[3]{17}$ or $\sqrt{7}$.

As in Example **1**, we have

$$\sqrt[3]{17} = \sqrt[6]{17^2} = \sqrt[6]{289},$$

and

$$\sqrt{7} = \sqrt[6]{7^3} = \sqrt[6]{343};$$

so that, since 343 is greater than 289, it is clear that $\sqrt{7}$ is greater than $\sqrt[3]{17}$.

124. Since

$$\sqrt[n]{ab} = (ab)^{\frac{1}{n}} = a^{\frac{1}{n}} \, . \, b^{\frac{1}{n}} = \sqrt[n]{a} \, . \, \sqrt[n]{b},$$

we see that the product of two surds can be simplified by reducing the surds to the same order.

Example **1**. Find the product of $\sqrt{27}$ and $\sqrt{48}$.

$\sqrt{27} \times \sqrt{48} = \sqrt{27 \times 48}$, since the given surds are both of the second order,

$= \sqrt{3^4 \times 2^4}$, by putting 27 and 48 into factors,

$= 3^2 \times 2^2 = 9 \times 4 = 36$ *Ans.*

Conversely, we can sometimes put a surd into factors, thus,

Example **2**. Express $\sqrt{147}$ in its simplest form.

$$\sqrt{147} = \sqrt{49 \times 3} = \sqrt{49} \times \sqrt{3} = 7\sqrt{3} \text{ } \textit{Ans.}$$

125. Surds are said to be *like*, when they can be reduced so as to have the same irrational factors.

$5\sqrt{20}$ and $2\sqrt{45}$ are *like* surds, for

$$5\sqrt{20} = 5 \times \sqrt{4} \times \sqrt{5} = 10\sqrt{5},$$

and

$$2\sqrt{45} = 2 \times \sqrt{9} \times \sqrt{5} = 6\sqrt{5}.$$

Clearly, the algebraical sum of like surds is obtained by collecting the coefficients, the result forming the coefficient of the sum, the irrational factor of the sum being the same as in the surds.

Example **1**. Simplify $2\sqrt{98} - \sqrt{18} + 5\sqrt{8}$.

$$2\sqrt{98} - \sqrt{18} + 5\sqrt{8} = 2\sqrt{49 \times 2} - \sqrt{9 \times 2} + 5\sqrt{4 \times 2}$$

$$= 14\sqrt{2} - 3\sqrt{2} + 10\sqrt{2}$$

$$= (14 - 3 + 10)\sqrt{2}$$

$$= 21\sqrt{2} \text{ } \textit{Ans.}$$

Example **2**. Simplify

$$2\sqrt{80} + \sqrt{3} - 4\sqrt{12} - \sqrt{20}.$$

Given expression

$$= 2\sqrt{16 \times 5} + \sqrt{3} - 4\sqrt{4 \times 3} - \sqrt{4 \times 5}$$

$$= 8\sqrt{5} + \sqrt{3} - 8\sqrt{3} - 2\sqrt{5}$$

$$= (8 - 2)\sqrt{5} - (8 - 1)\sqrt{3}$$

$$= 6\sqrt{5} - 7\sqrt{3} \text{ } \textit{Ans.}$$

Note that unlike surds cannot be added or subtracted, so that $6\sqrt{5} - 7\sqrt{3}$ admits of no further simplification.

126. A *compound surd* is an expression involving two, or more, simple surds.

Compound surds are multiplied together in the same way as other compound algebraical expressions. [See Article **27**, page 2148.]

Example. Multiply

$$3\sqrt{5}+2\sqrt{3} \text{ by } 2\sqrt{5}-5\sqrt{3}.$$

We have to multiply every term of the one expression by each term of the other. Hence, the product consists of

$$(3\sqrt{5}\times 2\sqrt{5}) + (2\sqrt{3}\times 2\sqrt{5}) - (3\sqrt{5}\times 5\sqrt{3}) - (2\sqrt{3}\times 5\sqrt{3});$$

or

$$30 + 4\sqrt{15} - 15\sqrt{15} - 30,$$

which, on collecting terms, gives $-11\sqrt{15}$. The work can be arranged as in Article **27**, thus,

$$\begin{array}{l}
3\sqrt{5}+2\sqrt{3} \\
\underline{2\sqrt{5}-5\sqrt{3}} \\
\overline{30+4\sqrt{15}} \\
\quad\ \ -15\sqrt{15}-30 \\
\overline{30-11\sqrt{15}-30} = -11\sqrt{15} \ \underline{\mathit{Ans.}}
\end{array}$$

127. If we multiply together the sum and the difference of two quadratic surds, we get a rational expression for the product.

For, by Article **34**, page 2150,

$$(\sqrt{x}+\sqrt{y})(\sqrt{x}-\sqrt{y}) = (\sqrt{x})^2 - (\sqrt{y})^2 = x-y.$$

Two binomial quadratic surds, which differ only in sign, are said to be *conjugate* to one another. Hence, a binomial quadratic surd is *rationalised* by multiplying by the conjugate surd.

128. When a fraction has surds in the denominator, the denominator can be rationalised, and the numerical value of the fraction is then found more easily.

Example **1**. Rationalise the denominator of $\frac{14}{\sqrt{7}}$.

We have only to multiply numerator and denominator by $\sqrt{7}$. Thus

$$\frac{14}{\sqrt{7}} = \frac{14\times\sqrt{7}}{\sqrt{7}\times\sqrt{7}} = \frac{14\sqrt{7}}{7} = 2\sqrt{7} \ \underline{\mathit{Ans.}}$$

Example **2**. Rationalise the denominator of

$$\frac{2\sqrt{3}+3\sqrt{2}}{5+2\sqrt{6}}.$$

The denominator becomes rational if we multiply by the conjugate surd $5-2\sqrt{6}$. We therefore multiply both numerator and denominator by $5-2\sqrt{6}$. Hence,

$$\begin{aligned}
\frac{2\sqrt{3}+3\sqrt{2}}{5+2\sqrt{6}} &= \frac{(2\sqrt{3}+3\sqrt{2})(5-2\sqrt{6})}{(5+2\sqrt{6})(5-2\sqrt{6})} \\
&= \frac{10\sqrt{3}+15\sqrt{2}-4\sqrt{18}-6\sqrt{12}}{25-24} \\
&= 10\sqrt{3}+15\sqrt{2}-12\sqrt{2}-12\sqrt{3} \\
&= 3\sqrt{2}-2\sqrt{3} \ \underline{\mathit{Ans.}}
\end{aligned}$$

Example 3. Rationalise the denominator of

$$\frac{1}{1+\sqrt{2}+\sqrt{3}}.$$

We have

$$\begin{aligned}
\frac{1}{1+\sqrt{2}+\sqrt{3}} &= \frac{1+\sqrt{2}-\sqrt{3}}{(1+\sqrt{2}+\sqrt{3})(1+\sqrt{2}-\sqrt{3})} \\
&= \frac{1+\sqrt{2}-\sqrt{3}}{(1+\sqrt{2})^2-(\sqrt{3})^2} \\
&= \frac{1+\sqrt{2}-\sqrt{3}}{3+2\sqrt{2}-3} \\
&= \frac{1+\sqrt{2}-\sqrt{3}}{2\sqrt{2}} \\
&= \frac{\sqrt{2}\,(1+\sqrt{2}-\sqrt{3})}{2\times 2} \\
&= \frac{2+\sqrt{2}-\sqrt{6}}{4} \ \underline{\mathit{Ans.}}
\end{aligned}$$

129. We come now to an important proposition in surds.

If $a+\sqrt{b} = x+\sqrt{y}$, where a and x are rational, and $\sqrt{b}$ and $\sqrt{y}$ are irrational, then will $a = x$ and $b = y$. For, since

$$a+\sqrt{b} = x+\sqrt{y}.$$

Therefore,

$$a-x+\sqrt{b} = \sqrt{y}.$$

Squaring both sides we have

$$(a-x)^2 + 2(a-x)\sqrt{b} + b = y;$$

so that

$$2(a-x)\sqrt{b} = y - b - (a-x)^2.$$

Hence we have an irrational quantity equal to a rational one, *unless the coefficient of $\sqrt{b}$ is zero*, in which case the left-hand side of the equation becomes zero. But a rational and an irrational quantity cannot be equal. Therefore the coefficient of $\sqrt{b}$ must be zero, *i.e.*, $a-x=0$, so that $a=x$. It follows, from the given relation, that $\sqrt{b}=\sqrt{y}$, or $b=y$.

NOTE. Since $a=x$ and $\sqrt{b}=\sqrt{y}$, it follows that

$$a-\sqrt{b} = x-\sqrt{y}.$$

It must be remembered that the result just established is only true when $\sqrt{b}$ and $\sqrt{y}$ are really irrational, *i.e.*, b and y cannot have values which are perfect squares.

For example, it is true that

$$4+\sqrt{9} = 3+\sqrt{16};$$

but this does not tell us that $4 = 3$ and $9 = 16$.

130 If

$$\sqrt{a+\sqrt{b}} = \sqrt{x}+\sqrt{y},$$

then will

$$\sqrt{a-\sqrt{b}} = \sqrt{x}-\sqrt{y}.$$

For, squaring the given relation, we have

$$a+\sqrt{b} = x+y+2\sqrt{xy};$$

and, by Article **129**, we may equate the rational terms, obtaining

$$a = x+y, \quad . \quad . \quad . \quad . \quad (1)$$

and we may also equate the irrational terms, obtaining

$$\sqrt{b} = 2\sqrt{xy}. \quad . \quad . \quad . \quad . \quad (2)$$

Subtracting (2) from (1) we get

$$\begin{aligned}
a-\sqrt{b} &= x+y-2\sqrt{xy} \\
&= (\sqrt{x}-\sqrt{y})^2.
\end{aligned}$$

Therefore,

$$\sqrt{a-\sqrt{b}} = \sqrt{x}-\sqrt{y}.$$

131. The square root of a binomial which consists of a rational term and a quadratic surd can sometimes be found.

Example. **Find the square root of $9+4\sqrt{5}$. Let**

$$\sqrt{9+4\sqrt{5}}=\sqrt{x}+\sqrt{y}. \quad . \quad . \quad (1)$$

Then, by Article 130,

$$\sqrt{9-4\sqrt{5}}=\sqrt{x}-\sqrt{y}. \quad . \quad . \quad (2)$$

Multiply (1) by (2). Then

$$x-y=\sqrt{9^2-(4\sqrt{5})^2}=\sqrt{81-80}=1. \quad . \quad (3)$$

Squaring (1) and equating the rational parts, we obtain

$$x+y=9. \quad . \quad . \quad . \quad . \quad (4)$$

Solving (3) and (4) we find

$$x=5,\ y=4.$$

Hence,

$$\sqrt{9+4\sqrt{5}}=\sqrt{5}+\sqrt{4}=\sqrt{5}+2 \ \underline{Ans.}$$

132. We can, however, generally write down the square root by inspection. The square of $\sqrt{x}+\sqrt{y}$ is

$$x+y+2\sqrt{xy}.$$

Therefore,

$$\sqrt{x+y+2\sqrt{xy}}=\sqrt{x}+\sqrt{y}.$$

Hence, the square root of $A+2\sqrt{B}$, *where the coefficient of* $\sqrt{B}$ *is* 2, is $\sqrt{x}+\sqrt{y}$, x and y being such that

$$x+y=A \text{ and } xy=B.$$

In the example of the last Article, to find the square root of $9+4\sqrt{5}$ we must first make the coefficient of $\sqrt{5}$ equal to 2. Thus

$$9+4\sqrt{5}=9+2\sqrt{2^2\times 5}=9+2\sqrt{20}.$$

To obtain the square root we have now only to find two numbers whose sum is 9 and whose product is 20. These are easily seen to be 4 and 5. Hence

$$\sqrt{9+4\sqrt{5}}=\sqrt{4}+\sqrt{5}=2+\sqrt{5} \ \underline{Ans.}$$

133. Equations Involving Surds. We shall now solve one or two equations in which the unknown quantity appears under the square root sign.

Example 1. Solve $\sqrt{x}+\sqrt{5x+1}=2$.

We bring a single radical term to one side of the equation, and put everything else on the other side. Thus

$$2-\sqrt{x}=\sqrt{5x+1}.$$

By squaring, we get rid of the radical on the right-hand side

$$4+x-4\sqrt{x}=5x+1.$$

We now collect terms, and again put a single radical term on one side and everything else on the other, and square. Thus,

$$4\sqrt{x}=3-4x.$$

Therefore,

$$16x=9-24x+16x^2,$$
$$16x^2-40x+9=0,$$
$$(4x-9)(4x-1)=0.$$

Therefore,

$$x=\tfrac{9}{4} \text{ or } \tfrac{1}{4} \ \underline{Ans.}$$

Example 2 Solve

$$\sqrt{16-7x-x^2}=x^2+7x-\frac{1}{4}.$$

Here it should be noticed that the coefficients of x^2 and x under the radical sign, *viz.*, -1 and -7, are in the same ratio to one another as the coefficients of x^2 and x in the rest of the equation. Whenever this is the case, the equation is transformed into a form readily solved if we put the radical equal to y.

Thus, let

$$\sqrt{16-7x-x^2}=y.$$

Then,

$$16-7x-x^2=y^2. \quad . \quad . \quad . \quad (1)$$

Therefore,

$$x^2+7x=16-y^2.$$

Therefore the given equation becomes

$$y=16-y^2-\frac{1}{4};$$

or

$$4y^2+4y-63=0.$$

Whence,

$$y=\frac{7}{2} \text{ or } -\frac{9}{2}.$$

Substituting these values of y in (1) we obtain two quadratic equations, *viz.*,

$$16-7x-x^2=\frac{49}{4},$$

and

$$16-7x-x^2=\frac{81}{4}.$$

Solving these, we obtain four values of x,

$$x=\frac{1}{2},\ -\frac{15}{2},\ \text{or}\ \frac{-7\pm 4\sqrt{2}}{2} \ \underline{Ans.}$$

EXAMPLES 33

Simplify

1. $\sqrt{45}-\sqrt{20}$.
2. $3\sqrt{48}+5\sqrt{27}-2\sqrt{12}$.
3. $4\sqrt[3]{24}-\sqrt[3]{81}$.
4. $\sqrt{13}\times\sqrt{52}$.
5. $\sqrt{32}+\sqrt{72}$.
6. $\sqrt{27}\times\sqrt[3]{9}$.
7. Multiply $3\sqrt{2}-\sqrt{5}$ by $2\sqrt{2}+3\sqrt{5}$.

Find the square roots of

8. $11+4\sqrt{6}$.
9. $52-7\sqrt{12}$.
10. Simplify

$$\frac{1-\sqrt{2}+\sqrt{3}}{1+\sqrt{2}+\sqrt{3}}-\frac{1-\sqrt{2}-\sqrt{3}}{1+\sqrt{2}-\sqrt{3}}.$$

Solve the following equations

11. $1+2x\sqrt{1-x^2}=9x^2$.
12. $\sqrt{5x+1}-\sqrt{x}=1$.
13. $\sqrt{58-13x}-\sqrt{13x+7}=3$.

HARP PRACTICE

Pedal Changes for Major Scales. The Melodic and Harmonic Minor. Chromatic Scales. Fingering. Modulation. Key "Colour"

By ALGERNON ROSE

COMPARED with the pianist, the harpist may be said to learn his scales backwards in regard to their signature. Doubtless, many harp teachers have explained verbally how the pedal changes are made in the simplest way into all the different keys, but we have not come across any such information in print. The SELF-EDUCATOR may therefore be particularly helpful at this juncture.

The fact that the natural scale of the double-action harp contains seven flats, B, E, A, D, G, C, F, need not perplex. These flats correspond to the number of levers in the pedestal of the instrument. Write them down in their proper order on a piece of music-paper. To put the entire compass of the harp into a key which has six instead of seven flats—namely, G♭—what has the student already done? He has knocked off the last flat, F, in the signature of the harp's natural scale. In other words, he has put down the F pedal one notch. Likewise, to play in the key which has five instead of six flats (D♭ major), he deletes the next flat, C, by slipping down the C pedal one notch. To play in A♭, which has four instead of five flats, he gets rid of the next accidental, G. How? By lowering the G pedal one notch. To transpose the instrument into E♭ major, which has three instead of four flats, he expunges the D♭ in the signature by depressing the D pedal one notch. To modulate all the strings into B♭ major, which has two instead of three flats in the signature, he takes away the redundant A♭ by lowering the A♭ pedal one notch. To get into the key of F major, which has one instead of two flats, he dismisses the E♭ by putting down the E♭ pedal one notch. Finally, to get rid of the B♭, he puts down the B♭ pedal one notch. All the pedals are now down.

It is as if a company of soldiers were kneeling instead of standing to shoot. Every string throughout the instrument has been raised half a tone, just as the sights of the soldiers' rifles have been raised to get a longer aim. So the key of the harp is now C♮, represented by the white notes on the piano. The next problem is to get into the sharp keys. What has the harpist to do? The key with one sharp is G major, in which the accidental is F. To add this, press down the F♭ pedal to the second notch. This raises all the blue strings a second semitone. The key with two sharps is D major, of which the second accidental is C. Press down, therefore, the C♭ pedal to its second notch. This raises all the red strings another half-tone. That key which has three sharps is A major. G♯ has to be added. Therefore, lower the G♭ pedal to its second notch. E major rejoices in four sharps, the

Ex. 16. MODULATION FROM C MINOR TO G MINOR [G Minor]

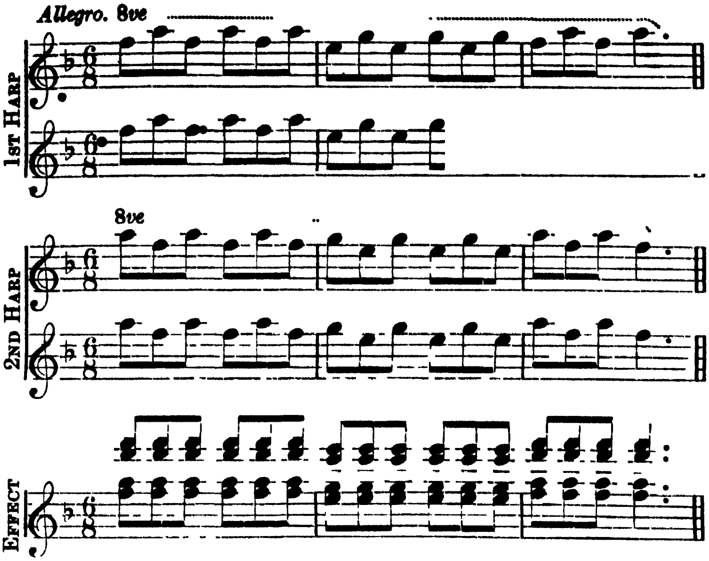
Ex. 22. CROSS FIRE



fourth being D. Consequently, to get it, down goes the D♭ pedal to its bottom notch. B major is the key with five sharps, the fifth being A. So lower the A♭ pedal to its second notch. The key with six sharps is F♯ major, the sixth being E♯. In the same way, depress the E♭ pedal as far as it will go. Lastly, the key with seven sharps is C♯ major, the seventh accidental being B. Therefore, lower the B♭ pedal in the same way.

All the pedals are now down to the second notches. It is as if the company of riflemen are in a prone position, with all their sights put up as far as they will go so as to enable shooting at the maximum range. In the same way that, if all the pedals are put up, there are seven flats in the signature of the piece to be played, so now, when all the pedals are down in the second notch, the harp is transposed into a key with seven sharps.

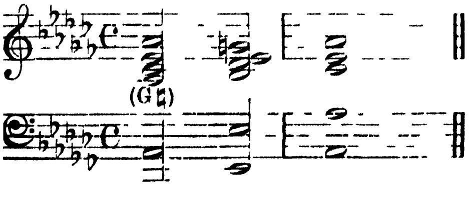
Minor Scales. Hitherto we have confined our attention to the major scales. But the minor form, which, as its name implies, occupies a subordinate place to the major, has undergone many changes. Originally it was the tone-system in common use, having been derived from one of the ancient Greek forms and introduced thence into the music of the Early Christian Church. In ancient harp music there are plenty of melodies built up on the old Greek scale. Being the most ancient of stringed instruments, the harp was tuned in a minor rather than, as now, the major mode. Consequently it is the system of tuning rather than the nature of the instrument itself which makes it so difficult to-day to render chromatic passages on the double-action harp. Even if the instrument, however, were tuned differently, it would not enable it to meet the requirements of certain modern composers. The only result would be so to confuse the player as to necessitate his relearning the instrument. The old Greek minor scale is shown in Ex. 17. (The previous Example, Ex. 16, is referred to later.)

But this system gave no leading note or sound a semitone below the tonic, essential in the modern form of the scale. If the G only was sharpened, that meant that the interval from F♮ to G♯ exceeded a whole tone. It was long considered admissible to augment the tone in such a way. So the F was raised to F♯, and the first alteration of the Greek system sounded as Ex. 18.

Yet, although the effect was delightful as the sounds rose from the lowest to the highest notes, they were too much like the major scale when they went downhill. Consequently, the sharps to G and F in descending were omitted. That simple alteration gave the Western world what is known as the "Melodic Minor Scale." In the method of transition coming down the change contrasts pleasantly with the well-defined steps going up. The æsthetic reason for the charm which the ear finds in the melodic minor are discussed at length in Helmholtz's "Tonempfindungen" and Pole's "Philosophy of Tone" In the melodic minor the sound-ladder is as written in Ex. 19.

The Harmonic Minor. Considering how many modes, or series of different scales, were required to satisfy the ears of the Greeks, as those of the Indians and Chinese to-day, it is remarkable that Europeans for a long period contented themselves with only two forms, the major and the melodic minor It took centuries before theoreticians would allow that an augmented tone was permissible. They agreed that a leading note going up to the tonic was wanted. This necessitated, to their minds, the F♯ as well as the G♯. Practical musicians, nevertheless, began to associate F♮ with G♯. Eventually, therefore, practice overruled theory. Not only was the ancient F♮ restored, but the descending was made to conform with the ascending scale. The result was our modern sequence, known as the harmonic minor. [Ex. 20]

Ex. 23

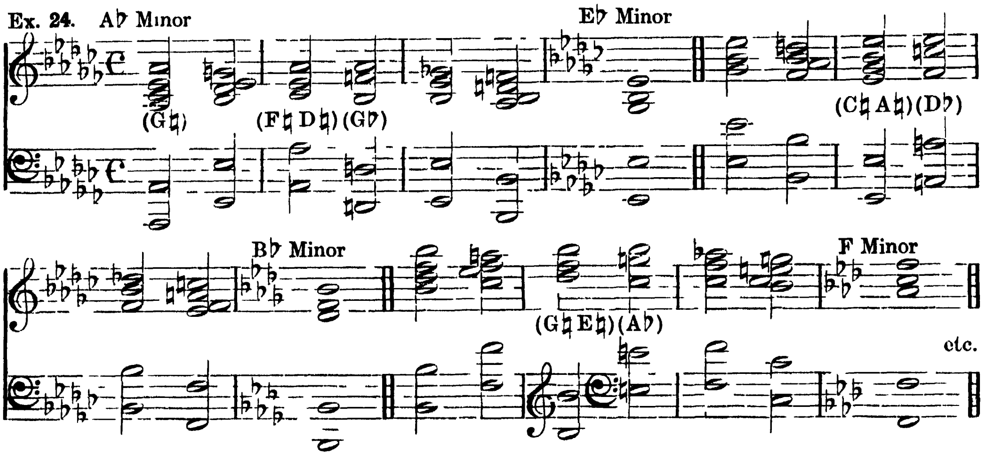


The problem of putting new wine into old bottles, we know, is difficult to solve. The modern musical wine, with its abundant discords, is somewhat at variance with the anatomy of the ancient harp. Ingenious as is the double-action mechanism of the modern harp, composers are too often unmindful that it is essentially a diatonic instrument. It will have been perceived, by the pedal changes already given, that transition from major keys to those nearly related to them is simple. But the student will long since have become aware that, if the F♭ pedal is depressed, he cannot raise the tone of one F without affecting similarly the sounds of all the other F's, or any other note chosen, throughout the scale. To make an instrument, therefore, which is essentially anti-chromatic dodge about in detached semitones renders exceedingly difficult, if not impossible, the execution of rapid passages where the accidentals ascending are unlike those used when descending.

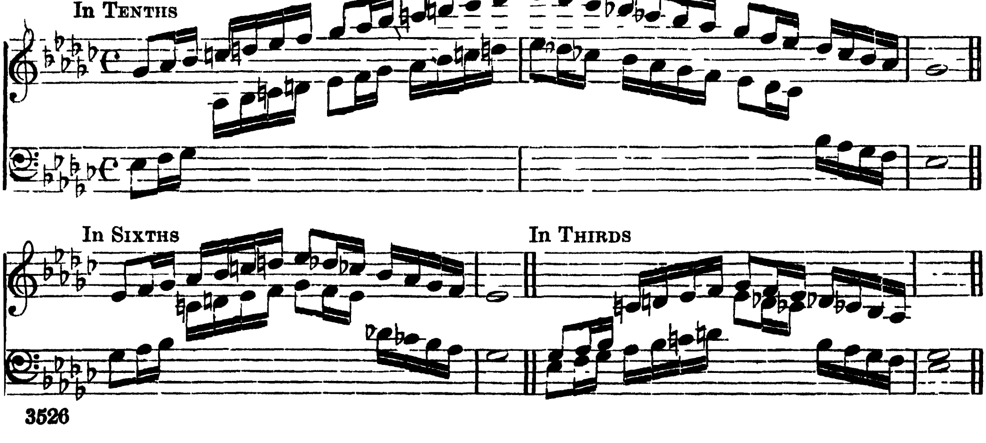
Wagner, and later eminent composers, have not infrequently recorded passages for the harp which are most embarrassing. Professor Prout instances, in the final scene of the "Walküre," a phrase consisting of four groups of semiquavers in each bar, requiring, in almost every little batch, a change in the harp of two and sometimes three pedals. Clearly such sequences of notes are opposed to the character of the instrument. Yet an orchestral player is expected to make bricks without straw, and the sooner the ambitious student realises that fact the better will it be for him ultimately.

The Chromatic Harp. To meet the demand of certain modern composers who score for the harp as if it were a piano, M. Gustave Lyon, of Paris, introduced in 1903 a harp without pedals, but with the strings arranged so that those representing the white notes of a keyboard are on one side of the player and the black notes on the other. Although this arrangement met with favour at the Brussels Conservatoire, it has not been taken up by harpists generally. As pointed out by Mr. George Morley, it deprives the instrument of its strong individuality without imparting to it the capabilities of the piano. Therefore, the student can scarcely hope to have access to such an extra instrument on the orchestra. If he is ambitious, there is nothing for him but to get through, as best he can, the enharmonic briars and brambles with which the modern composer takes a weird delight in pricking the harpist's fingers.

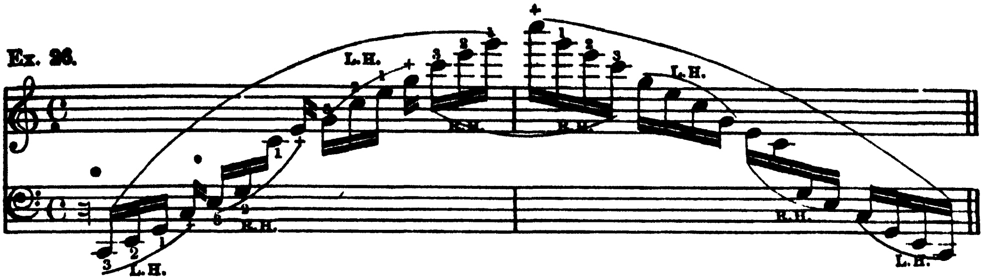
Ex. 24. A♭ Minor



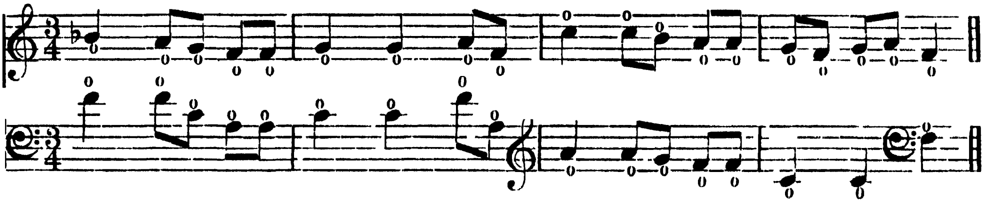
Ex. 25 E♭ Minor



Ex. 26.



Ex. 27.



Chromatic Difficulties. As a preliminary illustration of the difficulties to be encountered, let the student practise slowly with one hand, going up and down the scale in semitones. Endeavour to play each note in strict time A child can do this on the piano without trouble, but to accomplish the same thing on the harp means putting into action in rapid succession, for the first octave only, some five pedals, quitting them as promptly, and repeating the same gymnastics in the octave above. [Ex. 21.]

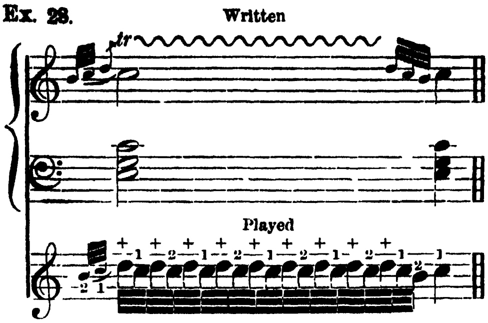
It is customary with composers who are considerate to warn the player to prepare in advance for a pedal change by inserting in the music "G♮" "F" "E" or whatever note is coming that is foreign to the key signature. When minor keys are executed at even moderate speed it will, of course, be evident that the requisite pedals must be changed almost instantaneously.

Two Harps. But in one sense the composer, instead of being denounced for writing detestable passages, ought to be thanked by harpists. The peculiar difficulties he has set down have frequently led a careful conductor to engage two performers instead of one at a concert, and, consequently, pay double fees. Two harps also, by interweaving parts and playing what are known as "cross fires,' get a clearer and better effect in certain passages. [Ex. 22]

Now put up all the pedals so that the harp is in its natural scale, or signature, of seven flats. Take the minor scales systematically, as was done in the case of the major. A minor third below C♭ is A♭. This, therefore, is called the "relative" minor of the major scale already played. But the semitones in the minor scale, instead of, as in the major coming between the third and fourth and seventh and eighth notes in ascending or descending, now occur in the harmonic minor, it must be remembered, between the second and third, fifth and sixth, and seventh and eighth, and the same in descending. In the melodic minor, however, they come between the second and third and seventh and eighth notes going up, and the sixth and fifth and third and second coming down. The latest word in harp-playing at the time of writing has been said by M. Raphael Martenot. But even he, in his "Methode de Harpe: Théorique et Practique," confines the attention of the advanced student, when it comes to minor scales, to the harmonic form. Before beginning the A♭ harmonic minor, play with all the pedals up the tonic chord. Next try the dominant chord given in the example, consisting of the notes E♭, B♭, D♭, E♭, and G♮. To get the G♮, lower the third pedal on the right to the first notch. [Ex. 23].

The Fingering. No matter how many or how few sharps or flats a minor scale contains, the fingering is uniform in all keys. When the harp is played in octaves, it is the same for both hands. Herein the student has a great advantage over the pianist. Prepare the left hand for the A♭ (third ledger line, bass clef, below staff), and the right hand for the A♭ (first space, bass clef) an octave above. Care should always be taken in preparing the fingers not to touch the strings prematurely, so as to prevent any unnecessary vibration. The student also should make it a rule to familiarise himself thoroughly with one difficulty and overcome it before proceeding to the next. Strike each A♭ with the third finger; the B♭ with the second finger; the C♭ with the first; and the D♭ with the thumb; always making preparation in advance. For the E♭ above use the third finger; for the F♭, the second; the G♮, the first; and A♭, the thumb. For the B♭ strike with the second; the C♭, the first; the D♭, the thumb; and the E♭, the third. For the F♭ use the second; G♮, the first; A♭, the thumb; and B♭, the second. For the C♭ above, the first; the D♭, the thumb; E♭, the third; and F♭, the second. For the G♮, the first finger; A♭, the thumb; B♭, the second; and C♭, the first. For the D♭, the thumb; E♭, the third; F♭, the second; and G♮, the first. For the top A♭, completing a four-octave scale, use the thumb.

Ex. 28.



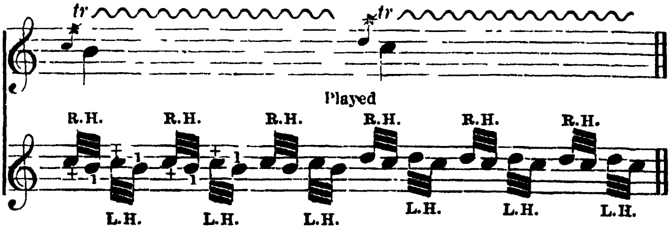
In descending, reverse the order of the fingers, so that the digits strike the same notes in like sequence as in ascending. Now, there is nothing bewildering in all this. It is really simple. The student should write out the notes and fingering for himself. He will then observe that, in going up, the third, second, first and thumb are used twice. Then comes a change to second, first, and thumb, followed by first, second, first, and thumb; and that order is continued up to the top A, the same rule applying when coming down.

Modulation. The gymnastics, therefore, do not occur in the fingering, but in the pedalling. Always accustom the eye to read at least a bar ahead, because the pedals have to be changed and released while the scale is being played. As uniformity in the rate of progression by both hands is indispensable in scale practice, the effect will be unsatisfactory if pauses are made to enable the feet to do their work. A "scale" implies a ladder, as the word is derived from the Latin, *scala*. The art in scale playing is therefore to run up and down the imaginary ladder in such a way as to make the gradation in the series of tones or half-tones so regular that the steps may not be noticed. The sounds must flow evenly, thereby concealing the art which is necessary for their production. But the musician's ear is dissatisfied if one minor scale, say, in seven flats, is ended abruptly, and the next, in six flats, begins immediately, without some appropriate chord intervening. What is wanted is a tonal bridge, so that the two keys may be linked by appropriate modulation. To transpose the harp from a major scale in seven flats into one in six, we knock off, as already explained, the last flat in the signature—namely, F—by depressing the second pedal on the right one notch. But before doing this, after completing the scale of A♭ minor, confirm it by its dominant chord, which contains G♮. For this the right pedal has to be put down.

To get the first inversion of the new dominant, before finishing with a perfect cadence leading into E♭ minor, put down to the first notch the second (F) pedal and the third left (D), reinserting the G♭ by releasing the third right pedal. After practising the E♭ minor scale, modulate in the same way (by depressing the C and A pedals one notch, and releasing the D pedal) into the key of B♭ minor, with five flats. The obliteration of one flat in each succeeding signature is effected by depression of the pedal in question one notch, as explained in the major scales. Thus we go from B♭ minor, with five flats, to F minor, with 4, C minor, with 3 [Ex. 16], G minor, with two, and D minor, with one, until we arrive at A minor, which is without accidentals in the signature. Then we add one sharp for E minor, which has F♯ in its signature, because it is the relative of G major. So the F♭ pedal is slipped down to its second notch. In the same way add a second sharp for B minor, a third for F♯ minor, a fourth for C♯ minor, and so get round the circle. For the modulations we give an example from Mr. Oberthur's "Harfen-Schule." By raising the alternate scales a tone at a time, and similarly altering the pedal indications, the student should have no difficulty in transposing on paper the other minor scales with their modulations. [Ex. 24.]

The Melodic Minor. Although the harmonic minor form of ascending and descending the scale may suffice usually, it behoves the student, whilst accepting general principles, to prepare himself for the many violations he will find of them in certain orchestral parts. Having become familiar with the harmonic minor scales in octaves, the amateur, however, who is confining his attention to solo work can devote his leisure to arpeggio exercises in keeping with the character of his instrument. But the student who has a hope of eventually securing an orchestral engagement at a provincial festival cannot afford to overlook the tendency that some modern writers have to make their music jump about in semitones remotely related to the signature of the key in which the work begins. Plenty of fresh difficulties to overcome will be found if the melodic minor scales are now tackled through all keys, not only in octaves, but in tenths, sixths, and thirds. The difficulties of pedal arrangement necessitate movements of the feet which cannot be made rapidly enough to correspond with their relative strings so as to enable the scales to be executed in quick time. Moreover, such pedal adjustments cause a great deal of noise. Yet, as an exercise for familiarising the student with chromatic entanglements, persistent attempts to execute slowly the scales in intervals which cannot be performed quickly will give him, often by means of borrowed notes, such as using a

Ex. 29.

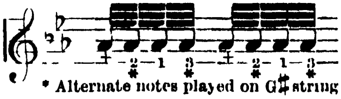


G♯ for an A♭, etc., an insight into the most expeditious way of rendering, instinctively, unusual notations as artistically as possible. [Ex. 25.]

Key "Colour." Sound, like colour, is dependent upon the rapidity or slowness of vibration, the undulations which produce low notes being less rapid than those which give us the high ones. In like manner, the colours of the rainbow recorded by the spectrum almost double themselves, when passing from red to violet, in velocity of pulsation. When a piece, therefore, is played throughout in C♭, and is afterwards transposed to a higher key, the complexion, or colour, of the music changes.

But it is as easy to play in one key as in another on the harp. The student should take advantage of this fact. He can spare himself thereby the monotony of constantly repeating one exercise in the same key as he would have to do if he practised any other instrument. He should now go back, repeat, and, if ingenious, add to the exercises already tabulated, and increase his interest in them by trying them in all the keys. If, for example, he practises the scale of C major by depressing all the pedals to the first notch, striking the notes very slowly, he can then transpose the scale into the key of G, slightly increasing the speed. Afterwards, he can continue it in D major. Next go to A major, E, and so on, until he has modulated through all the keys and obtained infinite variety whilst exercising his fingers all the while in the same manner. He will soon find himself able to play in any key his fancy dictates. But he should remember this fact. The tone of the harp is richest in its natural key, and least sonorous when the pedals are depressed to the second notch. Why? Because the strings are then shortened, and it stands to reason that a long string possesses more resonance than one which has had an inch cut off it. Therefore, although on the piano the key of F♯ major, with six sharps, and G♭ major, with six flats, sound alike, this is not the case on the harp.

Ex. 30. HOMOPHONES



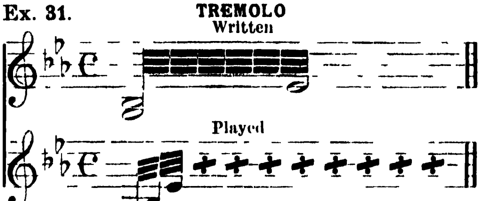
* Alternate notes played on G♯ string

To play in the former key, the harpist has six of his pedals down to the second notch, so that most of the strings are considerably shortened. On the other hand, if he plays in G♭ major, he has only one pedal, the F♭, down to the first notch. This accounts for the reason why, in an orchestral score, the harp part sometimes appears to be written in a wrong key. Should the harpist come across a solo in F♯ major, he will do better justice to himself and his instrument by playing it in the enharmonic key. But for practising purposes, if he succeeds in getting a rich tone out of the sharp key, he will add to his confidence when playing in the natural scale. Now take groups of four notes, first with the left hand and then with the right, as here indicated, and exercise the fingers with them through all the keys. Endeavour to strike each note with equal force. Be careful to keep strict time. [Ex. 26.]

Harmonic Sounds. On the harp, harmonic effects are particularly beautiful, although only one such sound is produced from each string instead of several, as can be obtained from each string of a violin. To produce the harmonic, press the middle red string very lightly at exactly half its length. Do this with the first joint of the first right finger, curved down while the thumb strikes the note. Immediately this sounds, remove the finger from the string. Do not bend the second, third, and little fingers too much. Hold them gracefully. Now, with the left hand, try the octave C below. Press the middle of the string gently with the fleshy part of the palm, not the ball of the thumb. Sound the note as before with the thumb. Harmonics on the harp are finest in the bass and middle register of the instrument, and are seldom written above D, fourth line, treble clef. In the music, they are denoted by an O over the notes, or sometimes by "s.h.," meaning *sons harmoniques*. Try a simple melody in this manner. Practise first with one hand, then the other. Afterwards play with both together. [Ex. 27.]

Homophones. From the explanation given of the pedals, it will be understood that in harp music there are neither double sharps nor double flats. When such occur in modern compositions, the harpist has to play the enharmonic equivalent. On the piano there is only one key for D♭ and C♯, for E♭ and D♯, for F♭ and E♮, for F♮ and E♯, for G♭ and F♯, for A♭ and G♯, for B♭ and A♯, for C♭ and B♮, and for C♮ and B♯. But on the harp, by means of the pedals, each of the foregoing notes can be represented by separate strings next to each other. These are called "homophones," or "synonyms." [Ex. 30]. By means of such doubled notes, extraordinary effects can be obtained of a delightful character impossible on any other instrument, after the harpist has put down, say, the pedals for D♯, E♭, F♯, G♭, A, B♯, and C♭. This leads us to "sliding" effects.

Ex. 31. TREMOLO



The Glissando. On the piano it is possible to accomplish this in a complete scale only, along the white keys, or in C major. By means of the pedals, the harpist has the advantage of the pianist. Delightful glissandos on the harp can be made in every key, at any rate of speed, and with any degree of strength desired, from the softest whisper to the loudest sound the strings can give. Further, by means of the pedals, glorious effects can be obtained on the double-action harp through the use of "homophones," to which we have alluded.

To produce this effect, slide the thumb and third finger, or the thumb, first, second, and third fingers along any arpeggio passage after the pedals have been suitably arranged. Pass the thumb down the whole succession of the strings. Prepare the first, second, and third fingers to execute the last notes just before the thumb reaches the bottom of the passage. For the ascending glissando, use the first finger. After sounding the top note, take the hand instantly off the strings. Directions for this manner of playing are indicated either by the word *glissando* or *strucciolamento,* meaning, "to slide." After practising this effect with one finger of each hand, try two fingers, because the gliding can be done effectively in thirds, sixths, octaves, tenths, as well as seconds and fourths.

Damped Sounds. The French for "damped" or muted sounds is *sons etouffés.* To get this effect, place the whole of the hand flat against the strings with the fingers shut and their tips touching the strings. Sound the string by the thumb, and force the ball of the thumb against the string to damp the sound. Keep the thumb rigidly upright. Use the tips of the fingers by pressing them against the strings, to give the thumb the necessary leverage. For sounding the next note, the thumb is got ready by a slight movement. Notes to be played in this manner are marked in the music thus ⊕. For marches, chords struck in this way are very appropriate. To play them, keep the elbow low. Round the fingers less than usual. The palm must be close to the strings, so as to stop the sounds at once. As the right wrist is supported by the soundboard, the damping with the right hand is done by the fingers.

To accomplish the shake the student must practise patiently and continually. The shake is produced by sounding one note and the next higher to it quickly, and repeating the operation as long as is necessary. Take care to move the fingers only. Keep the wrist flexible, and avoid any motion of the arm. Although only two notes are sounded, the shake is done best by using three fingers. Strike the upper note with the thumb. Sound the other note with the first and second finger alternately. [Ex. 28.]

Chain Shakes. It is well to practise the shake all up and down the scale. Use both hands alternately. Sound the notes at first very slowly. Always practise the shake in strict time. After exercising the fingers deliberately, double the speed. Go back to the slow tempo. Try again, as rapidly as possible. In other words, shake slowly for four bars, and then do the next four bars quickly. To trill powerfully and firmly, the thumb and the elbow must always be held high [Ex. 29]. A delightful tremolo effect is obtained by doing the shake on *homophones* or strings lying adjacent which give the same sound after the pedals have been adjusted to bring them into unison. If the tremolo passage, or the shake, is a long one, use the thumb and three fingers instead of two. Played very softly on the harp, the tremolo, or shake, has a distinctive charm. It is then marked *bis bigliamento,* which means whispering. [Ex. 30].

Tremoloed Arpeggios. This glorification of the ordinary arpeggio was introduced by the harp virtuoso, Parish Alvars. It requires considerable practice. Briefly, it is the rapid repetition of three or four notes, as shown in Ex. 31.

The guitar sound effect is indicated in harp music by the words *sons d'ongles,* or nail-sounds. These are created by striking the strings near the wrest-pins with considerable force, using the nails. Employ the tips of the fingers if the nails are not strong enough.

Lute Sounds. The words "near the soundboard" usually indicate the lute effect. It is supposed to resemble the tone of a wire-strung lute when struck by a plectrum. In this case press down the soundboard slightly with the fingers of the left hand, after each note has been struck as before near the pegs with the right hand. The pressure of the left fingers on the soundboard must be at the opposite end of the string actually struck. So as to give resistance to the tips of the fingers, use the thumb as a lever on the body of the instrument. This manipulation gives a portamento effect to the vibration, so that the sound of the string seems to be carried on to the next one.

Unique Effects. Amongst peculiar achievements indulged in by good harpists is that of altering the pitch of a sound by pressure of a pedal. Thus, play B♭. Immediately press down the B♭ pedal one notch. The vibration of all the B♭ strings pulsating in sympathy with the one struck will be raised half a tone to B♮. The sound, although the string is not again struck, glides up spontaneously a semitone with an æolian effect. This ingenious device is often used when two notes, one half a tone above the other, are connected by a slur. In music, the indication is *liez par la pedale,* or linked by the pedal. [Ex. 32.]

Continued from page 3458

By W. S. MURPHY

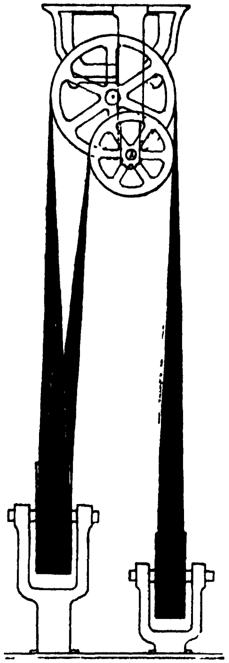
Machine Driving Belts. Driving power from steam, gas, and water has to be transmitted to the machinery by means of shafting, with tooth and pinion wheels, by ropes, or by belts on pulleys. In some factories we find a combination of all three methods. The main drive may be transmitted from the engines by ropes on to the main shafting, tooth and pinion wheels taking the power along the ceilings of the machine-rooms on shaftings, from which belts take the power to the machines. Every workman has, or ought to have, a good opinion of the products of his trade. If you ask a millwright what is the best sort of drive, he will say that it is the tooth and pinion, of course, and give very strong reasons for his opinion ; if you ask a rope-maker the same question, he will prove to you, beyond all cavil, that the rope drive is unequalled, for heavy work especially ; and the leather belt maker has an even stronger assurance of the superiority of leather belts over all other power transmitters. It may be trade conceit, but we hold strongly to the idea that the belt drive is superior to all others for general purposes. Rope drives are difficult to regulate, the ropes being apt to develop different rates of speed, and produce an oscillating motion very trying to machinery ; the leather belt, being a unity, runs at one speed. Tooth and pinion wheels are liable to break without a moment's warning, a sudden jar smashing the teeth and bringing the machinery to a standstill while a new wheel is being got and put in place ; leather belts, on the other hand, give long warning, and in case of a break, a repair sufficient to carry through the work of the day is only a matter of a few moments.

Engineering Skill Useful. As he is the coadjutor of the engineer and machinery user, the belt-maker should possess more than a smattering of mechanical science In the course of his work he will be called upon to solve many problems in mechanics. A leather belt maker who acquires a reputation for ability to help the engineer or the factory manager over difficulties is sure of success ; without that reputation and ability, he might never get a footing on the market. Moreover, the belt-maker is frequently offered tasks involving a high degree of engineering skill. To the uninitiated it seems impossible to transmit power round a corner with belts ; but it can be done, as our illustrations [23 and 24] show. It is in extensions of works that most of these problems come into existence. For some reason, the added building cannot be built in line with the old factory ; the new wings must be set at obtuse angles ; the main shaft of a new department needs to be set at right angles with the engine—for these eccentricities, and many others, the belt-maker has to be prepared.

At the very least a knowledge of mechanics is a defensive weapon without which the maker of belts may often be unjustly put down. The belts are frequently blamed for the faults of the machinery. Many instances of this could be given. A common cause of dispute between the belt-maker and the belt-user is the heating of bearings that stiffen the drive and bring about a disastrous break. When the cause is hurriedly sought, the bearing has cooled down, and because no other thing seems guilty the belt is blamed.

Use of Belts. The earliest and most obvious use of the leather driving belt was as a substitute for cord in power transmission over short distances. We can trace the steps by which the belt entered industry in the cotton manufacturing process. First there was the spinning wheel, the spindle of which was driven by a cord from the wheel ; next the improved hand loom, with leather thongs on the picking handle ; then the spinning machines, with shafting driven by water power, and the belts connecting the pulleys on the shafting with the spinning frame. For a long time the belt drive was only used for small work—the driving of lathes, planers, looms, and all machine tools ; but the main drive was entrusted to the millwright. To the cautious, solid-working engineers of the early nineteenth century, the belt seemed a risky vehicle for high powers. What they would say now, if they saw a belt carrying 500 h.-p., it is impossible to guess ; but the fact would certainly surprise them. Makers of power transmitters have contended for the main drive as the prize to be won. Both engineers and leather manufacturers in this country seemed for a long time to consider leather belt out of the running for that high function. Between the engine and the driving machinery a space of as much as 150 ft. sometimes intervenes ; to piece the available lengths of leather hide together into such a length seemed, before it was successfully undertaken, a task insurmountable. The breadth, too, for carrying high powers was a problem. Ropes could be multiplied to need, tooth and pinion wheels could be made any size, woven belts might be made any breadth ; but the breadth of the hide alone was accepted as the limit of the breadth of a belt.

An American Example. Here we come upon one of the indirect benefits civilisation has derived from colonisation of wild and distant lands. So long as he had a millwright or a rope-maker handy, the engine builder might never have given leather a chance of helping him ; but away out in the backwoods of America the case was wholly different. The hardy lumberer had water-power, timber, and oxhides in plenty ; but the millwright was far away, and freight of iron and steel is costly. But the pioneers of our race are handy men, to whom practical difficulties are merely a stimulus to invention. They made water-wheels and driving shafts of wood, and driving-belts out of the raw hides of oxen. When the bullocks were skinned, the hides were nailed upon wooden frames, and there dried and cured with the hair on. Cut into strips, the hides were softened by friction and grease, and laced together into the lengths and breadths required with raw-hide thongs. When population came along, and the settlement grew into a town, machinery also came, and the raw-hide belts rose to higher usefulness, their lightness, strength, and handiness giving the belts preference over all other transmitters. The belt-makers in the Motherland were not long in profiting by the example of our kinsmen beyond the seas, and began to undertake the whole of the power transmission, from engine to machine. Within recent years the trade has grown to large dimensions, and driving-belts are the familiar friends of all engineers. Larger and larger belts are being demanded, and, of course, a corresponding improvement in strength and lightness required. Belts 6 ft. in breadth and of great length are constantly in use at the present day, and belt-makers will cheerfully guarantee efficiency in belts 12 ft. broad.



28. TRANSMITTING POWER
(Shaft is at right angles to machine)

Values of Belts. The qualities required in a driving-belt are strength, durability, and conveying power, with a minimum of stretch. On these points ample data have been supplied by the trade. In the various tables compiled we have found considerable discrepancy ; but the following have been drawn from reliable sources and practical experiment :

TENSILE STRENGTH OF LEATHER BELTS PER SQUARE INCH.		
Tannage.	Pressure at Breaking-point.	Per Cent. of Stretch.
	lb	
Best British Oak-tanned	5,746	24
Best Foreign Oak-tanned	4,974	25·4
Common British Oak-tanned	4,243	25
Common Foreign Oak-tanned	2,708	—
Finest Chrome-tanned ..	10,050	32
Alumned and Stuffed ..	11,900	38·3
Alumned Rawhide ..	13,100	31·4

One square inch of belting is equal to a belt 4 in. broad, ¼ in. thick. These tests are purely experimental, and bad conditions will altogether throw them out ; but a wise belt-user is sure to allow a considerable margin of strength.

Belt Velocities. The ability of belts to transmit power may be increased or diminished by several conditions. It is well known that wooden pulleys have a greater adhesion than metal ones, and lie more kindly to the belt. Observing this, some engineers offer leather-covered or rubber-covered pulleys to manufacturers desiring the best kind of drive. Wooden pulleys, or pulleys covered with leather or rubber, almost double the draught of the belt ; but the bare metal pulley wears longest and gives the most constant drive. Our calculations, therefore, are based on the use of metal pulleys. What might be called velocity problems take three forms, proceeding from two known factors to an unknown. First, and most important : at what speed will a belt, running at a certain velocity on a given diameter of pulley, drive a shaft ? Secondly : what is the diameter of pulley required to develop a certain belt velocity, with a shaft running at a given speed ? Thirdly : what is the belt velocity developed by a shaft running at a given speed, with a pulley of a certain diameter ? The three factors are mutually related and coefficient, change in the one altering the other two. The table itself, shown on next page, best illustrates the principle.

Transmitting Power. We have left the most important set of questions to the last. Every user of power is deeply concerned about how much horse-power he can get out of his engines and gearing. The question the belt-maker has to answer more frequently than any other is : What is the transmitting power of your drive ? This is the crucial point, and really involves all others. Horse-power 1-in. width leather belt will transmit :

SINGLE BELT.		DOUBLE BELT.	
Diameter of Pulley.	Belt Speed per Minute.	Diameter of Pulley.	Belt Speed per Minute.
Ft.	Ft.	Ft	Ft.
1½	2,400	1½	1,333
2	1,600	2	1,000
2½	1,240	2½	1,875
3	1,066	3	730
3½	950	3½	625
4	800	4	500
5½	680	5	400
6	533	6	335
7	457	7	286
8	400	8	250
9	355	9	222
10	250	10	200

TABLE OF BELT VELOCITIES.

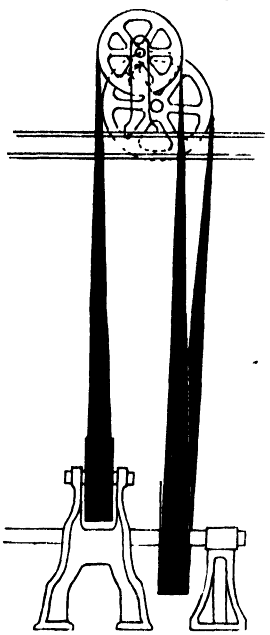
Slipping Belts. The practical details a leather belt maker has to consider are very numerous, and we can only touch on a few of the more important. When the belt slips, it is a temptation to adopt flanged pulleys ; but this may only add to the mischief. The pulley is most likely off the plumb, and the belt, bearing up against the flange, is cut and frayed to pieces in no time.

To many the side of the belt which should lie next the pulley seems a matter of indifference, and some prefer the grain side because it presents a rougher surface. Here are two errors. Hardness is the last quality to be desired in a belt surface. The natural bend of all leather is towards the flesh side. Nature is emphatic on this point. The skin is a wrap round the body of the animal, and curves to the flesh it covers. Given fair play, the flesh side of the belt will hug the pulley and carry away every ounce of power from the driver and put it on to the driven pulley.

Belt to Pulley. The relations of belts to pulleys call for attention. The pulley should always be wider than the belt, and allow for the play of the drive. Narrow pulleys cut and score belts. The diameter of the pulley should be proportioned to the thickness of the belt. For heavy drives a thick belt is needed, and a machine user wants to get the highest shaft speed possible from his drive. He therefore is apt to work with small pulleys. But to bend a belt ⅜ in. thick round a drum 4 in. in diameter is suicidal The bend produces creases, the creases wear, and the belt cracks. A gentle curve produces no appreciable strain on the leather, but a severe bend undoubtedly does, and takes from the tensile strength of the belt.



24. TRANSMITTING POWER (Power at right angles to shaft)

Compound Drive. Perhaps the most remarkable discovery made in regard to belting during the past forty years was the principle of compounding introduced by John Tullis. Seeing a locomotive engine with coupled wheels working with a heavy load on one pair of rails, the inventor thought that a pair of belts working on one pulley ought to carry something like double the power. He tried the idea by experiment, and found the theory correct. This simple expedient has saved much trouble and expense. If you want to transmit, say, a third more power, the common recourse would be larger or more pulleys and wider belts ; but all you have to do is to put a belt on the top of the old one already working. Each belt takes its own drive from the engine to the shafts, and increases the driving power by 100 per cent. Compounding has given a mobility to belt-driving very wonderful to the inexperienced. On a single driving pulley you can put six driving belts, and let each driving belt drive a different shaft, with practically the same result as if you had erected six driving pulleys.

Successful Compounding. Many instances are given by the inventor of success in the use of compound belt-driving ; but we can only give two instances which illustrate the service of the device in overcoming a difficulty. Some years ago, extensions were being made in a London flour mill, demanding from 80 to 100 per cent. more power. The engine was quite capable of doing this, but the 14-in. belt was good for no more than it was driving. The first idea was to put in wider pulleys ; but, as this involved much expense, both driver and driven being confined in a small space close to a main wall, the compound drive was resorted to. A 17-in. double orange-tan belt was put on next the pulley, and the old 14-in. double was put on top of it. This gave 100 per cent. more power at once, and the belts worked satisfactorily. A firm of linoleum manufacturers in Antwerp were also taken out of a difficulty They were driving with a pulley of small diameter at high speed, and the double belt in use at first was unable to lift the load. Two single orange-tan belts, each 22 in. wide, were put on, and the whole difficulty was overcome.

LACTIC AND SOME TOXIC ACIDS

The Acid of Milk and its Properties. The Amides. Prussic and other Acids and their Antidotes. Cyanogen

By Dr. C. W. SALEEBY

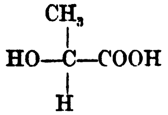
FURTHER on in the series of hydroxy acids we come to an extremely important body known as *lactic acid.* It is none other than hydroxy-propionic acid. Propionic acid has already been named and its formula given. Plainly, the hydroxy acid derived from it must have the formula CH_3-CHOH-COOH. This differs from the formula of propionic acid only in the middle term, which contains a hydroxyl instead of a hydrogen atom. Lactic acid is so called because of its production in milk, and a good deal has already been said of it, apropos of butyric acid and its production. Thus, the easiest fashion in which to prepare lactic acid is simply by lactic fermentation of sugar. When milk turns sour the cause is the production of lactic acid from the lactose of the milk under the influence of the lactic acid bacteria, first discovered by Pasteur. The characteristic sugar of milk, known as *lactose*, has the formula $C_{12}H_{22}O_{11}$. Add to this one molecule of water, and we see how the whole may split up into four molecules of lactic acid $C_3H_6O_3$. The process is really much more complicated than this statement, which will suffice, however, for our present purpose. In 1877, Lord Lister discovered what he called the *bacillus lactis*, which may or may not have been identical with that previously found by Pasteur. To-day we know a very large number of different bacteria that can cause this fermentation; indeed, more than a hundred different bacteria are known to do so.

Lactic acid is of great interest for three distinct reasons—in the first place, chemically; in the second place, historically; and in the third place, practically. We must proceed, then, to consider it from these three points of view, though the very interesting history of the subject can be discussed only incidentally.

The Pure Chemistry of Lactic Acid. Hitherto we have spoken as if there were only one lactic acid, but as a matter of fact, there are more than one. In the first place we must note, merely as a matter of theoretical importance, that there is a second lactic acid which differs from the first in the internal arrangement of its atoms. Its constitutional formula differs from that of ordinary lactic acid, already given, since the hydroxyl group is in a different place. It runs thus: $CH_2OH—CH_2—COOH$. From the purely chemical point of view we may say, then, that there are two hydroxy-propionic acids, and we may distinguish them by the Greek letters *alpha* and *beta*.

But if we confine ourselves to ordinary lactic acid, we find that it also is of more kinds than one. In the first place, there is the acid which is obtained from milk by a process so important that we must afterwards describe it carefully. This acid is optically inactive—that is to say, it has no action upon the plane of a ray of polarised light when this is passed through a solution of it. But we have already seen that there is at least one optically inactive organic acid which, on investigation, proves to be inactive merely because it consists of suitable proportions of two acids, one *lævo-rotatory* or left-handed, and the other *dextro-rotatory* or right-handed. The same is true of lactic acid. If we take muscular tissue and treat it suitably, we obtain lactic acid from it, and this, since it is derived from flesh, is usually known as *sarcolactic acid* (Greek *sarcos*, flesh). The name implies, by the way, that it comes both from milk and from flesh, which is absurd, but still it is convenient. Now sarcolactic acid differs from the more familiar lactic acid of milk in that it consists almost entirely of the right-handed acid. The two acids are of equal, though opposite, optic activity, and the inactive acid derived from milk therefore consists of the two acids in equal proportions.

Asymmetrical Carbon Atoms. Already some brief mention has been made of the question of symmetry in organic compounds—that is, symmetry of molecular constitution. We may now proceed to give the rigorous chemical definition of what is known as an asymmetrical carbon atom. It is one, each of the four hands of which is holding on to a different atom or group of atoms. This is the case in lactic acid, as we shall readily see if we write out the formula in the graphic form:



$$\begin{array}{c} CH_3 \\ | \\ HO—C—COOH \\ | \\ H \end{array}$$

Now the above formula is undoubtedly correct, but it is not the only possible formula. Suppose we held it up to a mirror and read it in the mirror, it would be the same and yet not the same. Your two hands are the same, and yet they are not the same. You would recognise this if you were suddenly provided with a left hand at the end of your right arm instead of your right hand. Similarly, in the case of many organic compounds, the molecular structure of two bodies may differ only as one's right hand differs from one's left. Your two hands are both human, and at birth, at any rate, were both identical in every respect save one; it is just that one respect in which right and left-handed lactic acids, for instance, differ from one another, and in that alone. We have purposely used the analogy of human hands because it seems a happy one, and because the association of ideas cannot fail to recall it to the reader's mind whenever he is asked to explain, at a moment's notice, the difference between two such closely similar bodies. But, of course, we must not be confused by the use of the terms right and left-handed in the names of the acids. They are so-called not by analogy with hands, but because they turn the plane of a ray of polarised light to the right and left respectively. A little criticism can show, by the way, that the terms right and left can really have no meaning in relation to rotation, and it is a curious and significant fact that language provides us with no better substitutes for them than *clockwise*—that is, in the direction of the hands of a clock—and *contra-clockwise*.

The philosophic reader will see that, in discussing a matter apparently so prosaic as the difference between two kinds of acid found in sour milk, we are on the verge of considerations which raise the whole question of a conception no less stupendous in its significance than our fundamental conceptions of space and spatial relations.

Molecules and Light. If the reader be one of those who ponder over things after he has read them, yet another consideration will occur to him. When we were discussing the refraction and the reflection of light in the course on Physics, it was pointed out that our statement of the dogmatic laws of these phenomena must not lead anyone to suppose that we understand the actual relations of ethereal waves to ponderable matter. Is it not evident, however, that we are beginning to accumulate facts that will help us when we realise that, of two molecules, which differ from one another only as a right hand differs from the left, one will act upon a plane of etheral vibrations so as to turn it clockwise, and the other so as to turn it contra-clockwise ? Why and how, we cannot yet say, but we must hold fast to the extremely important generalisation that *polarised light can be rotated only by bodies whose molecules possess an asymmetrical carbon atom.* So much for the pure chemistry of lactic acid.

Sour Milk. It has been proved beyond dispute that the souring of milk, or its lactic acid fermentation, depends necessarily upon the presence of living organisms. It does not occur spontaneously. If the organisms be excluded, milk may be drawn and kept for months without undergoing any change that can be detected. Pasteur first distinguished the lactic ferment from the alcoholic ferment. He found that when milk turned sour, there was usually a grey deposit consisting of bacteria. "Pasteur then introduced a trace of this deposit into a solution of sugar to which he had added a decoction of yeast and some chalk, and in this artificially-prepared liquid he thus obtained lactic acid fermentation. From this fermenting fluid he again transferred a slight trace to a similar solution of sugar, and so on, invariably obtaining the lactic fermentation and invariably finding the same corpuscles in the deposit." ["Bacteriology of Milk," page 155.]

We shall proceed to quote freely from the standard, if not indeed the only, notable work that has yet been written upon the bacteriology and bacteriological chemistry of milk and its products. "The lactic organisms produce appreciable amounts of lactic acids only at somewhat elevated temperatures. If the amount of acid rises much above 2 per cent., the growth of the lactic acid bacteria is inhibited." In general, the lactic acid bacteria do not form spores, and can therefore be killed readily by heat. Some are anærobic, growing best in the absence of free oxygen. They sour milk best in deep vessels, and produce a right-handed lactic acid. Others produce various gases in the course of the fermentation—the production of which gives their character to certain kinds of cheese. The arrest of the process of fermentation by its own products may be noted, as it is similar to what we have already seen in the case of alcoholic fermentation, and would appear indeed to be a general principle in fermentative processes. Milk turns sour most readily "at between 35° C. and 42° C., and when 2 per cent. of lactic acid is reached, the process of further production ceases. If the milk be then neutralised with carbonate of lime, the process of fermentation will recommence until the acidity again stands at 2 per cent."

Milk and Hot Weather. Everyone knows that during the hot months of the year infants die like flies in all our large cities. One of the chief causes of this is the decomposition of the milk on which they are fed, and the reason why the hot months are so fatal, and why a cool summer saves many thousands of lives, is that the temperature we have indicated is the best temperature for the fermentation of milk, which proceeds rapidly in proportion as that temperature is approached. Part of the modern treatment of milk is to cool it to a point little above freezing point within a few seconds after it is first drawn. Really, no milk should be sold which has not been subjected to this process, unless it is to be drunk immediately after being drawn.

This is not the place in which to discuss the origin of the lactic acid bacteria. It has been conclusively proved that they are never a normal and original constituent of the milk, but are invariably "a secondary contamination of the milk from some external source."

Evil Results. The reader must not imagine, however, that the lactic acid fermentation of milk is to be looked upon as entirely evil. It has two very different aspects. The lactose of milk is one of the most valuable of its food constituents, and if it be decomposed before the milk is drunk the food value is lost. This is a serious matter in the case of an infant, but not the most serious. For the lactic acid is itself injurious to the delicate internal structure of an infant, as also is the growth of the bacteria which produce it. Well worthy of note is the significant fact that the one carbohydrate supplied by Nature for food purposes—namely, the lactose of milk—is far more resistent to fermentation than ordinary sugars. This is one reason why sugar of milk is much preferable to cane sugar or to glucose in the artificial feeding of infants.

Good Results. But, on the other hand, lactic acid fermentation of milk is of very considerable economic value *in the right place.* In this complex world there are few things that are wholly good or wholly evil, and probably none that are good or evil in themselves. These adjectives can be applied only to the appropriateness or unappropriateness, the fitness or unfitness of things—in short, not to themselves, but to their relations.

Thus lactic acid fermentation causes what is known as the ripening of cream, and this is a process of very great value, as everyone ought to know who has ever tasted butter. At the present day economic bacteriology—which is to be discussed in a subsequent course—is making an exhaustive study of dairy bacteriology, and very notably of the conditions of lactic acid fermentation, which is all-important in the making not merely of butter, but still more of cheese. The lactic acid bacteria constitute about 95 per cent. of all organisms present during the ripening of cheese. We have already hinted that the appearance of Gruyère cheese is due to the activity of organisms which, in the course of the production of lactic acid, also produce gas.

The Views of Professor Metchnikoff. Quite recently the world-famous scientist, Professor Metchnikoff, of the Pasteur Institute, has made studies which suggest a new importance for lactic acid This subject must briefly be referred to, and for further details the reader may be referred to Metchnikoff's "Nature of Man" (English translation, Heinemann, 1903), and also to the second of Professor Metchnikoff's Harben Lectures, delivered at King's College on May 28th, 1906. In the chapter entitled, "The Scientific Study of Old Age," in the book referred to, Professor Metchnikoff points out that civilised man suffers considerably from the effects of fermentation within the alimentary canal He goes on to show that the lactic acid bacteria contained in milk, and especially in sour milk, are inimical to the development of the ordinary bacteria of putrefaction, since these latter multiply only in an alkaline medium. He says "the lactic acid microbes produce large quantities of acid, and so hinder the multiplication of the organisms of putrefaction. Putrefaction takes place rapidly, in spite of the presence of the lactic acid microbes, if there be added soda to . . . meat or milk." "It is plain, then, that the slow intoxications that weaken the resistance of the higher elements of the body . . . may be arrested by the use of kephir, or, still better, of sour milk. The latter differs from kephir [an effervescent alcoholic sour milk prepared by the inhabitants of the Caucasus from the milk of goats, sheep, and cows], in that it contains no alcohol, and alcohol in course of time diminishes the vitality of some important cells in the body. The presence of a number of the lactic acid bacteria is inimical to the growth of the bacteria of putrefaction, and so is of great service to the organism."

Hence, Professor Metchnikoff and many of his disciples make a point of drinking some sour milk every day, and the evidence seems to be accumulating in favour of the view that this practice promotes health by "preventing the development of butyric and putrefactive ferments which should be regarded as redoubtable enemies."

The Amides. The group NH_2 is known as the *amido* group, and may replace various other atoms or groups in many organic compounds. Thus we have amido acids very closely allied to the hydroxy acids which we have just been considering. In them the amido group replaces the hydrogen of the acid. Similarly, there are a number of amides in which the amido group occurs. The most familiar of these is *acetamide,* the name of which indicates that it is a derivative of acetic acid. Indeed, it is simply acetic acid of which the hydroxyl has been replaced by the amido group. This acetamide must be regarded both as an acid and a base. It is a base in virtue of its relation to ammonia, and thus, like ammonia, it forms a hydrochloride, the formula of which is that of acetamide plus that of hydrochloric acid. But, on the other hand, it may be regarded as an acid, since certain metals can replace one of the hydrogen atoms of the amido group. It is a white crystalline solid, in this respect resembling all the other amides except formamide, $HCONH_2$, which is a liquid.

Prussic Acid. It can be shown that hydrocyanic acid or prussic acid, with its salts, the cyanides, is related to the amides which we have just been considering. This is an extremely important body from many points of view, and must be carefully considered. Its chemical name indicates its formula, which is HCN. Its popular name indicates its relation to the well-known pigment called *Prussian blue.* Though this body is an extremely powerful poison, it is a very feeble acid. Its history is of very great chemical interest, for it was very carefully worked at by Gay-Lussac, who came to the conclusion that its constituent CN must be regarded as a unit. Subsequently he discovered that this unit exists by itself, and he gave it the name of *cyanogen.* It was from this time that there dates the extremely valuable idea in chemistry of a "compound radical."

Preparation of Prussic Acid. There are several ways in which prussic acid can be prepared, and we may first of all name some of those which are of chemical interest. For instance, it is produced by the distillation of formamide, the body we have just discussed. Remembering the formula of formic acid, the reader will be prepared to believe that that of formamide is $HCONH_2$. Each molecule of this simply splits up into one of prussic acid and one of water. Again, in confirmation of the acid nature of this acid, it can be prepared by decomposition of a cyanide. This is usually done when it is required to be free from water or anhydrous, dry sulphuretted hydrogen acting on dry lead cyanide.

$$H_2S + Pb(CN)_2 = PbS + 2HCN.$$

This process, however, is extremely dangerous, since prussic acid is volatile, and it must, therefore, be carried out under conditions which ensure that the operator is not subjected to the risk of breathing it.

The commercial process for the preparation of this acid depends upon the decomposition of a complex salt which we shall study shortly, and which is known as *ferrocyanide of potassium*, its popular name being *prussiate of potash*. The decomposing agent is sulphuric acid.

Characters of Prussic Acid. At ordinary temperatures the acid is a colourless liquid which, however, boils at only 26·5° C. The vapour, as might be expected, is inflammable, yielding carbonic acid, water, and nitrogen. At not very low temperatures (– 15° C) prussic acid freezes. As prepared by ordinary means, the acid is mixed with water, with which it mixes in all proportions. The acid is extremely difficult to keep, as it is apt to undergo what is called spontaneous decomposition. Though it is chemically an acid, it scarcely reddens blue litmus paper at all. It forms salts with alkalies, but it is so weak that it is incapable of decomposing even an alkaline carbonate. It is thus classified by toxicologists or students of poisons with two other acids, *oxalic* and *carbolic*—later to be studied—which exert their characteristic actions upon the body independently of their acid properties. Unlike sulphuric acid, for instance, they are poisons not because they are acids. Oxalic and carbolic acids possess also the caustic properties typical of acids, but prussic acid, which is a far more deadly poison than either of them, has no caustic properties at all.

Prussic Acid and Living Matter. Prussic acid must by no means be considered the most deadly of poisons so far as its dose is concerned. Quantities of it are constantly given in medicine—in dilution, of course—scores of times greater than would be fatal in the case of many other substances. But it is pre-eminent on account of the rapidity of its toxic action. One drop of the pure acid merely placed within the eye of a dog will kill it instantaneously. This body is a protoplasmic poison—that is to say, it is directly toxic to protoplasm wherever found, whether in the lowliest plant or the highest animal, and yet it does not coagulate proteids such as are found in all protoplasm, nor does it act by withdrawal of water. From our present point of view, we may divide the various salts of this acid into two distinct groups. In general, the single cyanides, such as potassium cyanide, are almost as poisonous as the acid itself. On the other hand, the double cyanides, and also the single cyanides of iron and platinum, have no poisonous properties at all. This fact is easily explained. The toxic cyanides are those which are instantly decomposed by the body, prussic acid itself being liberated. The innocent cyanides are so because they are incapable of decomposition by anything in the body. Such a single cyanide as that of potassium is readily decomposed even by carbonic acid, which abounds everywhere in the body

Why Prussic Acid is a Poison. A complete chemical explanation can be given of the reason why prussic acid kills every form of living matter. It absolutely and instantaneously arrests that oxidation, without which protoplasm cannot continue to live. Thus, in the case of instantaneous poisoning by prussic acid, the whole of the blood of the body is found to be of a bright colour. It contains nothing but oxyhæmoglobin, the decomposition of which has been entirely arrested by the prussic acid. The poison acts indifferently upon every kind of tissue in the body—alike on the muscles, the glands, the nerve cells, the nerve trunks, and the nerve endings. Its extreme volatility helps to explain the rapidity of its action, but is of importance in regard to the treatment in cases of prussic acid poisoning.

Antidotal Measures. All treatment of these cases is usually futile, but nevertheless occasions may arise in which the readers of this paragraph may save a life if they are energetic enough. The all-important question is one of time in these cases, and what is done must be done quickly. It is usually quite useless to give doses of atropine subcutaneously, for time is not available. Brandy may be accessible, however, and also inhalations of ammonia. But far and away the most important help which can be rendered by the bystander is the performance of artificial respiration. The chemical antidote for prussic acid is of no value in practice. It consists of the administration of a mixture of a ferrous salt, a ferric salt, and caustic potash, with the formation of non-poisonous Prussian blue in the stomach. Even if all these substances were ready at hand, however, they could not avail to neutralise the prussic acid which is instantaneously absorbed from the stomach.

The very marked values of this drug in medicine are due to its local depressing effect upon nervous tissue, which it makes less sensitive. Needless to say, it can be used only in extreme dilution.

Ferrocyanide of Potassium. The important double cyanide known as *ferrocyanide of potassium* is prepared in large quantities by the interaction of metallic iron, carbonate of potash, and many kinds of animal refuse. The salt forms permanent crystals which lose their water on heating, yielding a white powder We have called it a double cyanide as if it were the combination of potassium cyanide and ferrous cyanide. But it must not so be regarded chemically. It is, rather, a compound of potassium with the complex radical *ferrocyanogen*, which has the formula $Fe(CN)_6$ Its formula is $K_4Fe(CN)_6$ Closely allied to this important salt is the ferricyanide of potassium, which forms red crystals, whereas those of the ferrocyanide are yellow. When these two salts interact with other iron salts they yield richly-coloured bodies which are of value as pigments *Turnbull's blue* is formed by the mixture of the ferricyanide and a ferrous salt, while *Prussian blue* is formed by the mixture of the ferrocyanide and a ferric salt.

Cyanide of Silver. One of the most important of the metallic cyanides is the cyanide of silver AgCN. This salt is precipitated when nitrate of silver acts on prussic acid. It is a white substance which resembles chloride of silver.

warp, and were equally strong in every direction, the door would simply be made from one piece of stuff 1½ in. thick, or perhaps of two or more pieces, edge to edge, in order to obtain the width. But a door made in that way would not do at all. Its width would vary with the state of the atmosphere, and it would be certain to warp very badly. In addition to these two defects, it would be likely to split lengthwise. It is necessary to frame it together from comparatively narrow pieces arranged so that the grain runs in both directions, and so makes shrinking or splitting practically impossible. The widest places are the panels, but shrinkage in the panels does not affect the exterior dimensions of the door. If the panels were tightly held at their edges there would be a risk of their splitting through shrinkage, but they are merely slipped into their grooves when the door is framed together, and unless there are already incipent cracks in them, they will adjust themselves in the grooves rather than split through shrinking.

An example of shrinkage is shown in **39**, in which a wide piece of wood is screwed or nailed on a frame which cannot shrink with it. The plate of wood has shrunk in width, and, being held by the nails, could not contract freely across its width as it would if unattached. The consequence is that it cracks, and is then free to spread apart at intermediate places. In so wide a piece no care in seasoning the wood could entirely prevent this effect. The cracks could be prevented by using a number of narrow pieces side by side, instead of one wide piece, but a framed and panelled plate would be the only way to prevent variation entirely.

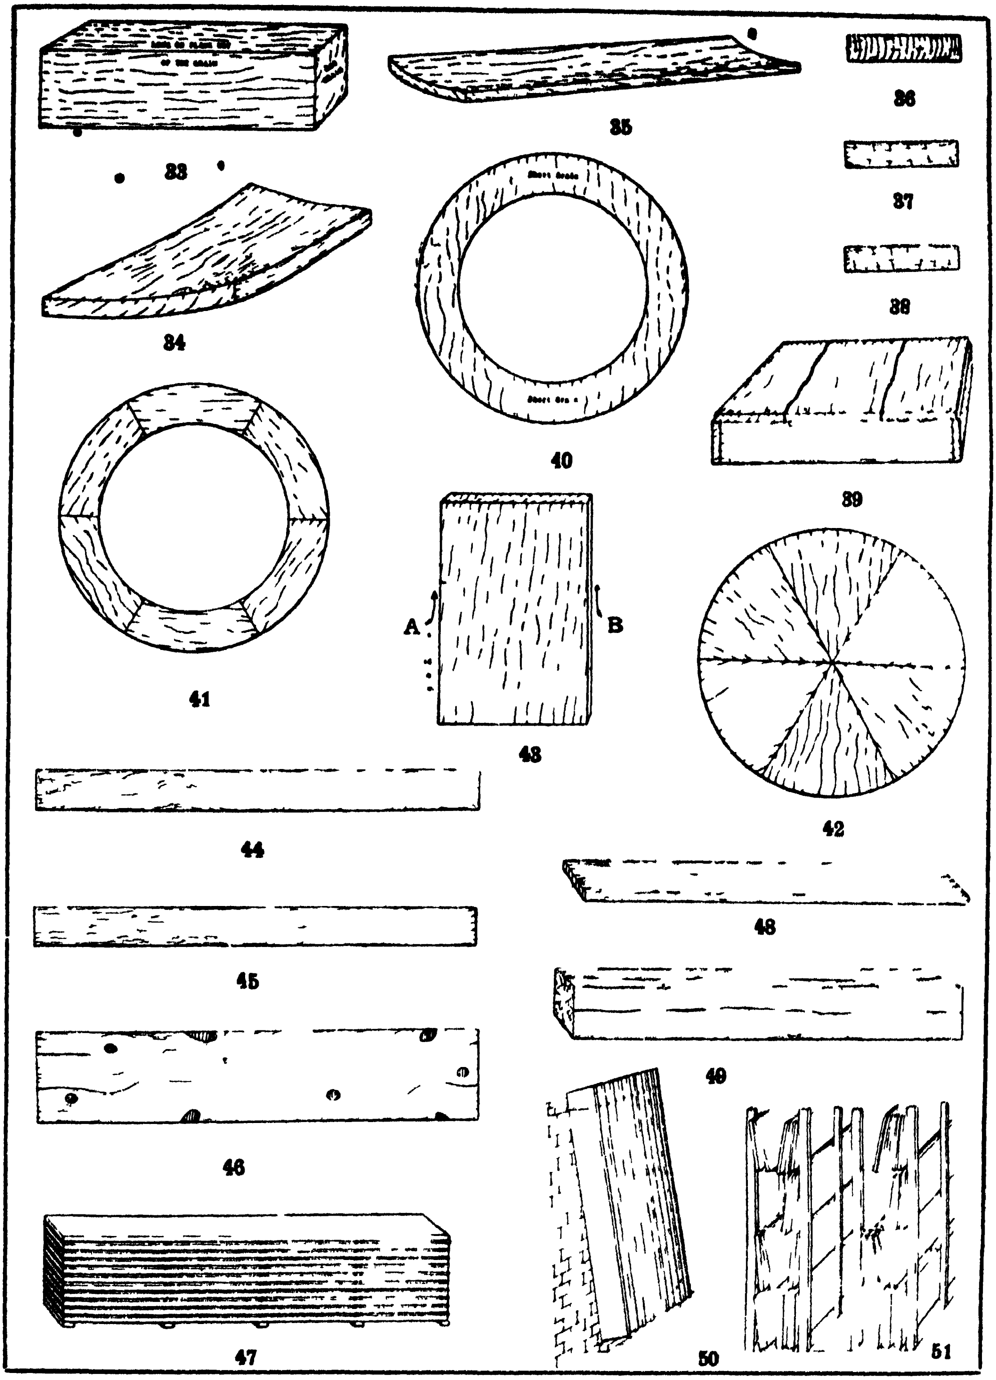
Rings Built in Segments. Figs. **40**, **41**, and **42** show how these weak features in wood necessitate building up in circular work. A ring cut from the solid, as shown in **40**, would be worse than the solid door previously instanced. It would be worse because its interior is cut out, and the short grain is consequently very weak. Such a ring would be built in segments, as shown in **41**, but at least two layers of segments would be employed, so that the end joints of each layer could overlap each other. Otherwise it would be weak at the joints. It is true that such a ring might be more simply made by cutting out two entire rings from the solid, and putting them together with their grain crossed; but the objection to it would be that they would shrink in opposite directions, and overlapping edges would result. A circular plate built as in **42**, even of a number of layers breaking joint with each other, is not so strong a construction as two or more thin plates, cut from the solid and put together with grain crossed, but its advantage is that uniform end grain is presented round its circumference and the plate can never become elliptical through shrinkage.

Properties of Wood. In the behaviour of wood, when it is operated on with tools, there is also a considerable field of knowledge which the woodworker has to acquire. It is necessary to know its weak parts, so as to avoid splitting when boring holes or driving nails. In planing and finishing surfaces, especially if the grain be not straight, it is necessary to avoid tearing the surface up in consequence of planing it against the grain [**43**]. It is necessary to know how and to what extent a piece of wood is likely to shrink or become distorted when a fresh surface is exposed in cutting it, and also how to treat freshly-cut wood to prevent it from warping. Waste should, of course, be avoided as much as possible in marking out and cutting wood, and the good and inferior parts should be used in the places for which they are most suitable. A piece of timber with curly and crossed grain [**44**] is not so strong as a straight-grained piece [**45**], because it is more easily broken across its grain. A piece with a great many knots [**46**] is not suitable for sawing into narrow strips unless the knots can be avoided without much waste, because a knot in a narrow strip naturally diminishes greatly the strength of the strip. Similarly, in a wide piece a shake or crack is a source of weakness, and such a piece would be better sawn up so that the sound pieces on each side of the shake could be used separately. End grain joints are avoided, if possible, because a continuous piece is better and stronger; but joints running with the grain are not objectionable, and if properly made are quite equal to, and in some cases even better, than a solid piece of the full width.

Seasoning. What the carpenter requires to know about timber is only a small section of a vastly wider subject, but it is sufficient for the purposes of his trade. The botanical character and growth of timber trees, and the methods of their conversion into the commercial forms of boards, planks, battens, etc., do not immediately concern him, though it is desirable that he should have some knowledge of these things. When timber comes into his hands it has been through the sawmill, and has undergone a process of seasoning.

Seasoning is simply allowing the cut timber to dry for three or four years before using it, or, alternatively, hastening the removal of the sap and moisture by artificial means If this were not done it would shrink and warp after being worked up, and if evaporation were prevented by paint or other means it would decay. The natural sap is more objectionable, and takes longer to dry out than water which has penetrated after the wood has been seasoned. One of the methods of artificial seasoning is to place the timber in running water to wash the sap out, and thus leave only water to be dried out of the pores. Another method is to dry quickly by artificial heat, preferably moist, to prevent a too rapid drying of the exterior. The air is generally kept in motion by fans.

Slow natural seasoning is generally considered better than any of the artificial methods, because the latter often have injurious effects on the quality of the wood. The best method of natural seasoning is to stack the timber in sheds to protect it from the weather, and to have free circulation of air. Air space must be allowed between individual pieces, and they should also be arranged so that they are kept forcibly flat and straight. This is generally done



TREATMENT OF TIMBER

33. Difference between plank way of grain and end grain **34.** A piece of wood that has become winding or twisted or warped by unequal strains **35.** A plank become curved through unequal drying **36.** End view of a plank sawn so that the annual rings will stand wear well and shrink least **37** End view of a plank which would be inclined to shell out in the middle upper face **38.** End view of a plank with better wearing qualities than 37 but *inferior to 36* **39** Shrinkage in wood causing reduction in width and development of cracks **40** Example of weakness due to short grain **41.** The strongest form of wood ring **42.** Best method of constructing a wood disc **43.** Wood grain in planing If planed in the direction *of arrow A, the edge would be torn and rough. If planed with the grain in direction of arrow B, edge would not tear up* **44.** Crooked grain **45.** Straight grain **46.** Piece with knots, shakes, and curly grain **47.** *Boards piled flat with strips between* **48.** Small end cracks caused by too rapid drying **49.** Balk with cracks caused by circumferential shrinkage after being squared **50.** *Boards stacked on end against a wall* **51.** *Boards stacked on edge in a rack* by piling them on top of one another and keeping them slightly separated by inserting thin strips between [47]. Balks are generally stacked in squares, with each layer transversely to the next and with considerable spaces between the members of each layer. Deals are often stacked in a pile all longitudinally with each other, but so that they break joint, with spaces between. This latter method is often adopted also for narrow boards, but one of the reasons for this overlapping is to make a steadier pile than would be possible if the spaces between were continuous from top to bottom. Generally, the air is not allowed free access to end grain, because the evaporation of moisture there is so much more rapid, and this often results in splitting at the ends, owing to the wood contracting more rapidly there than farther along [48]. To prevent this the end grain may be painted or greased to close the pores, or strips of wood or hoop iron may be nailed over it. The length of time occupied in natural seasoning depends on the size of the wood and on atmospheric conditions. Generally, timber is not considered fit for carpenter's use till at least two years after being felled and for indoor work considerably more than that. The thorough seasoning required for the more exact work of joinery and cabinet-making, however, is generally assisted by resawing, or further reducing the size of the wood.

Timber as a Material. Timber was undoubtedly one of the very earliest materials employed by man, being easily worked and always ready to hand everywhere As, too, the requirements of mankind have increased, and his tools become more numerous and specialised, he has been able to use timber more and more extensively, and to utilise it in constructions that would have been impracticable when facilities for its working were less developed. Within the last half century especially the introduction of machines for performing all the common operations has immensely reduced the time and labour involved when such things are done slowly and laboriously by hand. The carpenter still retains his trade, but instead of considering himself competent to undertake anything and everything constructed in wood, he is now only one among many classes of woodworkers, and nearly all the work requiring physical strength rather than brains is done for him by machines—sawing, planing, mortising, tenoning, and the rest.

This, however, has not really lessened the great importance of his craft or the amount of training required for its proper acquisition, nor, probably, the number of carpenters employed; for if the work done by machinery now could be executed only by hand, most of it would not be done at all, because the expense would render it a luxury for the few. The poor would not have wood floors to their houses, nor elaborate and highly-finished wood fittings everywhere.

Timber differs from most other materials in the great variation which exists between different kinds, and in the differences in strength between good and indifferent specimens. It is not possible to calculate the resisting power of timber so accurately as is done with most other structural materials. In designing timber structures the sections of the individual parts have usually been decided more by judgment than calculation. In steel and iron, strengths can be calculated from test pieces, and these materials will not deteriorate with age alone, nor are they subject to diseases, as timber is. Hence, too, the reason why a much higher factor of safety must be adopted in using timber than in metal.

Hard and Soft Woods. Wood is termed *hard* or *soft* according to the kind of tree from which it comes, but in both classes there are great differences in degree of hardness. Of these two the hard wood forms the largest section, but carpenters use more soft wood. In order to divide definitely the varieties of trees into the two classes of hard and soft, those with broad leaves are classed as hard, and those with long, narrow leaves as soft. This places some rather hard woods, such as yew, in the soft wood list; but outside of the various kinds of pine there are only a few soft woods, and they are so little used that they are scarcely worth considering. The shape of the leaves seems a detail, but they are typical of the character of the tree. A broad-leaved tree is slow in growth, and does not attain so great a height compared with its circumference as a narrow-leaved tree does. The increased time occupied in its formation generally results in a closer-grained and harder wood being formed. Most of our native trees are hard wood, the oak standing at the head of the list.

Sources of Soft Woods. The important soft woods are all varieties of the pines or coniferous trees, and are imported from North Europe and Canada. Most of our hard wood is imported also, because we have no timber forests in Britain, and could not possibly grow the commonly-used timbers fast enough to keep pace with our rate of consumption.

Formerly, when we had a large home supply of oak, that was the wood most commonly used, and it occupied a more important position than the pine that has taken its place. Now oak occupies a secondary position, especially as most of this wood is now imported, and is not considered equal to British oak. Against this difference in the kind of wood now most popular, however, we must place the fact that for much of the work for which oak was formerly used, such as shipbuilding and the framework of houses, steel and masonry have been substituted.

Recommendations of Soft Wood. The reason why the soft woods are popular is because they are cheap, light, straight-grained, and easily worked; while for many purposes they are equal to the hard woods. The latter, however, differ so much in their physical characteristics, that each is best adapted for special purposes, and consequently they serve these purposes better than soft woods, though no single hard wood has so wide a range of usefulness as soft. In very many cases also hard wood is used solely for the sake of appearance. This is the case to a very large extent in cabinet-making. In ordinary carpentry hard

wood is used only because of its superior durability and strength, or of some characteristic that specially adapts it for the purpose in view, as, for instance, the use of ash where a flexible wood is required. But the fact remains that the hard woods used by the carpenter are very limited in number. The chief, and by far the most important, is oak. The bulk of his work is done in soft materials, of which there are several varieties included under the generic names of pine and firwood.

The plate facing page 56 illustrates the grains of a large variety of hard and soft woods.

Commercial Forms of Timber. Timber in its commercial forms is usually of definite thicknesses and widths, and various names are applied to it according to these dimensions. If we consider them in the order of their size we have first the *balk*, or *whole* timber, or *log*. The term log really means the unsquared trunk of a tree, but is sometimes used in the same sense as balk, which means a squared trunk. The term is applicable to any large piece of timber, whether it represents the entire trunk of a tree or not. Unlike most of the other forms of timber, the dimensions are not of a fixed character. In length a balk may average 30 ft., but occasionally may be more than twice as long. Timbers of smaller section, such as boards, etc., range in length from about 8 ft. to 20 ft., 12 ft. being a common dimension. They are cut thus because great lengths are seldom required, except in engineer's work, and are not so convenient for handling. Balks were formerly squared with an adze, and to a considerable extent are still, but there cannot be much doubt that ultimately the saw only will be used, and the adze become obsolete for the purpose.

Next in size is a piece of timber called a *flitch*. This is one-half of a squared log, or balk, that has been sawn down the middle lengthways. In section its width is consequently about twice its thickness. Next in size comes a *plank*. This term is often loosely used to describe timber that strictly comes under the name of *board*. The difference between the two is that a plank must be over 2 in. thick and over 10 in. wide, while a board must be less than 2 in. thick, and may be any width over 6 in. *Deals* and *battens* come in regard to size between planks and boards. They are thick, but comparatively narrow. A deal measures from 2 in. to 4 in. thick by 9 in. wide. A batten is of about the same proportion, but rather smaller in width and thickness. *Quartering* is produced by sawing deals into two, three, or four strips. *Scantling* is a general term applied to sawn wood of any size. *Ends* are short pieces of plank, deal, or batten. In addition to these terms for sawn timber, there are *poles* and *masts*, distinguished from each other by their diameters, the former being less than 8 in. in diameter, and the latter more. These two terms are sometimes qualified to indicate further particulars.

Market Quantities. There are also names for quantities of timber. It is sold by the *standard*, which is 120 deals; by the *load*, which is 50 cub. ft.; by the *superficial foot*, the thickness being reckoned at 1 in.; by the *foot run*, when width and thickness are specified; or in some valuable hard woods by *weight*. *Match-boarding* and *flooring* is sold by the square of 100 superficial ft., or 10 ft. each way.

The foregoing are a few elementary facts, but behind them there is a great deal of complication and confusion through differences in sizes and methods of measurement. These things, however, concern the importer and dealer more than the carpenter. The standard of deals (nominally known as a 100, but really 120) varies in number according to the size of the deals. In the London standard the deal measures 12 ft. by 9 in. by 3 in. In the St. Petersburg standard, which is rather more commonly used than the London one, the deal is 12 ft. by 11 in. by 3 in., and there are only 60 to the 100. There are also a number of other standards, and the consequence is that in buying and selling timber the kind of standard has to be specified, and frequent translations made from one into another. No matter what the size of the deals, however, the cubic contents of each standard is always the same, with unimportant exceptions. The number of cubic feet in a St. Petersburg standard is 165, and in the London standard 270. In the measurement of balks there are two different methods—the *string* and the *caliper*—which do not give similar results. The nominal dimensions of sawn timber may also differ from the actual dimensions. Imported boards are usually a trifle over the specified thickness and home-sawn boards are usually under it. This is because in the latter case so many boards are sawn from a deal, and no allowance is made for the amount lost in sawdust. In thin boards this difficulty is sometimes got over by designating them as 4 cut, 12 cut, etc., according to the number of saw-cuts made in cutting a 3 in. deal into boards of that thickness.

There is now much greater variety in the market sizes of sawn timber than was formerly the case, and the carpenter can buy practically what he wants without having to reduce it himself from larger material, or use material of one particular dimension, when a slightly different size would suit his purpose better.

Qualities of Timber. Quality is specified by dividing timber into the classes of firsts, seconds, thirds, fourths, fifths, and sixths, the last being the poorest. *Firsts* are sometimes qualified also by adjectives, such as *prime*, *selected*, *sound*, *dry*, etc.

This is done in order to arrange a scale of prices according to quality, and also because in specifications it is often desirable to fix a standard of quality below which the contractor must not go. Otherwise, it would be superfluous to class timber, when every man who is familiar with it is capable of judging the quality of any piece individually.

The carpenter may generally assume that timber is not defective through a tree being felled before it was near maturity, or so late in life that the heart was decaying; and he can also assume that its after treatment, conversion, and seasoning has been carried out as carefully and correctly as was practicable, though the latter may often not be sufficiently complete to fit the wood for interior work. It is not often either that converted timber has any sapwood (the inferior outer portion of the trunk) attached to it. The defects to be looked for are of a natural character that could not be avoided. Where strength is required, straight grain [45], instead of crooked [44], and freedom from knots and shakes [46] or cracks, must be regarded as essential in a piece of wood of first-rate quality. Straight grain in soft wood is the rule rather than the exception. Knots are very objectionable, but often have to be tolerated, in spruce wood especially, because it is difficult to get boards without knots. Cracks generally occur as the wood dries in seasoning, and often cannot be prevented. They are objectionable, but whether they are a serious defect or not depends on the way in which the wood is to be used. A board with a crack in it is not sound, as a board; but the wood on both sides of the crack may be satisfactory, and it may be glued, or, with a little waste, cut, and the pieces on each side used separately.

Defects in Balks. In large balks there are sometimes defects that seriously impair the strength if the balk is to be used entire, or that cause waste in cutting up. Often the extent of the defects cannot be seen in the balk. There are several forms of shake or crack that occur in the trunk before the tree is felled. These may be either radial from the centre, or circumferential, between the annual rings. The former are known as *heart* and *starshakes*, the latter as *cup* or *ring shakes*. The precise cause or causes of these shakes are not certain, but they occur only in large trees, and are supposed to be due to interior stresses between the matured heartwood and the growing sapwood. There is usually nothing to indicate their presence until the tree has been felled, and they can be seen in the end grain. These, however, are not so common as shakes which develop from the exterior [49] after the tree is felled. In the trunk these may radiate from the outside towards the centre, or, as is very common in deals and boards, they may start at the ends. They are due to shrinkage caused by the too rapid drying of the outer wood. Precautions are taken to prevent them, but often they cannot be entirely obviated.

Cross Grain, Knots, and Shakes. Cross grain, knots, and shakes are the three chief defects to look for in judging sawn wood. But a board may not have these defects, and yet be in an unsound state in consequence of disease or of variations in quality. Or it may be so wet that, except for rough out-of-door work, it is unfit for immediate use. Timber becomes diseased locally through injury occurring to the bark of the growing tree, and from incipient decay due to numerous causes. It becomes uneven in texture and in degree of strength from variable density of the fibres and from unequal nourishment, or other variable conditions, as, for instance, persistent sunshine or wind chiefly on one side of the trunk. These variations, of course, are less marked in individual trunks than in separate trees which are grown on different soils, and either isolated or in close proximity to other trees. This last factor has a considerable effect on the character of the tree by forcing its upward growth, and more or less protecting it from the weather. Timber also, after it is felled, may be deteriorated by wood-boring insects.

There are also a number of diseases to which timber is subject. They are all indicated by discoloration or destruction of the fibres. The commonest of these is dry rot. This generally occurs in old timber that has been a long time in damp, warm, ill-ventilated situations. It is the result of a fungoid development that eats away the substance of the wood, leaving it in a dry, powdery condition, with a musty odour.

Preservation of Timber. In finished work it is a very common practice to protect wood from the atmosphere and the deteriorating effects of alternating dampness and dryness by coating the surface with paint, tar, varnish, or other preservatives. Other methods are employed to preserve the entire substance instead of affording only a protecting coat on the surface. The chief among these is *creosoting*, which is the forcible injection of oil of tar or creosote into the pores of the wood. This renders it poisonous to all forms of parasitic life, and effectually preserves the wood. But the objections to it are that it blackens and makes the wood highly inflammable, and for many purposes the smell of the tar is objectionable. It is used chiefly for out-of-door purposes where the wood comes into contact with the ground. Railway sleepers and paving blocks for streets are generally creosoted. There are several other less popular processes, but the principle in most is to preserve the wood by making it poisonous to parasitic life. Only a very small proportion of the wood used by carpenters is subjected to any preserving process, and it is only when wood is required to endure very trying conditions that there is any necessity for it, or any appreciable advantage in it.

Shipping Marks. These are marks chalked, painted, stamped, branded, or scribed on the ends of balks, deals, and most imported timber of any form. They indicate quality, the place of origin, the shipper's initials or private mark, and sometimes those of the person to whom they are consigned. Lists of them are contained in most publications dealing with the timber and building trades. Shippers frequently change their marks, and new firms are continually coming into existence, so that no list can be taken as permanently correct and complete. They concern the timber merchant more than the carpenter.

Storage of Timber. Timber stored in or near the shop for immediate use need not be stacked so methodically as for seasoning, but it should not be allowed to lie in positions that tend to strain or bend it; nor is it wise to let boards remain for a long time with one side exposed to the atmosphere and the other not. It is generally inadvisable to pile boards on top of one another, because of the difficulty of selection and withdrawal, when only the top ones are fully visible. It is better either to stand them on end against a wall [50], preferably with their upper ends in a rack, which keeps them edge outwards, or to stack them side by side on their edges [51], in a horizontal position in a rack. If kept lying in piles on their flat faces it is necessary to allow an air space between each by inserting strips [47], hence termed *stripping*.

If any piece be badly curved or twisted it should be subjected to treatment that bends it the opposite way; and if left like this for a few days or weeks it will probably remain straight, or nearly so, afterwards. Boards that are thus distorted should also, when possible, be selected for cutting into small pieces, because the distortion then may be reduced to nothing. Boards with knots, shakes, or other defects should be selected with a view to sawing them up and working them for parts where inferior stuff may be used, and the best pieces kept for parts where good quality is imperative.

Metal Accessories. Timber could not be used so generally or so effectively were it not secured and reinforced by suitable metal connections. These are chiefly of wrought iron, and their character depends on the class of carpentry for which they are used. In the heaviest work bolts and tie rods are very commonly employed for purposes where nails and pinned or dowelled joints would be sufficient if the work was of lighter character. Straps and stirrups are generally alternatives to bolts, and are often employed to avoid weakening the timber by boring holes for bolts.

Where whole timbers and balks enter into construction, castings and flat plates of wrought iron called *fishplates* are often employed in conjunction with bolts for holding joints together. For lighter work coach screws are common, and for the lightest, nails, screws, and glue.

Nails. Nails are the most common and simplest means of uniting pieces of wood. They are driven with a hammer through the first piece and their ends extend some distance into the connected piece; they hold by friction or the compressive force of the surrounding wood. Sometimes when the material is not thick and a strong hold is required nails of greater length than the total thickness are used, and their projecting ends are *clinched*, or bent over and hammered flush with the surface. But generally they should not be long enough for their points to come through the far side of the material.

Nails are sold in great variety, not only of size but of kind. There are consequently a number of names applied to them to qualify the term nail. When over about 5 in. in length they are called *spikes*. At the other extreme, in the small sizes, they are oftener known as *pins*, *brads*, or *sprigs*. The larger nails are sold by weight. Some small wire nails are sold in packets by count. The wire nail [52] is the most commonly employed and favourite form, especially when medium and small sizes are required. At one time the cut nail [53] was the most popular. It is either of steel or wrought iron, rectangular in section, with a slight amount of taper, and increased in size at the head.

Wire nails are made round, oval, and square in section; the last-named form is not much used, nor the oval so much as the round. They are parallel, with pointed ends and small heads, and are made in sizes ranging from about ¼ in. to 6 in. long. They vary in stoutness according to the work for which they are required.

Screws. In any other woodwork but carpentry screws [54] would come before nails in order of importance. Screws are superior to nails for all purposes, but they are more expensive and their insertion takes longer. They not only hold better when in place, but they can easily be withdrawn without injury to the work, and it is also often an advantage to be able to insert them without jarring the work as the driving of nails does. Screws are not made in quite so great a variety of form and character as nails, though their lengths are about the same. The tendency in recent years has been to reduce screws from many types to a few. The ordinary type of screw is pointed at the end, threaded for nearly two-thirds of its length, with a head tapering to about twice the diameter of the shank, and flat on the top. The chief variation from this is in having the head convex [55] instead of flat on the top, and a square shoulder instead of a bevelled one on the under side. This variation is only made to adapt the screw for purposes where there is an objection to sinking the head flush with the surface of the work. Screws are known by their lengths and sizes. They range from ¼ in. to 6 in. in length, and up to 3 in. each occurs in about ten different diameters, the extremes of which for a 3 in. screw are shown in 54. These diameters are known by numbers which are printed on the packets in which the screws are sold.

In order to distinguish the above from screws used for metal work they are called *wood screws*, and in Scotland *screw nails*. Their threads differ from those for metal in being farther apart, deeper, and thinner. This is necessary, because wood is a weak substance compared with metal, and no matter how thin and wide apart the threads on the screw are, they are still a great deal stronger than the intervening wood when the screw is in place.

Coach Screws. Coach screws [56] differ from ordinary screws in having square heads, like bolts, instead of flat slotted heads. They are turned with a spanner instead of a screwdriver, and are also a larger and stouter type.

Bolts. Bolts [57 to 61] are used in cases where screws threaded into the wood are not considered sufficiently strong to hold the parts together. Bolts go entirely through and hold the parts by the pressure which the head and nut exercise when the latter is screwed up. Large washers [62 to 65] are always used with bolts for wood, and the heads and nuts are usually square instead of hexagonal. In most cases also a short portion of the shank next to the head is square [57 and 59] to prevent the bolt from turning with the nut. When long bolts are specially made for a job they are often pieces of iron rod cut to length and threaded for nuts at both ends.

Fig. 60 is a *fang* bolt, the "fangs" or teeth of the nut gripping in the wood while the head is being turned. They therefore fulfil a similar function to the square necks in 57 and 59. Fig. 61 is a *strap* bolt, which is employed for attachment to the flat sides of timbers, when other modes of fastening would not be available, or so secure.

Besides holding parts together, long bolts sometimes serve the additional purpose of strengthening the timber with which they run parallel. In frame work they are often put through, or close to the under side of rails and cross pieces, and they thus support and stiffen the horizontal timber, and also hold the vertical parts of the frame together. *Door bolts*, *tower bolts*, or *socket bolts* are a different article, used for locking doors, and have nothing in common with screw bolts.

Figs. 62 and 63 are *parallel washers*, 62 being in wrought iron, or steel, 63 cast from a pattern. Fig. 64 is usually cast, and is bevelled to suit bolts that do not stand squarely with the faces of their timbers. Fig. 65 is a cast iron washer for two bolts, being preferable to single small washers.

Tie Rods. Tie rods fulfil a duty akin to that of bolts, both being in tension. They are not necessarily provided with heads like bolts, and in some few instances they may be tightened by a cottar instead of a nut. They are distinguished from bolts chiefly by their greater length and the fact that they are supposed to tie distant parts together rather than to go through solid material. They are used to a great extent in roof work.

Straps. Straps are pieces of thin rod iron of rectangular section, sometimes threaded at the ends for nuts, and bent to fit the pieces of timber that are to be held by them. They thus bind parts together rather more securely than bolts, and render it unnecessary to weaken the timber by boring holes. When used to support beams they are called *stirrups*. In a simpler form they are merely flat strips of iron, often with branches, that lie flat on the surface of timbers [66] and hold them together with their faces flush. Figs. 67 and 68 are stirrups.

Fishplates. Fishplates are flat plates of metal [69] which are bolted to the sides of large timbers in order to hold a joint together and keep the faces flush and in line. They are generally used in pairs, one on each side of the timber, and bolts pass through as in the case of shoes. The plates are generally the full width of the timber, and in length about six times the depth of the timber between them.

Cast-iron Shoes. Cast-iron shoes [70-73] have to be made from wood patterns specially made to suit the work in hand. They usually enclose and hold together the ends of two or more large pieces of timber that meet at an angle, and that could not be substantially held by bolts or straps alone. The castings have to be made to the correct angle and size to fit the timbers, and they are held by bolts which go through both casting and wood. These castings are typical of other forms which enter largely into the heavy carpentry of roofs. The pattern work is not difficult when the principles of the craft have been mastered, and a handy man might often be entrusted with such work preferably to putting it out.

Another class of work often used by carpenters dealing with shop and warehouse building is illustrated by the stanchions [74] and columns [75 and 76]. The pattern work for these might be done by an intelligent man. The important point in the design of such work is the firm fixing of the top and bottom with broad, bracketed flanges. These prevent risk of the stresses coming in any direction except right through the axis or centre, which would have the effect of bending instead of crushing the stanchion or column. It is also well to cast joggles on one flange [75], or both flanges, to be let into the masonry foundations. Information respecting pattern work and founding will be found in the course of Mechanical Engineering.

Miscellaneous Requirements. Besides the articles already mentioned, there are a number that are more in the nature of fittings or appurtenances, and are used more in joinery and cabinet-making than in carpentry; and if we go far enough we come to a large class of more or less ornamental metal work used only by cabinet-makers. Among those used by carpenters, the most important are hinges, locks, and handles. Hinges are of two types: *butt* and *strap*, the name generally applied to the latter being *cross-garnet*, or *tee* hinges. The butt hinges are intended to be sunk into the surface of the wood, and consequently they have plain, square edges which extend only a short distance from the pivot or pin. They are more commonly used than the cross-garnet type. The latter are used chiefly for gates and ledged doors. The plates or flaps of the hinge extend a considerable distance in order to stiffen the wood and obtain a stronger hold on it. Locks are made in great variety. They differ in character according to whether they are intended for doors, cupboards, or drawers. Door locks generally have to be either right or left-hand, to suit the door, the only exception being in a few kinds of lock that will suit either hand. Unless mortised into the door, a lock is screwed to the inside. Handles are used for a great variety of purposes, and vary greatly in form. They usually have to be screwed to the wood.

THE COLONIAL SERVICES

Conditions of Entry and Service in Clerical and Administrative, Railway, and Police Appointments in British Colonies

By ERNEST A. CARR

As a general rule, the young Briton in quest of a career in some portion of our Empire overseas would be well advised to turn his attention to private enterprise, whether farming, mining, commerce, or the professions, rather than to seek the services of the Colonial Governments. A moment's reflection will suffice to show the reason of this. Most of the governing bodies, it has already been pointed out, can obtain from local sources an ample supply of suitable material, and have, therefore, no need to turn to the Mother Country for recruits. This is especially true in respect of the larger and older branches of the Empire—Canada, Cape Colony, Australia, and New Zealand, for example—in which a new generation has sprung up on the soil to contest with immigrant residents such vacancies as arise from time to time in the official ranks.

An Authoritative Warning. These facts have led the Emigrants' Information Office, a Government bureau controlled by the Colonial Department, to issue a warning on the subject. In the preface to its "Handbook on Professional Employment in the Colonies"—a very valuable work which may be obtained, post free for threepence, from 31, Broadway, Westminster, S.W.—it is officially stated that: "Candidates from this country stand very little chance against persons on the spot of obtaining appointments in the Civil Service. Even telegraphists, railway officials and employees are now generally trained in the Colonies. There is, therefore, very little inducement for a person to emigrate on the chance of obtaining an appointment under a Colonial Government."

Apart from India and our Eastern possessions, which have been specially considered, the principal exceptions to the above general rule arise where certain Colonies, owing to the lack of training centres, the smallness of their white population, or other local causes, are unable to furnish enough qualified candidates for their own requirements. We shall therefore pass in review the various openings thus afforded to aspirants from Great Britain, and for our readers' convenience these will be discussed calling by calling, instead of grouping them according to locality.

Clerical and Administrative Posts. In this branch of the public service there is practically no Colonial demand for British candidates, and in general no opportunity is afforded them of obtaining an appointment before quitting the home country, while in several instances they are specially excluded in favour of local applicants. There is, however, an important exception on behalf of students from the British Universities who have failed to pass the contest for the Indian Civil or Police Services, or for Eastern Cadetships. These candidates may often secure good appointments on the West African Coast, or elsewhere, by applying to the Colonial Office, Downing Street, S.W. The posts thus available include cadetships for the grade of assistant district commissioner for the Gold Coast, with an initial salary of £250, and excellent prospects up to £2,000 or more. Such students are also selected sometimes by the Foreign Office for administrative posts in Egypt and British East and Central Africa, and by the British South Africa Company for their Rhodesian territory.

On the other hand, the clerical service of Canada is practically restricted to persons brought up in the Dominion, or able to enlist local influence on their behalf. The Government regulations in Queensland require candidates for ordinary appointments to have resided for twelve months in the State; and the New Zealand authorities expressly seek to dissuade applicants from going out to that country with the idea of entering its clerical service. Other Colonies are no less discouraging. The Agent-General of Victoria has courteously acquainted us that "very few vacancies have been occurring in the Victorian public service for some years past, and when they do, it is found that the local supply is more than equal to the demand. There are large numbers of applicants whose names have been recorded for some years past awaiting vacancies." For similar reasons, the Civil authorities in Cape Colony have suspended the entrance examinations, and the Transvaal Government notifies that "applications must be made in the Colony, and there is an ample supply of local candidates for the lower branches of the service, who generally have the preference."

Incurable optimists who are not daunted from emigration by these and similar reports, will find in the "Professional Handbook" the conditions of entrance for the clerical service of the various Colonies.

Railway Posts. Instead of being private enterprises, as in this country, the great majority of Colonial railways belong to the Governments, and, despite the allusion to railways already quoted from the "Handbook," these offer very much better chances of employment for a trained official than are afforded by the clerical services.

To enumerate here the various rates of pay for railway men in each of the likely Colonies would occupy an unwarrantable space. These figures can be learnt on application to the Emigrants' Information Office, or to the several

Colonial agents in London. For our present purpose, a brief indication of the prospects afforded to men from home will suffice.

South Africa. On the State railways in Cape Colony there is no demand for office clerks or artisans, but goods clerks and mechanics are sometimes engaged in England through the Agent-General for the Colony, 100, Victoria Street, S.W. The engagements are usually for three years, with payment of the passage out. Fitters are paid 10s. a day, and carpenters a little more; but it should be remembered that money at the Cape has only about three-fifths of the purchasing value it has in England. For the Natal railways, platelayers and signalmen, fitters, coachsmiths, and hammermen, are wanted from time to time—the first two classes receiving £10 to £17 monthly, and the others 9s. to 13s. a day. But these situations are generally advertised in England, and there is considerable risk in going out without a definite prospect of employment. The staff of guards, clerks, and checkers, on the other hand, is recruited on the spot, and experienced men who have gone out at a venture have as good chances of engagement as those who are Colonial born.

Australia. The rates of pay for railway employees in Australia and New Zealand are generally good, and the hours of duty light—from 48 to 57 weekly—but from every part of the Colony there comes practically the same report of the sufficiency of local candidates. Thus, the Government railways and tramcars of New South Wales employ a staff of nearly 18,000 men and boys, but openings for applicants from England rarely occur; the Victorian authorities notify that "there are always many more candidates than there are vacancies for them"; and the regulations in Tasmania and Western Australia practically prohibit the engagement of drivers, firemen, and certain other railway servants from outside sources. As a general rule, candidates for permanent employment must be under 35 years of age, and able to pass a medical examination. For clerks and superior officers an educational test is also usually prescribed.

The Canadian railways, like those under the Southern Cross, are officially reported to afford "little or no opening for men from England." But such announcements are intended only to discourage anything like a general movement to the regions concerned. Casual vacancies occur for which capable men, who have been trained on British railways, are in frequent request; and while an engagement before leaving home is highly desirable—and for heads of families is, indeed, imperative—these warnings need not daunt an efficient young railwayman without encumbrances from trying his fortunes in any Colony which, unlike Western Australia, has no prohibitive regulations. He should not take such a step, however, unless he has a little capital on which to live while seeking a post, nor without consulting the experts of the Emigrants' Information Office as to the likeliest field of employment.

Police Appointments. Our Colonial police are, in some few instances, municipal servants—as at Cape Town and Durban, for example. Most of the townships, however, are too small and scattered to maintain separate forces, and police control is therefore usually exercised by the Government of the Colony.

The life of a police trooper in the Colonies is at least as hard as in the home country, his prospects of promotion are generally but little better, and the increased cost of living often renders his higher wages an apparent rather than a real advantage. On the other hand, the semi-military duties of many Colonial forces, the chances they offer of sport and adventure, and that "call of the wild" which the great lonely spaces of the Empire utter to the imaginative ear, give these services an attraction not to be measured in terms of self-interest, and draw into their ranks many men whom the prospect of town or provincial police duty at home would repel.

The South African Constabulary. This body is engaged in police duties in the Transvaal and Orange River Colony, but in time of war may be employed for military purposes. It is sometimes recruited in England, but this has ceased for the present, and candidates must now make written application to the Chief Staff Officer at Johannesburg. Persons resident in the United Kingdom may apply, on the understanding that if approved they must pay their own travelling expenses to South Africa. They should state their age, height, chest measurement and weight, mention their qualifications, and enclose copies of their testimonials, including two from gentlemen of position, one of them a magistrate. The standard of height is 5 ft. 6 in., and the age limits are 20 and 35. Recruits are engaged for three years, with a provision for extended service. In addition to free quarters, rations, clothing, and equipment, and a horse when required for duty, members of the constabulary receive pay ranging from 5s. a day for constables to 10s for sergeant-majors and 15s. for warrant officers. Commissions are obtainable from the ranks

The London Staff Officer- from whom further particulars are to be obtained at King's Court, Broadway, Westminster, S.W – informs us that in his opinion the conditions of service in this corps will probably be changed when responsible government is established in the two Colonies concerned.

Rhodesian Forces. The British South African Police are a mounted force employed, under the control of the Imperial Government, in maintaining order in Southern Rhodesia. Non-commissioned officers and men are recruited locally, and sometimes by advertisement in England. Recruits must be at least 20 years of age and—unless they have served in another police force—not more than 25. They must be of good character, able to ride and shoot, between 5 ft. 6 in. and 5 ft. 10 in. in stature, and of proportionate build. Officers are occasionally sent out from England, but are usually appointed in South Africa. The rates of pay are as follows: Troopers, 5s. a day; sergeants, 6s. to 8s.; sergeant-majors, 12s. 6d.; commissioned officers, 15s. 6d. to 30s. and upwards—in each case with free quarters and rations.

The Southern Rhodesian Constabulary are employed as civil police in the towns, and are recruited at Salisbury, at Bulawayo, and occasionally in London. Men enrolled in England receive 2s. 6d. a day from the day of sailing, and are provided with a passage to South Africa, the cost of which they must meet by monthly deductions from their pay. Constables are paid 8s. to 10s. a day; detectives and sergeants, 12s. to 16s.; with free rations and equipment, but no quarters. The commissioned ranks receive from £404 to £500, and are filled by promotion from the N.C.O.'s.

Further particulars as to either force may be had of the British South Africa Company, 2, London Wall, E.C., who will always inform applicants whether recruiting is proceeding in England.

Cape Mounted Police. This is a semi-military force much resembling the South African Constabulary in its constitution. It is equally liable to army duties in case of emergency, the term of service is identical, the rates of pay and allowances are very similar, and the same physical standard is prescribed for recruits, but wider age limits are fixed—namely, 18 to 30 years. As recruiting in England has been suspended, applications for enrolment should be addressed to the Commissioners of the force, at Cape Town.

Cape Town and Durban Forces. When home recruiting is in progress for the first of these bodies, men are engaged by the Agent-General for Cape Colony, who will supply all requisite information on the subject. Constables in the Cape Town corps are paid £110, £125, and £140 during the three years of their engagement, with free quarters and uniform. The Durban Police Force is available to suitable applicants from the United Kingdom, the conditions of entrance prescribing 5 ft. 9 in. as the minimum height and 35 as the maximum age. Preference is always given to unmarried men. Candidates from this country should write for instructions to the Superintendent at Durban. The pay is £132 a year for constables, rising in two years to £144; and sergeants receive £162. Messing and quarters cost about £4 a month.

Natal Police. The local supply of recruits is generally sufficient to replace losses. When enlistment is open in England it is undertaken by the Agent-General for Natal (26, Victoria Street, S.W.). Recruits, who must be between 19 and 25 years of age and not less than 5 ft. 7 in. nor more than 6 ft. in height, are enrolled for three years, with the option of renewal. Constables receive 7s. to 8s. a day, with quarters; sergeants, 9s. to 10s.; and sergeant-majors, 11s. In the higher grades, which are filled by promotion, salaries range from £275 to £550.

Australia and New Zealand. In the Australian States, as in New Zealand, candidates must apply personally at the police headquarters in each Colony, and there is no demand for men from England. It would therefore be useless to detail the conditions of service in the several forces; they may be found by the curious in the Emigrants' Handbook, to which we have already referred.

Canada and the N.-W. Mounted Police. Even more exclusive than in Australia are the conditions of British Columbia, where at least a year's residence must precede any application for police employment.

The Royal North-West Mounted Police Force, however, is more readily accessible to English candidates. This distinguished police corps attracts far more British than Canadian recruits; and although all would-be entrants must present themselves in the Dominion for enlistment, a wise provision of the Commissioner enables them to make fairly certain of their chances before incurring the expense of the journey. On applying to that official at Regina, N.W.T., a blank medical certificate can be obtained, together with information as the the existence of vacancies, the standard of requirements, and the terms on which troopers are engaged. By returning the medical form filled in by a local doctor, a candidate residing in the United Kingdom can ascertain from the authorities his prospects of acceptance or rejection on the score of health.

The terms of service admit only single men between the ages of 22 and 40 who are active and able-bodied, and of excellent character. They must be able to read and write, and must understand the care of horses, and be good riders. The minimum height is 5 ft. 8 in., the chest measurement must be 35 in., or more, and the weight must not exceed 175 lb. Constables are enrolled for five years, and receive 60 cents a day, rising to 1 dol., with rations. Non-commissioned officers draw from 1 dol. 10 cents to 2 dol. a day.

The acting adjutant of the force, to whose courtesy we are indebted for much of the above information, concludes his letter intimating the existence of vacancies with the following useful remarks to candidates: "Applicants must be perfectly sound from a medical standpoint and have certificates of exemplary character. Intending recruits have to report at Regina at their own expense and be prepared to undergo a very strict medical examination by our own surgeon. They must assume all risks. Young men of about 22 years of age, well educated, and of strictly temperate habits, are most suitable for our service. In fact, intemperance is suppressed with a stern hand."

The Crown Colonies and Uganda. Candidates for police posts in Uganda or the East African Protectorate should apply to the Secretary of State for the Colonies. The appointment of officers of the police forces of the Crown Colonies is in the hands of the same official, and application should be made to his private secretary at the Colonial Office. The rank and file in these latter Colonies are, of course, natives.

DAIRY FARMING

Modern Dairying on the Continent and in England. How Production of Milk, Cream, Cheese, Butter, and Preserved Milk can be Improved. Tuberculosis

Group 1

AGRICULTURE

25

Continued from page 3471

By Professor JAMES LONG

THE art of dairying, like those branches of science which are playing such an important part in its development, was practically unknown to the agricultural world a quarter of a century ago. It was, in fact, impossible to obtain information in this country with regard to many of the features of successful practice as regards both butter and cheese manufacture which are now common property.

England Behind the Times. It is, however, almost proverbial that in some countries on the Continent the work accomplished was far in advance of our own, while investigation was proceeding upon definite lines, and scientific men were at work upon problems which were not even dreamt of in this country. We possessed neither the equipment for such work nor the men to undertake it. Indeed, at the present time, although large numbers of young men have been trained in the more recently established colleges and dairy schools, little has been done either in the form of demonstration or investigation, and we are, therefore, compelled to rely to a very large extent upon what is accomplished in America and on the Continent for many of the most important facts in relation to dairy science.

Modern dairying owes its incentive in large measure to the action of the British Dairy Farmers' Association, whose labours were consulted or employed right and left by other associations, and by the County Councils at the time of the establishment of the system of technical education. These men have done their work, and in large part have been succeeded by trained students who are now professionally engaged in the various departments of instruction and investigation.

Modern Dairying. In this country the production of milk for sale in its natural condition has become the most important feature of dairy farming, elaborate machinery as shown in 1 and 2 being employed to-day The limited size of our islands, with their large population, practically forbids the production of all the butter and cheese we require for our consumption. Thus, while the importation of fresh milk is practically prohibited by time and temperature, the daily demands of the people make it imperative upon the farmer to abandon to a very large extent the manufacture of the two chief products we have named for what in most cases is the more lucrative practice of producing milk for sale. There is, nevertheless, still great scope for the production not only of more milk, but of more butter and cheese, and in each case of better quality. The following figures, which relate to the year 1905, will furnish some idea of the enormity of our import trade, a trade which to a large extent should be in our own hands.

	Quantity		Value
Butter	4,147,866	cwt.	£21,586,622
Cheese	2,442,682	,,	6,339,811
Condensed Milk	893,634	,,	1,584,363

In addition, we paid 2¾ millions sterling for margarine, the total value in dairy produce amounting to 32¼ millions, or ten millions more than we paid ten years ago.

The Present Position of Dairying. We shall still further enable the reader to understand the present condition of the industry at home, and what it is still possible to accomplish, when we point out that the average consumption of milk is considerably less than half the average consumption of beer, though the average consumption of milk has increased during the past few years.

The products of British dairy farming are:

1. Milk for sale.
2. Cream for sale.
3. Butter.
4. Cheese, which is manufactured in five forms—(*a*) pressed, (*b*) blue veined, (*c*) unpressed, (*d*) soft, (*e*) cream, and
5. Condensed and other forms of preserved milk.

Skimmed milk is also sold in large quantities, but it is known to be largely employed as an adulterant of new milk.

Milk. Milk produced for sale varies in quality In accordance with the Government standard, it must contain 3 per cent. of fat. The richest milk produced by farmers and others—that from Jersey, Guernsey, and Devon cows—seldom finds its way into the market; it contains from 4½ to 5½ per cent of fat, individual cows often doing still better, and possesses greater value for butter production than the milk of other cattle

Cream. Cream is sold in two forms—(1) that which is skimmed by hand or by the separator, and sold quite fresh or in jars, in which it is preserved for keeping by the deleterious admixture of such drugs as boracic acid or formalin, by which practice its flavour is spoiled; and (2) clotted cream, almost exclusively the production of Devon, Cornwall, and Somerset. This material, richer in flavour, having been submitted to heat, keeps under *natural conditions much longer than cream* skimmed by hand or by the separator.

Butter. The butter we produce varies in quality and character as much as in price, 7d. a pound being by no means uncommon in some markets during summer, while 1s. 6d. and still higher figures are often realised by skilled makers, oftentimes amateurs, as the production of a Jersey or a Guernsey herd. British butter may be divided into two categories, that which is produced on the farm and that which is the product of the creamery or factory. The average samples of either are, perhaps, not superior to the best brands imported from France and Denmark, but the best brands in this country, such as those exhibited at the National Dairy Show at Islington in October, are incomparably superior to anything we import, or which, as we believe, it is possible to land on these shores in the present state of our knowledge. We are compelled to admit that our inferior brands of farm butter are less palatable than the uniform product of the Danes and the Normans, and it is for this reason that the character and the flavour of our best butter is practically unknown to the average consumer. The best imported butters are the factory brands of Denmark, and the best blended butters are those of France; following these in order come the products of Canada, Italy, Holland, Australasia, Germany, and Russia.

Cheese. Cheese is made in this country in great variety, although to a much less extent than in France. British cheese may be classed as follows:

PRESSED.

Cheddar, Cheshire, Gloucester, Leicester, Derby, Lancashire, Wiltshire Loaf.

BLUE VEINED.

Stilton, Wensleydale, Cotherstone, Dorset (chiefly skimmed milk).

UNPRESSED.

Caerphilly.

SOFT AND CREAM.

Yorkshire Curd, Godmanchester, Colwick, Slipcote, Coulommiers, Gervais, Pont l'Evêque (the three last-named are imitations of French articles), and Cream.

The most important British cheese is Cheddar, which is the type of the product which reaches us in such large quantities from Canada and Australia and the United States. In flavour and character it probably stands at the head of the cheese products of the world, although closely approached by the best Gruyère of France and Switzerland, and the Gouda of Holland. Cheshire of fine quality is largely consumed by the huge manufacturing and operative population of Lancashire, Yorkshire, and Cheshire. Leicester in its finest form is the most mellow of all British pressed varieties, but the art of making the best, if not lost, is now apparently but little practised. Stilton, made by a limited number of farmers, the majority of whom produce an inferior article, is practically on the market only during a limited season from December forwards, although it might and should be produced for sale during the whole year. Its superior quality as compared with the veined cheeses of the Continent, notably Gorgonzola, fits it for a lucrative and extensive export trade, but it is, even in our own country, superseded throughout the entire year by Gorgonzola of second and third rate quality hailing from Italy. Wensleydale, at its best, is equal to the finest Stilton produced. Our curd and cream cheeses are much fewer and infinitely inferior to those produced in France, in which country the soft-cheese industry is of enormous proportions, enabling milk-producing farmers to realise much better prices than are obtained in this country, though the same results are possible. We are content to import Brie, Camembert, Roquefort—a sheep's milk blue-veined cheese—Pommel, a mixture of cream and milk curd; Port du Salut, which somewhat resembles our Caerphilly, although superior in quality, and other varieties, all of which it is possible for our people to produce with great profit to themselves.

Condensed and Preserved Milk. Condensed milk is now manufactured both from the pure and the skimmed milk of the cow, which also produces the raw material from which various brands of dried or powdered milk are manufactured. Beyond the fact that the farmer produces the milk for the manufacturer, the preserved milk industry has practically no relation to dairy farming.

1. WASHING MILK CANS BY STEAM

Creameries. For many years the factory and creamery systems have been extending in all dairy farming countries, although in England, perhaps, least of all. The milk is contributed by the farmer, tested on its receipt, skimmed, the cream in most well-conducted establishments inoculated with a prepared starter containing the bacteria necessary for the production of flavour and quality, and subsequently churned in large quantities (2). Next to Denmark, which has led the world in this department of the dairy industry, Ireland is perhaps the most notable example of progress in the creamery system. As we write there are in Ireland 342 creameries on the co-operative system, apart from many others of a private character. Improved work has enabled the Irish, while increasing the price, to increase the yield also.

2. CREAM SEPARATOR CHURNING AND MAKING
(Photographed in one of Messrs Welford's dairies)

Value of Bacteria. The introduction of the *cream separator* more than twenty years ago by the Swedes and the Danes was almost contemporaneous with the inauguration of advanced dairying in this country; although followed by other inventions, it effected a practical revolution. Since that time the discovery that the flavour of butter and its keeping qualities are controlled by bacteria has enabled the maker to effect further improvements, so that the product of to-day, while far in advance of that manufactured by the past generation, will keep for a longer period. Much the same transformation has occurred with regard to cheese, which is now manufactured by all competent persons on the basis of scientific teaching.

Progress in one direction, too, has been accompanied by progress in another. The discovery of a method of manufacturing an imitation butter, known as margarine, by the aid of *oleo*, an important production of the Chicago stockyards, has led to its admixture with pure butter, and consequently to a form of adulteration which is now punishable by law, but which in this country is often difficult of detection. Butter, however, which normally contains from 12 to 14 per cent. of moisture, is also adulterated with water up to as much as 25 per cent., although a Bill for the prevention of the fraud, and limiting the water percentage to 16, has been introduced into the House of Commons by the Minister of Agriculture.

Sale and Yield of Milk. It is also instructive to learn that the farmer still sells his milk to the dealer, in spite of the existing law, by the barn gallon of 17 pints, practically 2 gallons with a pint overplus, which in earlier days was regarded as necessary to make up for the loss in retailing. Milk is usually sold under contract, realising a higher price from October to March than during summer, usually 1s. 8d to 1s. 9d per barn as against 1s. 4d. to 1s. 5d.

The dairy farmer's success depends almost entirely upon the productive powers of his cattle, and, therefore, upon his own skill as a buyer or breeder, and as a feeder. The average yield of milk in this country, as in America, is about 440 gallons per cow, which is an insufficient quantity to provide a profit. The fact, however, indicates that as there are large numbers of cattle which yield considerably more—from 1,000 to 1,200 gallons in individual cows, and from 600 to 700 gallons over whole herds—numbers of farmers must be owners of cows which yield considerably less than 400 gallons. The dairy farmer is more often than not a breeder of his own stock, and he should mate his cows with a bull of a milking strain, whose influence will assuredly result in the improvement of the milking properties of almost every heifer calf which is born to him. In this country we have no system of testing and recording cows as milkers, consequently we have no milking herd-book, or record, as is the case in the United States. For the same reason, too, a progressive farmer desiring to mate his stock and to breed upon scientific principles for the purpose, has no useful means of ascertaining where to obtain a bull of a known milking strain, or cows which are themselves milkers of the highest type.

Feeding Principles. Economy in milk production may be effected in another direction. There is nothing in the management of a herd so important as a knowledge of the principles of feeding. To rely solely upon the common produce of the farm—hay, straw, and roots—is in these days absolute folly; yet there are many dairy farmers who use neither corn nor cake, or who, making purchases of both, employ them without recognising the principles upon which they should be selected. This matter has been discussed in the section upon Foods and Feeding in Farming, but it is essential to point out that rich foods are necessary up to a certain point to provide for the manufacture of the solid materials which milk contains; and that those foods might be grown upon the farm in the great majority of instances at very much less cost and with far greater economy than by purchasing them, or their equivalent, in the market [see pages 2702-2706 and 2904-2909].

Improvement in Dairy Production. Our third proposition relates to the exercise of greater skill in the production of butter and cheese. It is possible that less than 10 per cent. of our farm manufacturers of these two products are failing to obtain better prices owing entirely to deficient knowledge. Dairy schools exist, and itinerary instructors travel in many counties at the expense of the ratepayer; nevertheless, large quantities of English farm butter are sold week by week at much lower prices than are realised by imported brands, while the quantities of first-class cheese which are obtainable by dealers are so small, and of second and third class cheese so large, that one is almost inclined to despair of the future of British dairying. Butter which realises 8d. per lb.—a very common price in summer—practically returns, allowing 1½d. a gallon for the skimmed milk from 4d. to 4½d. per gallon, whereas when 1s. 2d. to 1s. 3d. is realised—and still better prices than these are obtainable for first-class Jersey or Guernsey butter—7d. per gallon may be obtainable. There are two reasons for this, the more perfect removal of the cream from the milk, and greater skill in manufacture. It is precisely the same with cheese. Many makers fail to obtain more than 50s. to 60s. per cwt. Others, equally clever in marketing as in manufacturing, obtain from 75s. to 85s., and in exceptional cases still higher figures, without adding the value of the whey.

Marketing. This question, which brings into prominence the business side of the farm, is one which is very much neglected. The farmer is seldom found circularising the public, or taking any steps by advertisement or otherwise to obtain regular customers with whom he may conduct a weekly retail trade. His cheese is sold to a merchant; his butter, more frequently than not, to a local shopkeeper, who is clever enough to obtain a profit upon what he buys as well as upon what he sells.

Among other subjects that may be briefly discussed here are some which directly bear upon the economy of the dairy. It is the custom in this country to house cattle during the night early in October, but it has been shown by demonstration at the Harper Adams College at Newport, in Shropshire, that where the cows are kept out of doors on the pastures at night to the close of the year instead of bringing them in with October, money is saved. This is one among many questions which farmers should test for themselves, whatever their practice or belief may be. Again, in the rearing of young stock it has been demonstrated by the officers of the Yorkshire College that great saving may be effected by feeding calves upon skimmed or separated milk to which cod-liver oil has been added in order to replace the fat that has been removed in the cream. During successive years groups of calves were reared to maturity, the accounts being strictly kept, on two systems of feeding, with *whole* milk and with *skimmed* milk and oil, and in each case the results were in favour of the latter.

The practice of town cowkeepers, who buy of the best that can be found, is to fatten each animal for the butcher as its milk supply decreases, with the result that there is a continual drain of the best cows in the country, very many of which are of high value as stock for breeding purposes. Whatever may be the practice, the principle is wrong.

Tuberculous Milk. Since the discovery that the disease known as tuberculosis may be communicated to man through the milk which he consumes, great efforts have been made not only to confirm the belief, but to prevent the possibility of an affected cow being retained in any herd or dairy. Many breeders and cowkeepers have, in consequence, submitted their cattle to what is known as the tuberculin test. The injection of the serum known as tuberculin—which contains no living bacilli—is followed by symptoms which, where tuberculosis exists in the slightest form, indicates the fact, and enables the owner to remove her from his herd. There are, however, doubts both in the minds of scientific and practical men as to the efficacy of the test, in spite of the many apparent proofs which have been demonstrated, as well as to the truth of the fact that the germs of the disease are found in milk. Hence we may suspend our judgment in some degree, yet we are bound to express the belief that where the udder of the cow is tuberculous—and this is recognised practically by all public authorities—the milk which is drawn from it is a source of danger to human life.

THE NOVELISTS OF TO-DAY

Being the Conclusion of English Prose Fiction. A Note on the Present Condition of the Novel Short Studies in Meredith and Hardy. The Test of a Novel

Continued from page 3443

By J. A. HAMMERTON

WE completed with our previous study a rapid yet comprehensive survey of English Prose Fiction as it is embodied in the writings of the more notable novelists of the past down to Robert Louis Stevenson. The extent of the subject, and our desire to maintain throughout the historical method of treatment, left us little or no space to devote to the separate consideration of the great variety of literary forms which ight reasonably be included under the head of e Novel, not to say the still greater variety of hich the term Prose Fiction admits. But the udent anxious to pursue further the studies hich we have at least begun will find in what as been set down many finger-posts pointing he way to increased knowledge of the subject, hile the general reader will have secured hat might be termed a rough ground-plan, or orking outline, of all that is best worth reading n English Prose Fiction.

The Good Work of Our Own Day. For the present study we have reserved the work of those novelists who are still living and in most cases still writing, as we are persuaded that here is great need in a work of this kind to nsist upon the merits of living writers when so much of our attention must necessarily be drawn to the authors of the past. We have no sympathy with those critics who seem never so happy as when they are sneering at the productions of their contemporaries. A very little study of literary history will show that in all ages there have been critics who have maintained this pose. Shakespeare had many detractors in his own day, Scott was not without his adverse critics, Dickens was scoffed at as a writer of low Cockney books. Rather is it desirable to look around us, that we may discover what is good in the work of our contemporaries. And if we but do this to-day we shall be agreeably surprised to find how excellent is the prose fiction of our living writers.

The Novel a Perfected Instrument. If we have not many giants among us—and this is the most difficult of all things to determine, as we do require some distance of time to measure accurately the real dimensions of a great writer—there is no manner of doubt that the general level of excellence represented by the body of contemporary fiction is considerably higher than that obtaining in any former period of our literary history. The novel has become in our own day a perfected instrument. From a formless, lumpish, uncraftsmanlike thing, such as we find it in the hands of even great writers in the past, it has developed into an admirably proportioned and wonderfully effective literary medium.

What we are saying is that the average good novel of to-day is as superior to the average novel of the mid-Victorian days as a modern express locomotive is superior to the old "Puffing Billy." This means that the literary art, as distinct from genius, which may be, but is not always, above and independent of convention, has vastly improved from the days of our forefathers. Though all this will be held to require considerably more proof than we can possibly hope to advance in this very brief study, we may content ourselves by suggesting that in support of our assertion we have only to examine any representative story by such writers as Mr. Israel Zangwill, Mr. Eden Phillpotts, Sir Arthur Conan Doyle, Mr. Halliwell Sutcliffe, Mr. S. R. Crockett, Mr. R. S. Hichens, Sir Gilbert Parker, Mr. Neil Munro, Mr. A. E. W. Mason, and at least a score of other equally well-known writers, to realise how firm and admirably wrought is the texture of our contemporary fiction as compared with that of any previous period.

A Healthy Sign of the Times. The fact that side by side with what is entirely praiseworthy in the modern novel there exists a vast amount of fiction that is undeniably trashy, false to every canon of the literary art, useless and often worse than useless as furnishing for the mind, has led many hasty critics into unfortunate generalisations condemnatory of the whole body of contemporary fiction. In all times, and everywhere, the weeds have flourished as luxuriantly as the flowers—often more profusely. It is so to-day in the world of letters, but not more so than at any time in the past. That so many of our best living novelists are widely and intelligently read by an ever increasing public is of far more importance than the fact that an immense number of superficial writers secure large circulations for their works by the patronage of the uncultured. While we cannot hope in the little space that remains to us to do justice to the best work of our contemporary novelists, and while many worthy of some attention at the hands of all who would be well versed in living writers may have to be passed over with the mere mention of their names, we may at least do something to preserve a sense of proportion by ignoring entirely many more who have won only the ignorant approval of the mob.

The Two Greatest Novelists. There is, of course, a sense in which the two greatest living novelists, Mr. Meredith and Mr. Hardy, should have come into our previous study. As writers of fiction, both may be said to have ended their careers. It is a pity that it should be so; that Mr. Meredith should have written no work of fiction since 1895, and that

Mr. Hardy, who is not yet seventy years of age, should have laid down the pen of the novelist when he was only fifty-two, with all his brilliant powers at their ripest. But the fact is so, and we must not complain, for each has to his credit a splendid tale of work; and although they are essentially of the Victorian Age, it satisfies our pride no less than it fits in with our historical method to regard them as our contemporaries of to-day.

George Meredith. Stevenson owed a great deal to George Meredith (b. 1828); and this fact may be taken as specially significant. What, we may well ask, adapting a well-known line, do they know of Meredith who only Meredith know? The answer is that they know a great deal, but that the great deal falls very considerably short of the whole. Though his first book, a volume of poems, was published in 1851, Meredith did not begin to be appreciated by the public till quite thirty years later. Even to-day, though there exists what is called a Meredith cult, it cannot be affirmed that its "idol" is popular. We may reasonably doubt if he will ever be read as widely as, say, Thackeray; if he will ever become a "classic." But to the student of contemporary English fiction Meredith is something greater than a popular writer. He is, and has been for years, a great influence. Stevenson counts but as a unit among those who have been and who will be influenced by him. There are various reasons for the power he has exerted over his contemporaries. The chief reason is that he has chosen to look at life with his own eyes, and to describe it in his own words. The life he depicts may not be the life with which we are all familiar. His people are, as he has described them, "actual, yet uncommon" Meredith is a social satirist. Full often he smites and spares not. But it is scalpel work, never mutilation. He was a poet before he was a novelist, a philosopher before he was a poet, and his novels are poetry and philosophy combined. His place is with Browning and Carlyle. They and he have the defects of their qualities. But what splendid qualities these are! Meredith is thought-compelling. He gives exercise to the mind. He is a fellow-traveller on life's journey who gives readily from a store of experience that is vastly greater than our own.

How to Study Meredith. Some of us have not yet learnt that we get no more from a book than we bring to it: minds have to be "worked" as well as mines. The Meredithian mind is an intellectual Golconda. The right way to "work" it is to study the man and find out the origin and motive of his writings. None of Meredith's novels can be fully appreciated at a first reading. Knowledge, as well as industry, is essential. How, for example, can "The Tragic Comedians" be understood unless the reader know something of the career of the German Socialist Lassalle? But the diligent student will find Meredith to a very considerable extent self-critical and self-explanatory. As to his style: this is admittedly difficult; it is like a river with many tortuous windings but noble reaches. But his English, at its best, is the best English of the time. He is to be studied, not imitated; and the study should result in a disregard for the iteration of toil-worn phrases. "A writer," he says, "who is not servile and has insight must coin from his own mint."

Meredith's Style. It has been very happily said of him that "he thinks in metaphor," which is precisely what the ruck of mankind does not do. Hence, it is not surprising that to the average reader the works of this great novelist should present grave difficulties of style. Curiously enough, we find his poetry presenting a clearness and grace of diction, a simple beauty of words, which is nearly always foreign to his prose manner. The late Ashcroft Noble observed with much truth that "his speaking voice is an affair of organisation; his singing voice is the result of careful training." In other words, Meredith the novelist tells his story in a manner natural to the man; but in his poetry the conscious artist, under the restraint of his medium, has to rid himself of the perpetual involutions of metaphorical thought which are natural to him and characterise his work in prose.

Begin with "Richard Feverel." There can be no question that the best of Meredith's novels to begin with is "The Ordeal of Richard Feverel." If we ask "What is education?" we have here an answer equivalent to many debates in Parliament and many speeches on political platforms. We have education not merely described, but seen in action. If we ask "What is love?" "What passion?" we have but to take up "Richard Feverel" to see these two dominating attributes of our common human nature set forth with a freshness, a vigour, a reverence, a sympathy, a feeling for external nature—with a knowledge, in short—unrivalled by any other writer of contemporary fiction. If we seek an example of the analysis of motive we cannot do better than study, and we shall be the better for studying, the dissection of Sir Willoughby Patterne in "The Egoist," in modern fiction surely the most finished portrayal of any type of character, an "uncommon" character in which every reader will find some phase of his own self revealed to him. "Beauchamp's Career," "Diana of the Crossways," and "The Adventures of Harry Richmond" are the best of Mr. Meredith's other novels; "The Shaving of Shagpat" the most richly imaginative. To show that genius, if not always "the art of taking pains," does not despise drudgery, it may be sufficient to mention that for thirty years Mr. Meredith was literary reader to a well-known firm of publishers.

Thomas Hardy. If with Browning and Meredith we believe that

"God's in His heaven
All's right with the world!"

a study of the novels of Thomas Hardy (b. 1840) will be a somewhat mixed pleasure. Hardy, even more than Meredith, has great dramatic qualities. But Hardy's is the voice of the countryside—of the countryside that is far removed from town. To him the greenwood tree suggests not merriment, but destiny; a pair of blue eyes not heaven, but Fate. Life is a tragedy with a few interludes. The coast of Dorset might almost be the shores of old Armorica. Yet the philosophy of this Dorset seer is stern, not weeping. The words of religion are quoted freely in his novels, but in the spirit of the educated pagan. The peasants he introduces to us belong to a part of England the exclusiveness of which is only now being broken into. Their ways and modes of thought are depicted with a realism that is pitiless, though the novelist lightens his narratives with many a flash of genuine humour. Hardy is a writer who must be approached with an understanding of his own environment, which is the environment of the characters of his novels. The student must gain the novelist's point of view; then, even in the case of "Jude the Obscure," in place of the repulsion that many might otherwise experience simple admiration of the writer's art will be awakened. This art is undoubtedly circumscribed, but it is great art, nevertheless. Every incident in the novels written by Thomas Hardy is calculated with unerring skill; the movement is controlled from the outset with the deliberation of conscious art. The style is as direct as the plot; its distinction is derived from its subject-matter.

Hardy's Best Novels. With Hardy, style without thought is mere vanity. "A writer's style," he once wrote, "is according to his temperament; and my impression is that if he has anything to say which is of value, and words to say it with, the style will come of itself." Like Meredith, Hardy is a poet; like him, again, he is scarcely a "popular" author, though both have enjoyed in more recent years far more public favour than in the prime of their lives. We have said enough, perhaps, to show that he is an important novelist for the student. His best works appeared in the following order: "Under the Greenwood Tree" (1872), "A Pair of Blue Eyes" (1873), "Far from the Madding Crowd" (1874), "The Return of the Native" (1878), "The Mayor of Casterbridge" (1886), "The Woodlanders" (1886–7), "Tess of the D'Urbervilles" (his greatest novel, 1891), and "Jude the Obscure" (1894-5). The reader would do well to take up his novels in this sequence; but "Far from the Madding Crowd" may be mentioned as thoroughly representative of his art.

The Test of a Novel. At this point, and touching "Far from the Madding Crowd," we think it well to define more particularly than we have yet done the supreme quality of a good novel. We have in our previous study seen that the melodramatic story is one in which incidents are of first importance. Human nature, the facts of life, do not concern writers of this class of fiction. Their chief stock-in-trade is the "thrilling situation." True, in life there are many incidents as thrilling as any ever invented by the most ingenious sensation monger, but the difference lies in the fact that the great episodes of life, like the great rivers of the world, have their source in little things, and convey no lesson to us unless we know something of the source from which they spring. In all works by masters of fiction it will be found that the "supreme moments," the crises which they describe, have grown steadily, remorselessly, fatefully out of the lives of their "dramatis personæ," and have not been invented merely to "thrill" or shock the reader. This does not mean that the supreme moment must come late in the story; it may occur early in the narrative; but when such is the case it will be found to dominate the entire book, to shape and colour everything that follows.

The "Inevitable" Incident. If the reader will turn to "Far from the Madding Crowd," he will find that the fifth chapter contains one of the most tragic episodes in modern fiction, related in a simple, unaffected style, but coming like a peal of near thunder on a summer day, startling, portentous, "thrilling" if you will, but absolutely inevitable in the drama the novelist is unfolding. It tells how Gabriel Oak, the young farmer who is the hero of the story, has come within sight of his long-toiled-for success, and has thoughts of marriage, when, one night, he is reduced to ruin by the misguided zeal of a sheep dog, which drives some two hundred of his flock, whose lambs have not yet come, into a chalk-pit. "The sheep were not insured. All the savings of a frugal life had been dispersed at a blow. . . . It was as remarkable as it was characteristic that the one sentence he uttered was in thankfulness: 'Thank God I am not married! What would she have done in the poverty now coming upon me?'"

This tragic episode is described with perfect literary art and fidelity to life. It keys the whole story through the fifty odd chapters that follow. It exercises a mighty influence on the character of the hero and his relations with the other persons of the romance. It is essential to the story, woven into the web of it, impossible to be removed without ruin to the whole. That is what we mean when we speak of the incidents in the works of great novelists as being "inevitable." When the reader thoroughly appreciates this, he will have no difficulty in distinguishing between the novel of true character and drama and the novel of false character and melodrama.

Kipling and Social Criticism. One of the principal features in the fiction of our time is its note of social criticism, especially in regard to women. Mr. RUDYARD KIPLING (b. 1865), touched this note in "The Light that Failed"; but Kipling is to be found at his best in his short stories of Anglo-Indian life, such as "The Incarnation of Krishna Mulvaney," "The Courting of Dinah Shadd," "The Man Who Was," "Without Benefit of Clergy," "The Drums of the Fore and Aft," and "Georgie Porgie." In his prose as well as in his ballads he has depicted the Cockney soldier abroad with unerring insight and fidelity. His prose fiction is as worthy of serious study as that of any master of the near past. Whether his opinions please or irritate us, we must acknowledge that he possesses an absolute individuality in his style; that he is a "maker" and not a mere journeyman of letters. The clash of rival forces and the mystic spirit of the dreaming East have found reflection also in the work of Mrs. Flora Annie Steel (b. 1847), particularly in "On the Face of the Waters," and the short stories published under the title of "In the Permanent Way." The bitterness of outlook in the novels of Thomas Hardy is more than equalled in "The Story of an African Farm," written by Mrs. Olive Schreiner when she was quite a girl, and her one book of real literary value; but even this bitterness is excelled by the revolt of "The Gadfly," by Mrs. Voynich. Revolt, too, though of a more temperate kind is a characteristic of the novels—"Marcella," "The History of David Grieve," and "Robert Elsmere"—of Mrs. Humphry Ward (b. 1851), a granddaughter of Arnold of Rugby, and a writer whose work claims consideration with, as it is influenced by, that of George Eliot and Charlotte Brontë. Revolt again, with a more decided accentuation of the sex problem, is reverberant in "The Heavenly Twins," by Mme. Sarah Grand; "The Open Question," by C. E. Raimond (Miss Elizabeth Robins); "Keynotes," by George Egerton (Mrs. Golding Bright); and "The Yellow Aster," by Mrs. Mannington Caffyn—works noteworthy chiefly as representative of a passing phase of thought, rather than of enduring value.

The "Society" Novel. What is called the "society novel" includes among its writers Mr. E. F. Benson (b. 1867), author of "Dodo" and "Mammon & Co."; Mr. F. C. Philips (b. 1849), author of "As in a Looking-glass"; Mr. Percy White, author of "Mr. Bailey-Martin," "The West-End," and "Andria"; "Benjamin Swift" (Mr. William Romaine Paterson) (b. 1871), author of "Nancy Noon" and "Ludus Amoris"; Mr. John A. Steuart (b. 1861), author of "Wine on the Lees"; Mr. William J. Locke (b. 1863), author of "Derelicts"; Mr. Vincent Brown, author of "A Magdalen's Husband"; Mr. Edwin Pugh (b. 1874), author of "Fruit of the Vine"; Mr. Leonard Merrick (b. 1864), author of "The Man Who Was Good," and "The Worldlings"; "Ouida" (Mlle. de la Ramee), author of "Moths" and "The Waters of Edera"; Miss Braddon (Mrs. John Maxwell) (b. 1837), author of "Lady Audley's Secret"; Mr. W. B. Maxwell, a son of the last-mentioned writer, author of "Vivien," "The Ragged Messenger," and "The Guarded Flame," all works of distinction.

Mr. H. G. Wells (b. 1866), in addition to writing a series of remarkable semi-scientific, half-sociological works, which have caused him to be compared to both Jules Verne and Herbert Spencer, has in "Kipps" penned a social satire of exceeding power. Miss Violet Hunt, author of "A Hard Woman," "The Celebrity at Home," and "Sooner or Later," and Miss Beatrice Harraden (b. 1864), author of "Ships that Pass in the Night" and "Hilda Strafford," are writers whose works are representative of the mingled satire and brilliant pessimism which is to be found in the books of many women novelists.

Realists and Others. Among those who have sought, somewhat after the method of the French school, to photograph humble life, may be cited Mr. Arthur Morrison (b. 1863), author of "Tales of Mean Streets"; Mr. George Moore, author of "Esther Waters," and an acknowledged pupil of Zola; William Somerset Maugham (b. 1874), author of "'Liza of Lambeth"; and Mr. Richard Whiteing (b. 1840), author of "No. 5, John Street." In "The Passport," Mr. Richard Bagot (b. 1860) has written a brilliant exposure of Vatican intrigue; and religion and ethical questions are dealt with by Mr. William Hurrell Mallock, Dr. William Barry (b. 1849), Mark Rutherford (Mr. William Hale White), Mr. C. Ranger Gull (b. 1876), and Mr. F. T. Bullen (b. 1857). "Questions of the day" form the theme of such purely "popular" writers as Mr. Hall Caine (b. 1853) and Miss Marie Corelli. Mr. Coulson Kernahan (b. 1858) has achieved distinction in the department of allegory, and allegory may also claim "The Garden of Allah," by Mr. Robert Hichens (b. 1864), who has also written in "The Woman with a Fan," a striking novel of society life, and in "The Black Spaniel" touched the macabre vein, so distinctive of the work of Mr. Arthur Machen (b. 1863), author of "The House of Souls" and "The Great God Pan."

Modern Romance. In the realm of historical romance, prominent places are claimed for Sir Arthur Conan Doyle (b. 1859), author of "The White Company" and "Uncle Bernac," and the creator of "Sherlock Holmes"; Mr. Stanley Weyman (b. 1855), author of "A Gentleman of France," "Under the Red Robe," and "My Lady Rotha"; Sir Gilbert Parker (b. 1862), author of "The Seats of the Mighty"; Mr. Anthony Hope (Hawkins) (b. 1863), author of "The Prisoner of Zenda" and "Quisanté"; Mr. Maurice Hewlett (b. 1861), author of "The Queen's Quair"; Mr. S. Levett-Yeats, author of "The Chevalier d'Auriac" and "Orrain"; Mr. S. R. Crockett (b. 1860), author of "The Red Axe" and "The Raiders"; Mr. Bernard Capes, author of "A Castle in Spain"; "John Oliver Hobbes" (Mrs. Craigie) (b. 1867; d. 1906), whose tragic death occurred as these pages were being passed for press, author of "A School for Saints" and "Robert Orange"; Mr. Ford Maddox Hueffer (b. 1873), author of "The Fifth Queen"; "M. E. Francis" (Mrs. Frances Blundell), author of "Yeoman Fleetwood"; and Mr. F. Frankfort Moore (b. 1855), author of "The Jessamy Bride." Romance pure and simple and fascinating marks almost every book that has come from the pen of Mr. and Mrs. Egerton Castle, joint-authors of "Young April" and "If Youth but Knew." The quality of a rare humour distinguishes the stories of Mr. James Matthew Barrie (b. 1860), stories that stand quite by themselves, as "The Little Minister" and "The Little White Bird," and the short sketches collected in "A Window in Thrums" and "Auld Licht Idylls." The romance of adventure in Far Eastern seas has found in Mr.

Joseph Conrad (joint-author with Mr. F. M. Hueffer of "Romance") a skilful interpreter. Mr. Louis Becke (b. 1848) transports the reader to the islands of the Southern Seas, as in "Rodman, the Boatsteerer"; while Mr. R. B. Cunninghame Graham (b. 1852) has written with masterly touch of the romance of life in South America, as in "The Ipané." Australian life is reflected in the books of "Rolf Boldrewood" (Mr. T. A. Browne) (b. 1826) and Mr. E. W. Hornung (b. 1866), author of "The Rogue's March" and "A Bride from the Bush." Mr. Max Pemberton (b. 1863) has won wide popularity by his novels of pure adventure, a vein also profitably worked by Mr. C. J. Cutcliffe Hyne (b. 1866). South Africa as a field of adventure has been exploited to some purpose in the highly-coloured pages of Mr. H. Rider Haggard (b. 1856), author of "King Solomon's Mines," "She," "Ayesha" (an old title revived), and "Stella Fregelius." The roving spirit is well expressed in the work of Mr. Morley Roberts (b. 1857). Mention must also be made of the fine works of Mr. A. T. Quiller-Couch (b. 1863), author of "Troy Town," "The Splendid Spur," and "The Ship of Stars"; Mr. Theodore Watts-Dunton, author of "Aylwin"; Mr. Charles Marriott (b. 1869), author of "The Column" and "Genevra"; Mr. A. E. W. Mason (b. 1867), author of "The Courtship of Morrice Buckler" and "The Four Feathers"; Mr. John Oxenham, author of "John of Gerisau" and "Barbe of Grand Bayou"; Mr. R. H. Benson, author of "The King's Achievement"; and Mr. W. H. Hudson. There is also much to admire in the writings of the Rev. S. Baring-Gould (b. 1834), whose "Mehalah" has been widely read; Mr. Neil Munro (b. 1864), author of "John Splendid"; Mr. David Storrar Meldrum (b. 1865), author of "The Story of Margrédel"; "Zack" (Miss Gwendoline Keats); David Christie Murray (b. 1847), who has narrowly missed the first rank; Mr. W. E. Norris, author of "Giles Ingilby"; Mr. Alfred Ollivant (b. 1874), author of "Owd Bob" and "Danny"; Mr. Eden Phillpotts (b. 1862), author of "Children of the Mist" and "The Secret Woman"; Mr. Halliwell Sutcliffe (b. 1870), author of "Ricroft of Withens" and "Through Sorrow's Gates," a writer who comes close to Hardy in every respect except that of humour; Mr. W. C. Clark Russell (b. 1844), author of "The Wreck of the Grosvenor"; Mr. Robert Barr (b. 1850), author of "The Countess Tekla"; Mr. Laurence Housman (b. 1867), author of "An Englishwoman's Love Letters" and "A Modern Antæus;" Mr. Israel Zangwill (b. 1864), author of "Children of the Ghetto"; and Mr. Louis Zangwill (b. 1869).

Humour has admirable representatives in "F. Anstey" (Mr. F. A. Guthrie), Mr. W. W. Jacobs (b. 1863), Mr. Barry Pain, and Mr. W. Pett Ridge. Mention must also be made of the success of Mr. Joseph Hatton (b. 1840); while Mr. Jerome K. Jerome (b. 1859) has proved himself a novelist of great power and insight.

Some Prominent Women Novelists. "Lucas Malet" (Mrs. Mary St. Leger Harrison) in "The History of Sir Richard Calmady" made a reputation for power at the expense of more admirable qualities, but the book will not readily be forgotten. Other prominent women writers are Miss Rhoda Broughton (b. 1840), author of "Cometh up as a Flower"; Mrs. Katharine Tynan Hinkson (b. 1861); Miss Jane Barlow, author of "Irish Idylls"; Miss M. Betham-Edwards, author of "Dr. Jacob"; Miss Mary Cholmondeley, author of "Red Pottage"; Miss Una L. Silberrad (b. 1872), author of "The Wedding of the Lady of Lovell"; Miss May Sinclair, author of "Divine Fire"; "Maxwell Gray" (Miss M. G. Tuttiett), author of "The Silence of Dean Maitland"; Miss E. T. Fowler (Mrs. A. L. Felkin), author of "Concerning Isabel Carnaby"; "Sidney C. Grier" (Miss Gregg) (b. 1868), author of "Like Another Helen"; Mrs. W. K. Clifford; "Rita" (Mrs. W. Desmond Humphreys); Mrs. L. B. Walford (b. 1845), author of "The Mischief of Monica"; Miss Helen Mathers (b. 1853), author of "Comin' Through the Rye"; Mrs. Katharine S. Macquoid; Mrs. Campbell-Praed (b. 1852), and Mrs. Thurston, author of "John Chilcote, M.P."

The Literary Life. With this very brief glance at the more noteworthy novelists of the day, each of whom has written at least one, and many of them several books well worth reading, we have arrived at the end of our study of English prose fiction, and, indeed, within sight of the end of this course in English Literature, for what is to follow is merely in the shape of appendices, in which we shall endeavour to give in the briefest outline some courses of reading in classical, foreign, and American literature. Most of the other courses in the Self-Educator are concerned with the direct application of knowledge to the daily conduct of life and business. This course in Literature has been designed chiefly for the general reader, that it might aid him to the intelligent study of our great writers and those writers who, though falling short of greatness, have still something to tell that will add in some measure to his intellectual enjoyment. The career of the professional man of letters is in some ways the noblest and the most attractive of all, but the way to it lies through much tribulation, and is not lightly to be entered upon, unless the aspirant has as clear a "call" for the work as the candidate for the pulpit is supposed to have. We have made it no part of our business to indicate to the literary aspirant what his course of action should be, but in the course on Journalism, which immediately follows that on Literature, the aspirant will find how the door may be opened that leads to success in literature. For it is worthy of note that by far the largest number of authors whose names are familiar to the reading public have made their way to reputations in literature by entering the world of letters through the humbler but more easily opened door of journalism.

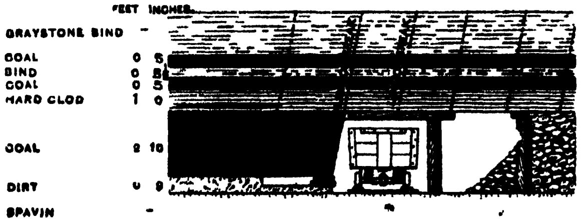
THE WORKING OF COAL

Underground Roads. Different Methods of Dislodging and Removing Coal from its Bed. Machines in Modern Coal Mining Practice

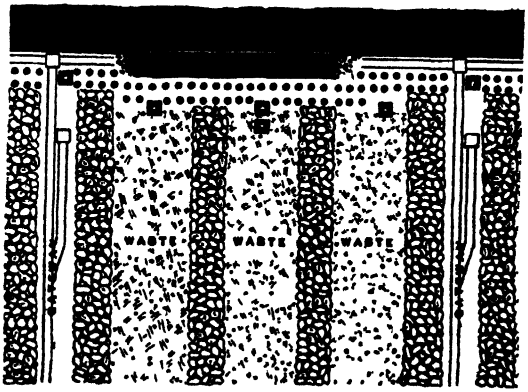
By D. A. LOUIS

THE first point to consider is the support of the shaft and the building and machinery on the surface, for whatever is taken out below will leave a space into which the roof will sink, and so in succession all the overlying strata, and presently the surface; moreover, should the shaft come within the sphere of influence all sorts of trouble would ensue Therefore, a block of mineral around the shafts is left intact, except for the roads driven through it It is known as the *shaft pillar*, indicated at the bottom of 88 and 90 and at the top of 89 It is usually rectangular, with the sides measuring from two thirds to the whole depth of the shaft, thin seams require smaller shaft pillars than thicker ones, and shallow seams less support than deeper ones When once the extent of the shaft pillar is decided the method of working is the next question that arises, whether *longwall* or *pillar and stall* methods will be employed



85 A COAL-FACE, WITH TUB, PROPS, AND GOAF

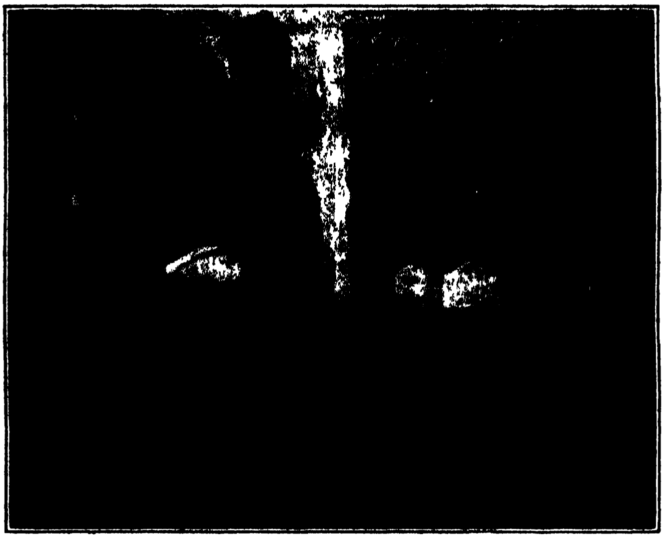
Longwall Working. The longwall is the simpler method, and, conditions being favourable, is usually adopted Galleries to form the main roads are driven in pairs for the sake of ventilation One road serves for the fresh air to travel along, and is known as the *intake air way*, while the other serves for the air that has traversed the mine to reach the upcast shaft, and is known as the *return air-way* When these roads have passed through the shaft pillar—and *longwall advancing* is the method of working followed—the extraction of the coal may commence at once A passage way is cut in the coal, right and left from the main roads, the coal being loaded in the tubs and taken away, while timber posts or *props*, and sometimes chocks as well—the small squares on figure 86 indicate chocks—are inserted to support the roof The tramlines are laid along this passage, so that the tubs or little waggons can be brought right up to the exposed surface of coal, called the *face* An arrangement at a longwall face is shown in elevation in 85 and in plan in 86 The coal is then cut away in slices To do this, the miners *hole* or *undercut* the coal—that is, make a long, narrow cut in a convenient position—with picks, all along the face, supporting it as the cut deepens by short props called *sprags*, and frequently the coal is further supported by a horizontal timber held in position by a prop below, and another jammed against the roof; it is known as a *coker meg* Undercutting by hand is illustrated in 87, and shows the method of cutting in the middle of a seam When the cut is sufficiently deep, and taken far enough along the face, a vertical cut is made, *nicking*, to loosen the undercut coal from the adjoining mass; then the sprags are withdrawn, and if the coal does not fall down of its own account, it is brought down by wedging or blasting The coal is loaded into the tubs and trammed away, and another row of props is put up between the first row and the new face Any waste brought down with the coal is packed up behind the miners, in the space from which the coal has been removed, making rough sorts of walls, which support the roof to some extent This waste area is known as the *gob* or *goaf*, and the piles of rock as *goaf packs* Two rows of props are always kept behind the miner, but when the third row of props is put in, the hindermost props are drawn out and used again, the roof then sinks on the goaf packs So the order of operations at the face is under cutting, spragging nicking, withdrawing sprags, bringing down coal, loading it up, tramming it away building up packs, setting up fresh props, advancing tramlines to new face, and withdrawing back props. In course of time the roof falls and loosely fills the goaf Special



86 A LONGWALL FACE

precautions have to be observed when drawing props.

Underground Roads. It is obviously useless to attempt to work a long face of coal with only one connection with the main road, as the back waggons would always be delayed by those in front, and *vice versâ*; therefore, the face is divided into convenient lengths called *stalls*, each stall being served by a road called a *stall road*, which is kept open in the goaf by means of walls built of the rubbish, called *pack walls* or *packs*, and those stall roads run into other roads known as *levels* or *gates*, branching obliquely from each side of the main road; they should not, however, start opposite each other. The levels are also made in the goaf. All roads in the goaf are troublesome to keep open; therefore, as the face advances, new levels are started to intersect the stall roads, so that the latter are kept as short as possible, inasmuch as that portion of each stall road behind the new level is abandoned, and consequently ceases to require attention. For the same reason, systems of intermediate roads are frequently introduced to shorten the gates or levels. In the diagram of an actual longwall working shown [88] the gates and levels are taken right to the coal face. The continuous lines show the roads still in use; the dotted lines, those abandoned in the goaf.



87. HAND HOLING IN THE MIDDLE OF A FACE (Photo by H. W. Hughes, Dudley)

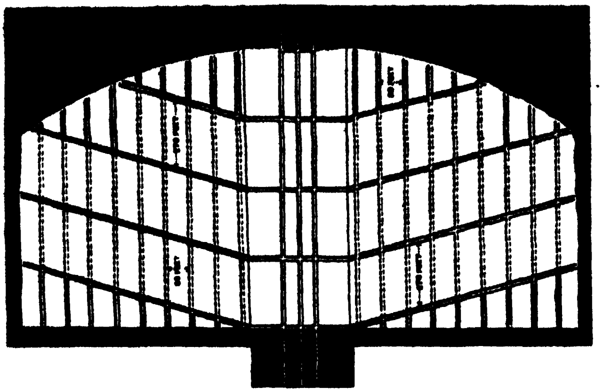
The direction that is given to the face is determined by convenience or by selection, and where the cleavage or cleat of the coal is strongly marked, the coal is worked more easily with the face running parallel to the cleavage planes, or, as it is called, *on bord*; but more coal in large pieces, or *round coal*, is obtained where the coal advances at right angles to the cleat, or *on end*. When the coal is worked at an angle of 45 deg, that is, between *on bord* and *on end*—it is said to be worked on *the cross*. The most expedient practice should be adopted, hence it happens that the longwall face is by no means always a long continuous face, but various kinds of sectional or stepped faces are introduced to meet special conditions. The step face in an inclined seam really resembles stope in vein mining.

Longwall Retreating. Longwall retreating is another modification of longwall. In this practice, main roads and gates are driven to the boundary, and the coal is worked back to the shaft. In this way the goaf is left behind, and no roads have to be maintained in it. Fig. 89 illustrates this method of working. The main roads are driven to the boundary of a panel, then two sets of headings, AA, BB, are cut, and then the connecting roads; ultimately the remaining coal is worked back in stepped faces, as indicated; the shading shows the part already worked out.

It will be observed that in longwall retreating the mass of coal is really divided up into solid blocks, with roadways separating them, and approaches slightly to the next method of working coal to be considered.

Pillar and Stall. The method known as *pillar and stall*, *post and stall*, *bord and pillar*, or *stoop and room*, as it is called in Scotland, is adopted when the conditions are not suitable for longwall working. In it the coal is removed in two stages, the first stage known as *working in the whole*, and the second stage as *working in the broken*. In the first stage, the coal is divided into rectangular blocks, or *pillars*, by roads driven at right angles to each other, but leaving sufficient coal on each side to protect the main roads. The roads driven parallel to the cleavage of the coal are known as *walls*, and those driven at right angles to this cleavage as *bords*. The bords are driven 4 yd. or 5 yd. wide, and the walls 2 yd. to 5 yd. wide, while pillars 40 yd., 50 yd., 60 yd., and more square are left, or sometimes the bord side is made longer than the wall side. The roof is allowed to fall in these vacated spaces. Some 30 to 35 per cent. of the coal is taken in the *whole* working. Small pillars are undesirable, because they themselves may get crushed if roof and floor are hard; whereas, if the floor be soft, such pillars press in the floor and cause it to work up in the bords and workings, producing what is called *creep*, which dislocates all arrangements. Fig. 90 is a diagram of one form of this method of working. The diagonal lines indicate the worked-out portion and pillars partially robbed, as the case may be.

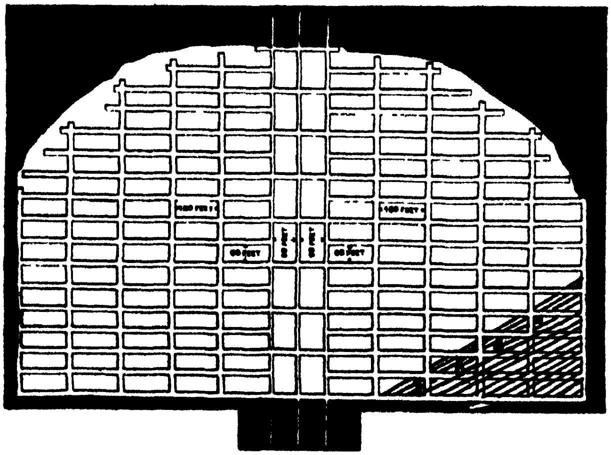
Working in the Broken. *Working in the broken or robbing the pillars* is the operation of the removal of the coal left as pillars by the working in the whole, and this is



88. LONGWALL ADVANCING

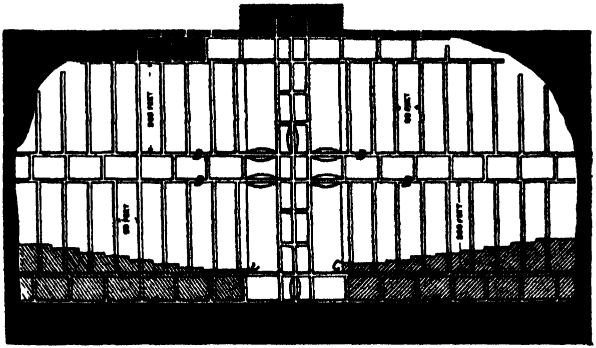
done in a systematic manner by various methods. In one of these, places, called *skirtings*, are driven from the tramway roads parallel with the wall, and the lines are laid along these, then another place is driven in each pillar parallel to and alongside the bord. This drivage is known as a *jenkin*, and is carried the full length of the pillar; then the coal is worked away in slices called *lifts* or *juds*, the tram rails being brought up the jenkin and to the face. To support the roof while the work is going on, props are used, or even props laid horizontally across one another to make a square pile, known as *chocks*. Several pillars are attacked at the same time, each pillar lagging a jud behind the preceding one, so that the work proceeds in step fashion. In this way the pressure of the roof is more equally distributed and the crushing of pillars is largely prevented.

Another mode of *robbing the pillars* is to drive simultaneously equal lifts from the bord and the wall until they meet, and then to take successive parallel lifts until the whole pillar is removed. This is shown in the figure; the numerals indicate the order of taking the lifts.



90. PILLAR AND STALL

Modified Methods. There are many modifications of pillar-and-stall. The Lancashire method is one well suited to inclined seams; the two main roads from the shaft are driven down on the dip or *to the deep*, and levels 30 yd. apart are driven from them to the boundary, each pair of levels being kept about 200 yd. apart, leaving the coal solid between them. On reaching the boundary two sets of levels are connected by a road, and the coal between is divided up into pillars by a series of drivages intersecting at right angles. The pillars are not all formed at once, but are gradually formed while the pillars already formed are being worked away, the step mode of procedure being again followed.



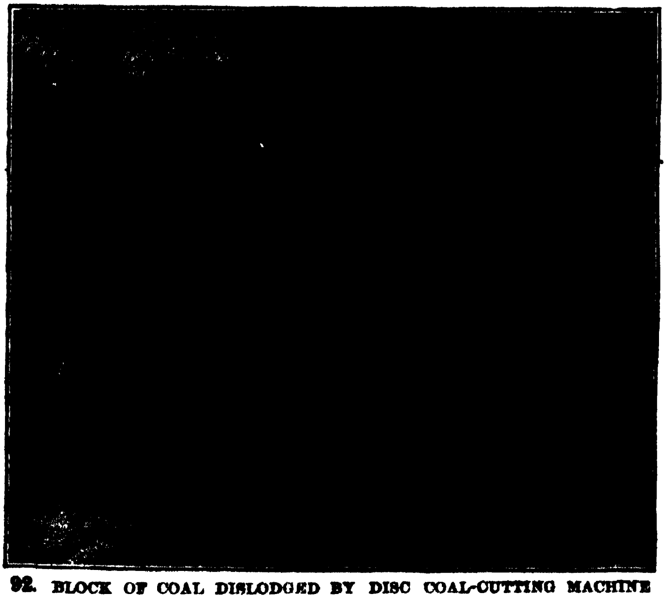
89. LONGWALL RETREATING

It will be noticed that this method resembles very closely the longwall retreating, and partakes of the characters of both longwall and pillar and stall.

District or Panel Working. This is a method of dividing a colliery into panels or *districts*, each of some 30 or 40 acres extent, and surrounded on all sides by a wall or *barrier* of untouched coal, which is holed through only at the points where the roads pass. Panel working is particularly advantageous with a tender roof and soft floor, for as only a small area of the seam is opened at a time, the roof does not weight so badly nor require so much timber. More round coal is produced; creep is prevented or restricted to the panel in which it arises, while the risk of explosion is decreased, because the gases given off in the district are not carried into the next, but pass direct to the return air-way, and should an explosion occur, it will most likely be confined to a limited area. Therefore, fewer men will be injured or directly affected by it, and more men saved. Moreover, as each district receives its own supply of fresh air, the atmospheric conditions throughout are far better for the men, and as the distance travelled by each current is shorter, even the last working-place of a district is more healthful than when panel working is not in vogue. In fact, if anything happen in one district, instead of inconveniencing the whole mine, as it might do under ordinary circumstances, usually only the district concerned is deranged.

91. DISC COAL-CUTTING MACHINE

Machinery at the Coal Face. Heading machines have for some time been used for driving the various roads in collieries. They generally operate by cutting a groove all round the face of stone or coal, leaving a block loose to be broken down and taken away by machinery or otherwise. A characteristic machine for this work is the Stanley heading machine. In it the cutters for making the groove are attached to the ends of two long arms, which are bolted at the other ends to a heavy casting; this is mounted on a shaft that can be revolved by engines, the whole being carried on a frame upon wheels. The arms revolve, and are kept to their work by a screw feed, and so cut the groove; they can cut about a yard an hour.



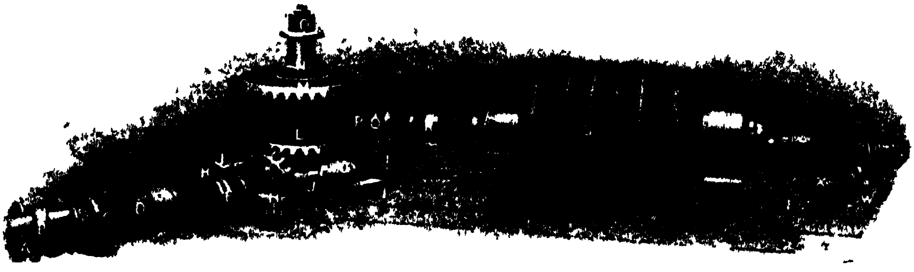
92. BLOCK OF COAL DISLODGED BY DISC COAL-CUTTING MACHINE

Holing or Undercutting by Machinery. We have seen that whether the holing is done at the bottom of the coal face or in the middle it looks an equally unpleasant occupation. Moreover, it will also be seen by reference to 87, that a very large amount of coal has to be cut away in order to give the hewer room to work. Now all this coal is broken up into small pieces and mostly lost. These are two obvious reasons for the use of *coal cutting machines*, but the advantages are numerous, and may be stated as follows: greater safety for the miner, reduced wages per ton, greater output per man underground, better quality of output, sometimes fewer explosives per ton, more regular timbering, easier control of roof, easier ventilation of straight faces, and more compact districts, shorter working-faces, more rapid advance of face, more even subsidence of overlying strata, less dead work and maintenance of roads, enforcement of systematic methods, lower cost of inspection, etc. When holing under coal, more headroom is provided for filling, seams too thin for hand mining are workable at a profit, reduced charges per ton for housing and for insurance are achieved, and seasonal demands or periods of brisk trade can be more readily responded to.

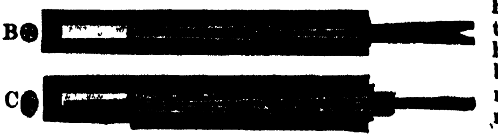
The features to be desired in a coal-cutting machine are: strength of structure and working parts, durability, convenience of operation, *protection of working parts, sufficiency of bearing surfaces, freedom of access to working parts, amount of small coal produced, adaptability to different conditions, simplicity of cutter picks and convenience of changing them, the amount of dust and noise made in working, interchangeability of parts, and amount of power required to operate.* And almost every machine invented claims advantages in these and other desirable respects.

93. SINGLE CUTTER

The object to be achieved is, of course, to cut a horizontal groove of adequate depth, from 2 ft. 9 in. to 7 ft. according to circumstances, in or beneath the coal. This is done by means of cutters which are brought into contact with the coal or rock and are made to travel with sufficient speed to abraid the coal and so to cut the groove. For this purpose the cutters are set in various fashions in different machines, for instance, round the rim of a wheel, making a sort of circular saw; in the links of a chain, making a sort of band saw; or spirally on a bar. Then two machines of the rock-drill class are also used for holing. There are a few mechanical points that are common to all types. For instance, they comprise engines usually worked by compressed air or electricity, with gearing to set the cutters in motion. They are mounted on skids, or rollers, or flanged wheels running on rails, and most of them are provided with an adjustable hauling arrangement by which they can pull themselves along the front of the coal face at any rate required.



94. WORKING PARTS OF ELECTRICALLY-DRIVEN BAR COAL-CUTTER



95. MULTIPLE WEDGE

The illustrations [91 and 92] will convey a very good notion of the working of a *disc coal-cutting machine*. The former figure shows the cutter just entering the coal face, and the latter shows the fallen block of coal which has come away very clearly. The arrangement for moving the machine along the face consists of a light steel rope passing from a drum on the machine round a pulley attached to a prop, set in advance, and thence back to the machine, so that, as the rope is wound on the machine by means of gear turning the drum, the machine itself is pulled along

In chain coal cutters, a travelling chain carrying cutters replaces the disc, otherwise the cut made is similar. With bar cutters, however, the action is different, and 94 shows the working parts of an electrically driven bar coal cutter. Fig. 93 a single cutter.

The Pick-Quick Electric Coal Cutter [94] consists essentially of five parts: the *cutter-bar* (AB), the *gear head* (LMNO), the *motor* (S), the *switch box* (T), and *hauling gear* (WX).

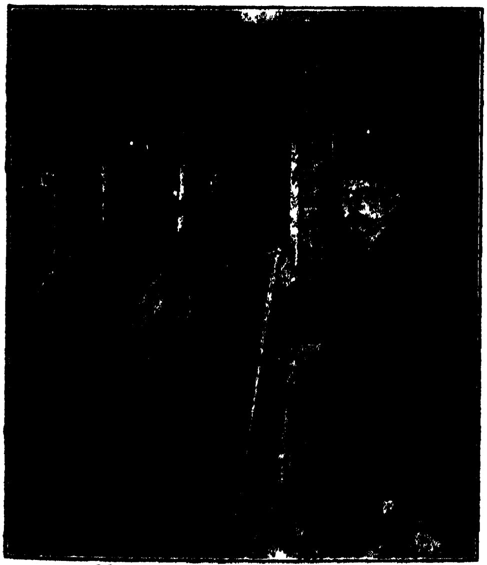
The *cutter bar* is of nickel steel and tapered, and is provided with cutters [A] arranged spirally and a spiral thread [B] to act as a worm conveyor for bringing out the cutting. The *gear head* encloses the main gearing, which consists of a pinion on the mortar shaft which drives a double bevel wheel, which, in turn, drives the cutter bar pinion, with a reduction of 2 to 1. The *motor* may be either direct current or alternating current, and the *switches* and resistance are enclosed in a flame-tight cast-iron box. The *haulage gear* is also worked from the motor, and the rate is adjustable. The machine can be adjusted to hole at any height from floor level upwards, and can be mounted on track wheels, flat tread wheels, or skids, and can be *flitted* or work its way back. There are, also, compressed air bar cutters.

Dislodging Mineral without Explosives. At times, explosives are inadmissible or inexpedient; hence, various other means have been introduced to get the stubborn holed mineral in which boreholes have been made. Cartridges made of lime have been used. Several of them are placed in the hole, and are then treated with water; they expand, and so force down the coal; but these only act in certain classes of coal. By far the most frequent substitutes for explosives, however, are wedges of different kinds—wedges with feathers, wedges with roller bearings and feathers, hydraulic wedges and multiple wedges are examples. In the case of the multiple wedge [95] the feathers are first placed in position, the split-wedge is driven between them as shown (*B*), and if necessary a third wedge is driven between the halves of the split-wedge; C shows this and the effect on the surrounding coal.

97. ELECTRIC LOCOMOTIVE WITH LOAD

Conveyers at the Coal Face. With the advent of the cutter, occasion has arisen to expedite the removal of the fallen stuff from the face to the main roads, and recently conveyers have been introduced for the purpose. They are erected on movable supports along the whole length of the face; the coal is easily loaded on to them, and is at once run away to be deposited into tubs waiting at the end of the conveyer, thus obviating the toilsome functions of the putter or the man who manipulates the tubs at the face. The conveyer is easily kept up to the face.

Improved Timbering. In various figures it has been shown, or it has been mentioned, that timber props, timber bars, and timber chocks or cogs are very generally used to support the roof in coal mines much in the same way as in metal mines. But it will be seen that the traffic is considerably greater in coal mines than in metal mines, and the main roads are generally correspondingly larger; moreover, many roads in coal mines have to be maintained in ground filled only with rubbish. Now, any disturbance of a main road means dislocation of the whole area concerned, which is very serious nowadays, when work must be done expeditiously to be remunerative; moreover, one of the most fertile sources of accidents injurious to the men is the falling of the roof. Hence it has become customary in many collieries to replace timber supports by steel ones. We have already referred to such substitution in the case of metal mining, and now show an application of this improvement to coal mining. Various practices have been introduced; the one now illustrated is that followed by Messrs. William Firth, Ltd., of Leeds. Fig. 96 shows steel props set at a coal face with wooden caps. These props are made from ordinary steel girders of section by cutting a piece out of the web at each end and turning over the top and bottom flanges until they meet and make a flat top and bottom that will not cut into the roof or floor or lid. Steel girders are frequently used in a coal mine road; they are not only stronger than timber bars, but they bend under great pressure, and so give warning of the settlement of the roof. Then when bent they can be used again with the convexity upwards or else be straightened and used again.



96. STEEL PROPS AT COAL-FACE

Special Timbering. A word may be said here, which would also apply to vein mining, in reference to driving through loose ground, by what is known as *spilling* or *spiling*, and which consists in supporting the weak parts, roof, sides, or floor by driving poles or boards over the last set of timber, 5 ft. or 6 ft. in advance, and supporting them by a temporary set of timber until they are far enough advanced to permit of fixing a permanent set, the ground being excavated the while to facilitate the passage of the boards. We shall now turn our attention to the means employed for getting the broken material from the place where it is deposited to the place where it is required.

Transport Underground. We have seen that in metal mines the usual practice is to run the broken material in single tram waggonloads by hand to the shaft, and the same practice is in vogue for conveying tubs of coal from the face to the nearest main road. But on these latter roads the tubs travel in trains, and either horse or mechanical haulage is employed. This is also done in many metal mines when the galleries are very long or when the waggons are run in trains. The use of ponies was formerly the general method; and such practice is still much followed. When, however, power is available, locomotives driven by compressed air or electricity may be found hauling trains of tubs in many mines the world over. Fig. 97 shows this mode of transport. But in most collieries traction of a less intermittent character is preferred; that is, an arrangement that can be always available to take in the tubs just as quickly as they are brought along from the face.

Self-acting Incline. A favourite method, when the material has to be brought from a higher to a lower level—one, too, that is equally applicable above ground—is the self-acting incline. In this practice the load tubs in their forward progress are caused to haul up the empty ones on their way to the working face to be refilled. And this is effected by having a wheel or drum fixed at the top of the incline round which a rope passes. To one end of this rope the full tub, or train of tubs, is attached, and to the other end the empties. The wheel is provided with a brake, so as to control the speed, and the incline is best made steep at the top and flat at the bottom, to enable the load to start quickly and to be easily stopped. Fig. 98 is a view of the self-acting incline above ground.

98. SELF ACTING INCLINE FOR BRINGING ORE DOWN TO A STATION

Single-rope Haulage. When, however, the material has to be drawn up an incline, what is known as *single-rope haulage* may be employed. A drum and engine are provided at the head of the incline; the former is furnished with a good brake, and can be thrown out of gear with the engine. This takes place when a train of empty tubs is lowered, for they are run down on the brake, and take the rope with them. When they reach the bottom, the rope is changed from the empty to the full train, the drum thrown into gear, the engines started, and the full tubs are hauled to the upper level when required.

Main-and-tail Rope Haulage. When, however, the levels of the road are irregular, or the incline is not steep enough for the empty tubs to run in-bye and draw the rope with them, then what is known as *main-and-tail rope haulage* is often adopted. There are two ropes. The heavier, or *main rope*, is the full length of the *engine plane* or road, and, passing from the engine, is attached to the front of the full train, and hauls it to the pit bottom; it is then transferred to the rear of the empty train, and follows it in-bye. The lighter, or *tail rope*, is twice the length of the engine plane, and passes round a pulley at the in-bye end. It is attached to the front of the empty train on the in-bye journey, and to the rear of the full train on the out-bye trip. The haulage engine in this case has a drum for each rope, either of which can be thrown in or out of gear as required, and each is provided with its own brake.

Endless Rope Haulage. In this system an endless rope extends from one end of the road to the other, passing round a return wheel at the in-bye end. The rope is kept travelling slowly by an engine placed at the surface or underground; in the former case the ropes are taken down the shaft. The tubs are hung to the rope either singly or in sets, and the rope may travel above or below them. There are many ways of attaching the tubs to the rope. A common and simple means in *over-haulage* is known as the *S-clip*. It is a clamp of round iron, bent to a double V, and pivoted at the centre of the tub. It grips the rope a short distance away along a line which is not over the centre of the track; hence, there is a slight side pull, and sufficient grip to move the tub along without doing the rope much harm. Lashing chains may also be used in this case, but in *under-haulage* a clip must be used to grip the rope, and Fisher's clip is an example of such an appliance. It consists of a hook, which is hung to the draw-bar of the tub, and hinged jaws, with a recess, to hold the rope; a sliding collar serves to lock the jaws, and the tub is released by knocking up this collar. Endless rope haulage requires in addition, driving pulleys, tightening pulleys, or other means of taking up slack; guiding pulleys and rollers; frequently, too, automatic detachers are introduced for releasing the tubs at the end of the journey. In some few cases an endless chain is used for haulage.

CLERKSHIP

25

Continued from page 3420

By J. F. G. PRICE

THE student has already been introduced to the subject of tabular bookkeeping, although it has not hitherto been referred to by that name. Specimens of books kept on the tabular system were given in the petty cash book on page 403, the three-column cash book on page 779, and the columnar purchases book shown in the previous article. The leading principle which those books were designed to illustrate is that items of a similar nature are capable of classification in the books of first entry, and that such classification has the effect of shortening the work of making the final entries in the ledgers of the concern. The principle is capable of considerable expansion in many directions in various businesses and institutions.

Tabular Cash Book. Dealing with the cash book first, it may be pointed out that this is the most important book in such institutions as charities and hospitals where, if a suitable form of cash book is prepared and the book carefully kept, there is frequently no need for any further financial record, as it is a simple matter to prepare a summary of the cash book at any time, showing the position of the institution As no trading is carried on, no profit and loss account is necessary, the principal account required by, and submitted to, the board of management being an account of receipts and payments, with a statement of outstanding liabilities to date The latter can easily be prepared from the file of unpaid accounts, and if that is kept up to date the combined cash summary and liabilities statement should be all that is required

The reason that the tabular system is so suitable for these institutions is that all their receipts and payments fall under a few well-defined heads. For instance, the receipts of a hospital consist of subscriptions, donations, patients' payments, legacies, and income from investments and properties. Many of them also receive grant from King Edward's Hospital Fund and from the Hospital Sunday and Saturday Funds. The receipts side of the cash book might therefore be ruled with columns providing for each of these classes of income, further columns being added for items of miscellaneous receipts and for the total. The payments will consist of the salaries and wages of the medical, nursing, and clerical staff, rent. rates and taxes, tradesmen's accounts, drugs and appliances, repairs, and miscellaneous expenses Columns would be provided for each head of expenditure and for the total.

Advantage of Classification. In the case of the large London hospitals, such a book as this would, of course, not be sufficient to record all the financial transactions; but even in their cases, such a cash book is of the utmost value in curtailing the clerical work, inasmuch as it classifies the items, and enables the postings to the general ledger to be made in total monthly. The accounts to which the receipts are posted are not, of course, the personal accounts of the donors, subscribers, etc., but nominal accounts for subscriptions, donations, or as the case may be.

In trading concerns, besides the three usual columns for discount, cash, and bank, it is very useful to have on the debit side a column for recording all receipts in respect of cash sales; and on the credit side, a similar column for cash purchases, as the necessity for posting such items in detail to the purchases and sales accounts is thereby obviated, all that is required being that the totals of the columns should be posted at the end of each week or other suitable period. Further, in dealing with the system of self-balancing ledgers, we saw that unless separate cash books were kept for each ledger, columns were necessary on each side of the cash book to record receipts and payments relating to accounts in the respective ledgers. The student, therefore, perhaps unconsciously, has gradually been becoming acquainted with the tabular system in relation to the cash book. A form of tabular purchases and sales book was shown and explained in detail in the previous article, and need not consequently be further dealt with now.

Tabular Ledgers. This brings us to the subject of tabular ledgers, the method of using which may not at once be apparent to the reader. Probably the greatest use of such a ledger in trading concerns is made in hotels where, in large establishments, there would be thousands of personal accounts in the course of a year. The charges to visitors consist of items of the same kind day after day, and it would manifestly be impracticable to have ledger accounts for the visitors on the usual lines, debiting them daily, and crediting the various accounts of the articles supplied, such as apartments, provisions, wines, etc. The staff required to keep books on such principles in a large hotel would be almost equal to that required to run the concern, and would not even then be such as to satisfy the requirements of the proprietor. To meet this difficulty, a form of book has been devised known as *the Visitors' Ledger*, which saves a considerable amount of labour, and yet gives all the information required for the general accounts of the business. An abridged form of such a ledger is shown on the next page. The entries in it are made either direct from slips supplied by waiters and other servants of the hotel, showing the charges to be made against each visitor, or from a day book in which the slips have first been recorded.

MONDAY, 1ST JULY, 1905

7	W. Scarlett	7 6	2 0		1 0				3 0			3 6		3 0	1 0	6		1 1 6		1 1 6				1 1 6	7
8	B. Gold ..	8 0	1 0					2 0										11 0	3 1 0	3 12 0			3 12 0		8
	Total ..	3 3 0	14 0	6	6 0	6 0	1 6	12 0	13 6	15 0	1 6	7 6	8 0	18 0	2 6	1 0	4 6	8 14 6	9 15 0	18 9 6	6 7 0	1 0	3 12 0	8 9 6	

The entries in this ledger require little further explanation than they furnish in themselves. A page of the book, or more, if necessary, is set apart for each day. The charges against each visitor are entered in the manner already mentioned, and cross-cast into the daily total column. Any amount brought forward from the previous day is added, and the total entered in the grand total column. If the visitor pays his account, the amount is entered in the column provided for the purpose, and the account thereby closed. If he does not pay, the amount is entered in the carried forward column, and will appear on the page for the following day in the brought forward column. Any overcharge or other allowance to which the visitor may be entitled, is entered in the appropriate column, and should any visitor leave without paying his account, or if, for any reason, any amount is left unpaid after a visitor has given up his room, the balance due from him is carried into an ordinary ledger, where an account is opened in his name, on which he is debited with the amount he owes.

Connection with General Books. The totals of the first sixteen money columns are entered daily in a summary ruled with corresponding columns, and at the end of a month a journal entry is made debiting *Visitors' Account* in the general ledger with the grand total, and crediting the various nominal accounts with their respective totals for the month. The visitors' account would then be credited with the cash received, and allowances made, and the balance of the account would represent the sum then due from visitors, and should correspond with the amount carried forward in the visitors' ledger on the last day of the month.

Before the totals are entered in the summary daily, care must, of course, be taken that the cross-cast agrees with the sum of the daily total column; and any discrepancy be rectified before the transfer is made. The daily total, plus the amount brought forward, must agree with the grand totals column, which, in turn, must equal the sum of the last four columns in the ledger. The "amounts paid" column should be carefully checked with the "visitors' cash" column on the debit side of the general cash book.

Visitors' Accounts. The accounts rendered to visitors are prepared on the same principle as the ledger, the only difference being that the form is ruled to cover a week. Columns are provided for each day, and for the total, while the different items of charge are shown one under the other instead of as headings of columns. The great advantage of rendering bills on this system is that they can be compiled day by day, and will be ready at any time a visitor calls for his account upon leaving.

The tabular ledger we have been considering owes its form largely to the necessity of carefully analysing the debits to the visitors, in order to ascertain the revenue under the different heads over which the income of an hotel business is spread. But there is another class of undertaking in which tabular ledgers are not less valuable, where the income is derived from practically only one source, but where there are many debtors with whom transactions take place only at regular intervals and then at some distance of time. Examples of such undertakings are gas, water, and electric light companies. This form of ledger is suitable also for the rate-collecting department of municipal authorities, and for the rent-collecting department of a large estate. The form reproduced on this page is ruled in a manner specially suitable for a gas company, but it will be apparent to the reader that it is capable of being adapted to the requirements of any of the businesses mentioned, and, indeed, to many others.

NEW STREET

	Name and No. in Street	Gas Consumed Quarter to Lady Day	Rate per 1000 Feet	Amount.	Meter No.	Meter Rent.	Stove No.	Stove Rent.	Arrears.	Total Amount Due	Paid. C. F.	Paid. Amount.	Bad Debts.	Arrears Forward.	Like Particulars for Midsummer Quarter	Do. for Michaelmas	Do. for Christmas.
1	W Smith	15,600	2 6	1 19 0	657	2 0			2 1 0	4 2 0	68	4 2 0					

This form practically speaks for itself, and very few words are necessary to elucidate it. The amounts due for gas consumed are obtained from the books of the men employed as meter readers, who make a quarterly inspection of the meters for the purpose of obtaining the particulars. The meter and other rents follow a fixed scale. Any charges other than those of a standing character, are not dealt with in this ledger, but are treated separately, and applications for amounts due for fittings, connections, etc., will be dealt with by another department.

Bad Debts Ledger. Any debts regarded as bad, although entered in the column for that purpose, are not thereby abandoned or neglected. The accounts are closed so far as this particular ledger is concerned, but they are transferred to a *Bad Debts Ledger*, which is also kept in a tabular form, and gives brief particulars of the nature, amount, and age of the debt. It is convenient in many businesses to keep such a ledger, for while a trader does not wish to encumber his ordinary ledger with accounts which may be regarded as dead—although there are balances due on them—he does not wish to lose sight of them. They are, therefore, transferred to a book which is largely in the nature of a register, in which only one line is devoted to each. They are thus in a form capable of easy supervision, and although not regarded as assets from the accounts point of view, they may, with careful watching and nursing, result in something being ultimately recovered.

The law of bankruptcy, as it exists to-day under the Bankruptcy Acts of 1883 and 1890, works, and is intended, as much for the protection of the debtor as of the creditor. The term bankrupt is generally applied rather loosely to any person in a state of commercial insolvency; but, strictly, it should be used only in reference to a person who has been adjudicated bankrupt by the Court. This statement necessitates an explanation of the steps which must be taken before the stage of adjudication can be arrived at.

The first step in bankruptcy proceedings is the presenting of a petition to the Court by a creditor or creditors for at least £50, asking that an order, known as a *Receiving Order* be made against a debtor. Every petition must be based upon what is known as an act of bankruptcy. There are several of these, and they consist of acts indicating either insolvency or an intention on the part of the debtor to defeat or delay his creditors by more or less fraudulent means. The act of bankruptcy upon which the majority of petitions are presented is known as failure to comply with the terms of a bankruptcy notice. This is a notice served upon a debtor by a creditor who has obtained judgment, requiring payment or security to the satisfaction of the creditor within seven days. If the terms of the notice are not complied with the debtor has committed an act of bankruptcy upon which a petition can be founded. Bankruptcy business is dealt with by a particular division of the High Court, and also by certain of the County Courts, and upon presentation of a petition a day is appointed to hear it. If the court is satisfied that it is equitable that a receiving order should be made it directs accordingly.

The immediate effect of a receiving order is that possession of the debtor's property is taken by an officer of the Board of Trade, known as the *Official Receiver*, and it becomes the duty of the debtor to lodge within seven days a statement of his affairs.

Statement of Affairs. The statement must be in a form prescribed by the Board of Trade in accordance with the Bankruptcy Acts, and it is in connection with this statement that we are now principally concerned. Several schedules are provided in which have to be entered (1) the different classes of creditors in three groups, (*a*) those holding no security, (*b*) those holding security to the full amount of their claims, (*c*) those holding security for less than their claims; (2) liabilities of the debtor on bills which he has received from customers and others and subsequently discounted, and upon which he is, therefore, contingently liable as endorser; (3) other contingent liabilities; (4) claims of the landlord for rent, which he can recover by distress; (5) claims for rates, taxes, wages, etc., by creditors who are given a special priority over others against the general assets not specifically charged to secured creditors.

A form is also provided in which the debtor has to set out fully the whole of his property apart from book debts, for which a special sheet is provided. A separate form is also supplied for any bills of exchange which he has on hand available as assets. When these forms have been completed they are summarised on a sheet in the following form, this sheet being known as the *Front Sheet:*

that some creditors, being given by law a special priority or preference, are entitled to payment in full before the ordinary creditors receive anything. The amount of their claim is, therefore, deducted from the total of the assets and the balance is the amount available for the ordinary creditors.

From the nature of the necessity of the preparation of the statement of affairs it is unlikely that the assets will exceed the liabilities, and there is, therefore, generally a deficiency of assets to meet the claims of the creditors. Even when a surplus is shown on a statement it is nearly always illusory and arrived at by the extravagant valuation of assets.

Deficiency Account. When a deficiency is shown it has to be explained in a further sheet, known as the *Deficiency Account.* It is required that this shall cover at least a year before the receiving order and begin, where possible, at a time when the debtor has a surplus of assets over liabilities. The object of the deficiency account is to show how that surplus has disappeared, and how the deficiency shown on the front sheet has arisen. The account, therefore, is largely in the nature of a profit and loss account and is made up in the form as shown on next page.

The complete statement of affairs has to be verified on oath by the debtor and lodged with the Official Receiver, who calls a meeting of the creditors to decide the course to be taken in dealing with the estate. They may decide to wind it up in bankruptcy, and apply to the Court to adjudge the debtor a bankrupt. If they take this course a trustee may be

STATEMENT OF AFFAIRS OF G. BLACK ON 30TH JUNE, 1906

	Deducted contra	58		Deduct Creditors for rent, rates, etc	58
					475
				Deficiency explained in Statement K	527
1,583			£1 002		£1,002

Front Sheet. It will be observed that this statement resembles in some degree an ordinary balance-sheet, in that it is intended to show the assets and liabilities of the debtor. A balance-sheet of a going concern is, however, prepared upon the assumption that there is no immediate necessity for the realisation of the property, which can therefore be stated at its value to the proprietor from the view of utility. The property of the debtor, on the other hand, is valued upon the basis of early realisation; it may be as a going concern, but is probably at break-up prices. It will further be noticed appointed at the meeting who will, after certain formalities, take over the assets from the Official Receiver and proceed to realise them for the benefit of the creditors. When they are fully realised, he distributes the proceeds amongst the creditors pro rata, after first paying his own remuneration and the costs and expenses of the bankruptcy proceedings. The distribution of a bankrupt's assets amongst his creditors is called a dividend.

Public Examination and Discharge. After the meeting of creditors, the debtor has to attend for his public examination, which consists of an appearance in open court, when he is questioned by the Official Receiver, the trustee, and any creditors who may so desire as to his past dealings with his property. After the public examination has been concluded the debtor may apply for his discharge from his bankruptcy. This application is heard in open court, and notice of the hearing is sent to all the creditors. At the hearing the Official Receiver reports the result of his investigations into the debtor's conduct and affairs, and the trustee and creditors may then be heard against the application by the Official Receiver after the debtor's public examination has been concluded. The Official Receiver reports upon the scheme or proposal, and if the Court is satisfied it is for the benefit of the creditors, the arrangement is sanctioned, and the debtor thereby relieved from the various disabilities of bankruptcy.

Reference has been made to creditors who have proved their debts. This relates to the manner in which creditors are required to lodge their claims in bankruptcy proceedings. When the Official Receiver issues notices for the meeting of creditors he sends out also what is known as a form of *proof of debt*. This is a skeleton form of affidavit which has to be completed and sworn by the creditor. It states that the debtor was, at the date of the receiving order, and then is, indebted to the person on whose behalf the proof is lodged in the sum named therein, and for the consideration stated. Any security held by the creditor has to be fully stated in the proof and valued. In order that the valuation made by the creditor shall be a fair one, the Official Receiver or trustee has the right in certain circumstances to call upon the creditor to deliver the security to him upon being paid the amount of the valuation. When no trustee is appointed at the meeting, the Official Receiver acts in that capacity.

DEFICIENCY ACCOUNT

Excess of Assets over Liabilities on 1st July, 1905	1,000	Net loss on trading from 1st July, 1905 as per books of business ..	221
Deficiency as per Statement of affairs	527	Bad debts as per schedule . ..	273
		Expenses incurred since 1st July, 1905, other than trade expenses, viz., household expenses of self and wife	300
		Other Losses and Expenses	
		Copper mine shares . ..	40
		Loss on bills discounted ..	100
		Losses by Stock Exchange speculations	533
	£1,527		£1,527

If the Official Receiver reports that the debtor has been guilty of certain offences the Court will either refuse the discharge or suspend it for not less than two years. The principal offences which will entail this consequence are inability to pay 10s. in the £, trading with knowledge of insolvency, speculation, failure to keep proper business books, fraud, and previous bankruptcy. If the discharge is granted the debtor is relieved from all liability for debts incurred prior to the receiving order but for one or two unimportant exceptions. A bankrupt who has not obtained his discharge is not allowed to contract a debt of £20 without disclosing the fact that he is an undischarged bankrupt. If he should do so he renders himself liable to imprisonment.

Compositions. To go back a short distance, it should be mentioned that the debtor sometimes brings forward at the meeting of creditors a scheme of arrangement or a proposition to pay a composition of not less than 7s. 6d. in the £ in consideration of being discharged from his liabilities. If the proposal is approved by a majority in number representing three-fourths in value of the creditors who have proved their debts, it is brought before the Court

Trustee's Accounts and Release. Accounts have to be kept by the trustee, showing the realisation of the estate, and the manner in which the proceeds are dealt with. The accounts are audited twice a year by the Board of Trade. When the trustee has realised all the assets and distributed the sum available, he applies to the Board of Trade for his release as trustee. He must give notice to the creditors of his intention to do so, and send to each of them a summary of his receipts and payments, showing, on the one hand, the amount the assets have realised as compared with the estimate placed upon them in the statement of affairs, and, on the other, the manner in which the amount received has been expended in payment of court and other fees, law costs, remuneration, and dividends to creditors. The Board of Trade audit the accounts to the close of the trusteeship, hear any objections by creditors to the granting of the release, and either grant it or refuse it until the trustee has complied with their requirements.

SHOPKEEPING
25

Continued from page 3449

CYCLOPÆDIA OF SHOPKEEPING

IRONMONGERS. Capital and Stock. Up-to-date Precautions in Buying. Stockkeeping. Profits. Working Departments

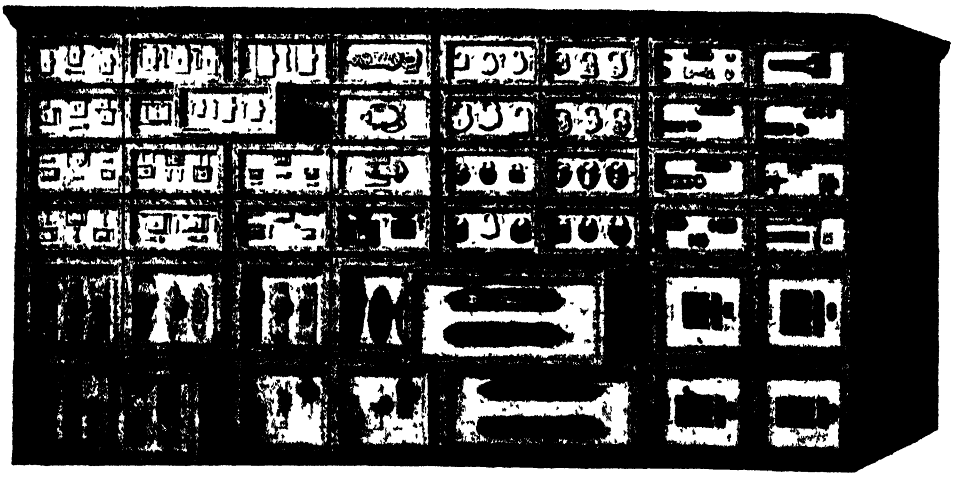
NO trade is more complex than that of an ironmonger. It embraces a dozen trades in itself, and no man has ever attained to a thorough knowledge of every branch of it. Many of the departments, which are sometimes separate trades, are considered independently in separate articles in this course. Our concern is with the young man who wishes to open shop as a general ironmonger. If he has had a practical training with an ironmonger, the branches which he will cultivate will vary from those he will exploit if he has capital, but little practical experience. Undoubtedly the easiest department to enter and understand is that of household ironmongery. Builders' and black ironmongery consist of merchandise which becomes familiar only after long acquaintance. Hence the competition of the draper and the stores is in household ironmongery. Neither class of opposition has entered seriously into the black and heavy departments.

Capital. The annual turnover of the ironmonger is seldom more than double the amount of capital sunk in stock. In a small concern, where hand-to-mouth buying is practised, the year's turnover may rise to three times the stock value, but such a case is exceptional. Hence, for a turnover of £1,000 per annum, the capital available should be not less than £500 if anything is to be allowed for shop fittings and a few pounds for cash in hand. The apportioning of capital upon stock must be decided by local conditions and the class of trade the ironmonger wishes to develop. The five-shilling handbook, "The Modern Ironmonger," published at 42, Cannon Street, London, E.C., suggests division as follows, and the allotments are as reasonable as any general advice can be:

	£
Fixtures, counters, etc.	60
Stock, general and furnishing, including hollow ware and enamel ware	250
Tools and cutlery	50
Brassfoundery	25
Black and builders' hardware	40
Sundries	40
	£465

The book mentioned is a valuable practical guide to anyone contemplating establishment as an ironmonger.

Stockkeeping. The interior of the old-time ironmonger's shop is conspicuously void of attractiveness. The science of stockkeeping does not find in the ironmongery trade the following which it does in other departments of retailing. To draw lessons from up-to-date stockkeeping for ironmongers we have to cross the Atlantic. Many of the "hardware stores" in the United States and Canada lead instead of lagging behind in efficiency and attractiveness of shopkeeping methods. So thoroughly is the need for proper system recognised that there are a few business houses there who devote themselves exclusively to the making and purveying of hardware shop fittings, and they seem to thrive. We select from American practice some up-to-date shopfittings, and it will be admitted that by system carefully calculated to suit the different departments of a hardware stock, an ironmonger's shop may be made to



1. UP-TO-DATE SYSTEM OF STOCKING SHELF HARDWARE

2. THE INTERIOR OF A MODEL IRONMONGER'S SHOP

look as attractive as that of any other tradesman. Fig 2 is an illustration of a modern American hardware store where properly designed fittings have enabled the paper parcels to be discarded, and nothing meets the eye but drawers, lockers and glass cases. Figs. 1 and 3 show in greater detail the system of fixtures adopted. The latter arranged for tools, is self-explanatory; the former, shows the drawer system of keeping builders' hardware and brass foundery, each drawer having in front a glazed compartment in which is placed a sample of the contents of the drawer. The value of such an arrangement for indicating the nature of the stock without deterioration is obvious.

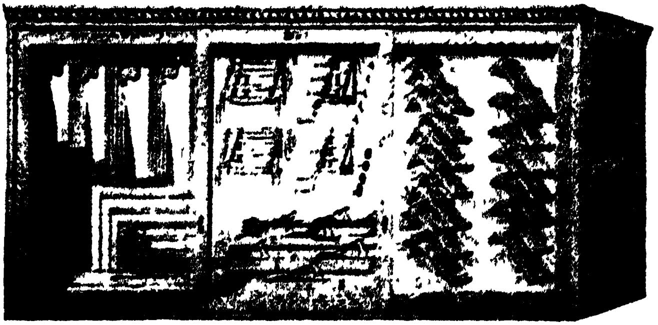
The next illustration [4] is of an American nail counter, each nail bin being mounted upon an axle which permits it to fulfil its function much better than the ordinary fixed bin. The show stand for scythes [5] is convenient in that it displays the articles well, and offers no risk of injury by exposed cutting edges. The shot case [6] is devised so that each turn of any handle below a glass disc admits into the drawer beneath exactly one pound of the shot, so that to extract 7 lb. of any desired size of shot it is necessary only to turn the proper handle seven times, after which the scooped-shaped drawer, the handle of which is visible, contains what is wanted.

Home-made Fittings. But apart from special fittings such as we have described, the ironmonger may improve his shelves by acting as carpenter. Hardware shelf boxes may be purchased, but they may easily be made by taking two stout pieces of wood of equal size to serve for back and front, and by fitting to these a piece of sheet iron bent to form sides and bottom. Fig 7 shows a fitting for keeping orderly stock of ropes in coils. The coils are beneath the floor, and a spring clip is fixed beneath each hole to prevent the rope running back. Fig. 8 represents a shelf fitted by an ironmonger's assistant with horizontal dividing shelves of wood and small vertical partitions of sheet iron cut to size. It would be difficult to improve upon such an arrangement for edge tools, such as bits, chisels, plane irons, etc.

The list of shop fittings given is intended to be suggestive, not exhaustive Almost every class of ironmongery may be better stocked by special cases or fittings purchased or home made, and the result of their use is better kept stock and prompter service

Shop Assistance. The ironmonger who begins business on the minimum capital possible will not need much shop assistance The help of an apprentice, message boy, or porter will suffice But it is to be hoped that trade will develop quickly, and bring the need for other help It is a common saying in the trade that one assistant or apprentice is required for every £1,000 of turnover This will be found to be approximately accurate

Ironmongers' assistants are badly paid, although probably not worse than the average

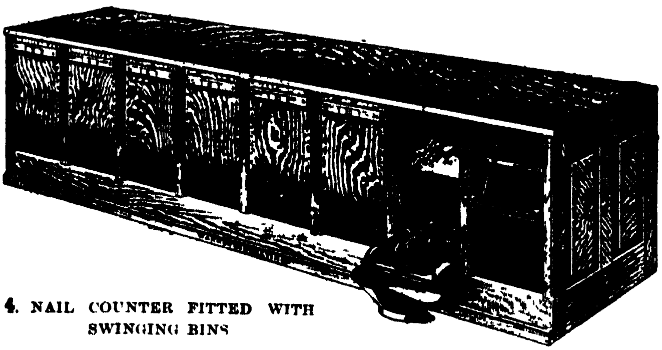


3. WALL CASE FITTED FOR TOOLS

shopkeeper's assistant. A few years ago the writer investigated this subject to some depth, and found that the average salary asked by over 100 assistants applying for a situation as chief assistant was about 30s. per week. In London, a good young assistant can be engaged for this sum, and in the provinces 25s. or even less will secure the services of a youth who has passed through a good apprenticeship training.

Quality of Assistants. There have been many complaints regarding the poor quality of the present-day ironmonger's assistant. There is reason in the complaint. Good men have ambitions, and in view of the fact that the capital necessary to open shop is large in comparison with other trades, ambitious men without capital are prone to enter other spheres, leaving the mediocre and poorer members to pass their days behind the ironmongery counter.

The Ironmongers' Federated Association has recently embarked upon a scheme of practical examinations for assistant ironmongers in the hope of raising the quality. The scheme has up to now achieved only moderate success. It has not been shown that the certificate of the Association carries with it an extra 5s. a week in remuneration, and assistants grudge the time and effort to qualify for the diploma. But, apart from direct and immediate pecuniary gain, the examination is an excellent thing, and a certificate stamps the man who has won it as having aspirations towards a knowledge of his trade far above the average.



4. NAIL COUNTER FITTED WITH SWINGING BINS

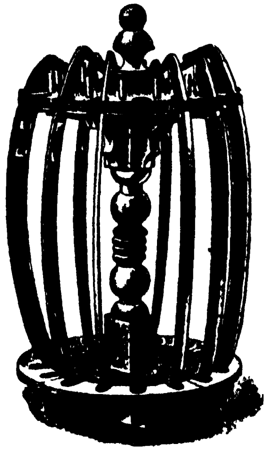
Buying. The success of a retail ironmonger is primarily a question of successful buying. It is a good rule to strive to build up a stock the individual articles in which are different as far as possible, from those stocked by competitors. For staple articles—nails, netting, hinges, and other things—this is impossible, but by seeking different patterns in household ironmongery, brassfoundery, and other classes where variation is possible, better prices are usually obtainable. It is usually difficult for the man who has been wont to buy in fair quantities for an employer in a large way of business to reduce the orders to the requirements and capital of his own modest start, and shipwreck has often been made from this circumstance. When accounts fall due for payment, a sovereign in hand is worth two locked up in shelf stock. Therefore the necessity to preserve a cash balance in hand, even if the stock suffer thereby, is imperative. Money is to be saved by taking advantage of cash discounts, and this cannot be done without the cash available as cash.

Factors versus Manufacturers. The factor—that is, the City wholesaler or commission merchant, who was always formerly the medium through whom hardware merchandise reached the retailer—is becoming a less important quantity in trade relation. The tendency is all towards the manufacturer getting into direct touch with the retailer. Indeed, the tendency is, in some directions, much further. It is sometimes that the maker gets into direct touch with the consumer. The policy of the retail ironmonger is, of course, all against direct trading between the maker and the consumer, and he will encourage firms who refrain from this undesirable but not infrequent practice. But he will, on the other hand, strive to purchase as much of his stock as possible from the makers and not from factors.

At first, especially if he begin business on small capital, this will be difficult, but as he feels strong enough to order individual "lines" in larger quantities he will pass the factor for the manufacturer. It will not be possible to dispense with the factor entirely. For imported goods, for instance, German, French, and American, the factor must be patronised. He may often be patronised unwittingly. A professing manufacturer may factor half the goods which he catalogues, as, indeed, nearly every Birmingham brassfounder does, although few retailers know it, but as a general policy the retailers will try to cultivate relations with the manufacturer in preference to the factor.

Catalogues. In a retail trade so diverse in its character as that of the general ironmonger it is impossible to hold in stock everything that may be asked for, and in no branch of shopkeeping is there greater need for a good system of keeping ready for reference a good range of illustrated catalogues. It is not enough that such catalogues should be in the office; they must be arranged and classified in such a manner that they may be placed before the customer at any required moment. Then there must be no need to spend time hunting for "that last quotation" to know what discount the catalogue prices bear. When a uniform discount prevails upon all the goods shown in a given book, it is an easy matter to have that discount indicated in cipher on the front of the catalogue or other readily accessible place. Where different discounts apply throughout a book, it means a little more work to record the details, but it is none the less essential.

Special Orders. Naturally, only price lists and catalogues which carry discounts sufficiently large to constitute a reasonable profit are shown to customers. In these days there are few maker's catalogues which do not fulfil this requirement. It is always well to exhibit to the purchaser catalogues carrying good long discounts. Assume that a special size of fishkettle has to be brought from Birmingham, the profit may vanish under the carriage charge if the trade discount be only 33⅓ per cent., but if a 50 per cent. catalogue be shown and list price be secured there is a good profit left after paying carriage. The customer is seldom willing to pay any special charge caused by filling an urgent requirement. He usually considers that this charge should come from the retailer's profit. Another reason for preferring the long discount catalogue when taking a catalogue order is that it gives the opportunity to allow something off The purchaser thinks he has a far better bargain at 15 per cent. from a 50 per cent. list than when he pays list price from a 33⅓ per cent. catalogue, although the former transaction yields the ironmonger a larger commission.

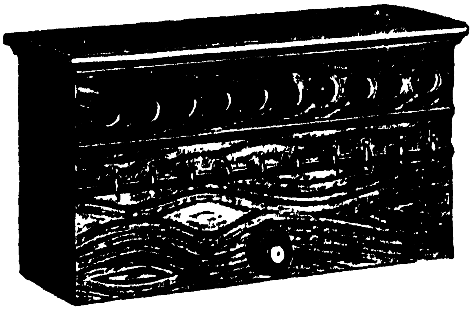


5 DISPLAY STAND FOR SCYTHES

Trade Discounts. In no trade is the system of trade discounts so complex. The ironmonger who understands all about trade discounts has a clear head. There are some articles which are subject to say, 80 per cent. discount, not many, perhaps, but enough to enable this to be taken as an example.

To the man with a non-mathematical head and no trade experience it would seem that to sell such goods at 75 per cent from list would be ruinous, whereas, in fact, the practice shows a 25 per cent. profit on cost. The instance may be given in illustration of the need for careful figuring in calculating prices by discount, especially if the discount be a long one.

Goods should be priced on a discount basis. This is the only way to preserve uniformity in selling prices, which is desirable. The customers should not, of course, be initiated into the mysteries of the discount system, as the knowledge furnishes them with a lever of comparison which may prove exceedingly inconvenient for the retailer.



6. A CONVENIENT SHOT CASE AND MEASURER

Price Maintenance. There has been much talk of price maintenance in ironmongery during the last few years. Although the attention which the subject has received at meetings of ironmongers' associations and in the trade may convey the impression that the movement towards the maintenance of minimum retail prices has acquired a strength and achieved a success greater than actual facts warrant, yet the practice is becoming fixed and is taking deeper root, thanks to the combination of ironmongers in trade associations. Fixed retail prices can be maintained by two methods, by the manufacturers insisting that purchasers of their goods must send the article purchased only upon certain conditions, and by a combination of all the retailers in a specific area under mutual agreement to maintain certain prices upon certain articles. The former method, that where the law is enforced by the manufacturer, is applicable only to proprietary articles—a specific carpet sweeper, a certain cartridge, a peculiar make of lawn mower, for instance—but is unsuitable for general classes of hardware made by many competing manufacturers. On the chief articles of sale, which have little or no distinction in pattern, although made by many makers, price maintenance is only feasible by harmony between the retailers in the district constituting the field of trading It is often difficult to secure this harmony. One recalcitrant member of the trade may prevent other 49 members desirous of uniformity in selling policy from practising that uniformity.

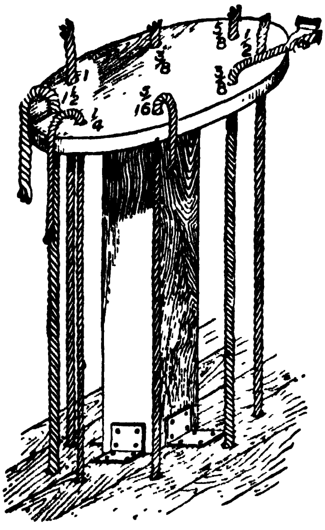
Manufacturers who adopt the price-maintenance scheme seldom insist upon the maintenance of full list prices; they usually stipulate only that there must be no cutting lower than a certain figure Thus, most manufacturers of lawn mowers, who allow 30 or 33⅓ per cent. trade discount from list prices, permit purchasers to sell at 15 per cent. from list Carpet-sweeper makers and a few other makers of proprietary articles of hardware follow similar systems.

Profits. The articles upon which retailers have arranged to maintain minimum prices are comparatively few, and the practice has a hold only upon isolated districts. Wire netting is the article which has received the greatest attention, and in some districts agreement has stopped the senseless habit of giving what is practically change for a sixpence and calling it carrying on the business of an ironmonger. A leading ironmonger recently proposed in the columns of "The Ironmonger" certain rates of profit which certain representative classes of hardware should carry. The rates are reasonable, and worthy of being put on record here:

	per cent.
Axles and springs	20
Agricultural implements	20
Bar iron, sheet iron, girders, steel	15
Baths (cast)	20
Bicycles	25
Belting	25
Corrugated sheets	15
Coffin-furniture	25
Cement	20
Dairy-machines (separators, churns, butter-workers)	20
Enamelled slate and wood mantelpieces	20
Fencing-wire	20
Files	25
Felt	25
Grates and ranges, registers, stoves, mantel-registers	20
Gas-stoves	20
Garden-seats and garden furniture generally	25
Garden-hose	25

	per cent.
Hollow-ware	35
Hurdles	15
Lawn-mowers	17½
Lead and glass	15
Mangling and wringing machines	25
Nails	20
Oil-engines	10
Oils (linseed, turpentine, machine oils, etc.)	25
Perambulators	35
Paints and varnishes	25
Rainwater goods	20
Ropes	25
Spades, forks, shovels, scythes	25
Sash-weights	20
Weighing-machines, platform - machines, coal-machines, etc.	20
Wire netting	20
Wrought-iron tubes	15
Brassfoundery, locks, hinges, screws, etc. (for builders)	20

These percentages are intended to be calculated upon selling prices, not upon cost prices, a point of some importance, as there is a material difference between the two. They must necessarily be considered as elastic in their application to different districts. Even given agreement between the hardware retailers in a certain area, any scheme of selling prices would have to consider the amount, strength and policy of competition from neighbouring commercial centres operating in the district. Much of the ironmonger's trade is of a semi-wholesale character—selling to builders, carpenters, and others, who expect to purchase under the usual retail prices, and the competition for whose custom is keen. It were useless for the local ironmongers to demand a 20 per cent. profit on nails if the travellers from an ironmonger in a town twenty miles off work their customers offering these goods upon a profit of 1½d. or 3d. a bag—pursuing the policy of setting a sprat to catch a whale.



7 ARRANGEMENT FOR STOCKING ROPES

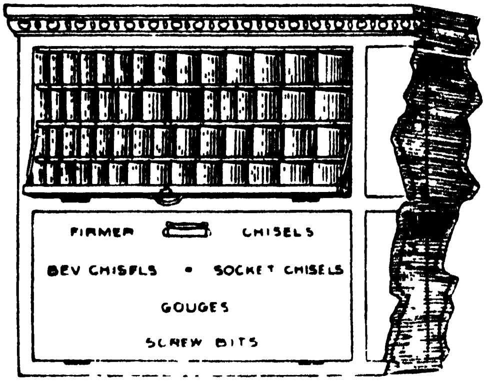
Tendering. Much of the business of many ironmongers comes in the form of orders secured only by competitive tender, and all who know anything of this class of trade know with what complaint it is carried on. Competition, which is the life of trade, is the slayer of profits, and competitive orders such as come in the way of the ironmonger are usually secured only by cutting down profits to the point of invisibility or beyond. Where association among all those tendering can be secured, agreement is possible, and reasonable profits attainable, but association to this end can seldom be attained. Under ordinary conditions, the ironmonger must recognise that he cannot secure an order in competition and a direct profit at the same time. Therefore, he must work for an indirect profit. Where the man, firm, company, or corporation placing orders by tender never give the opportunity of indirect profit, the better policy is to refuse to waste time in drawing up an estimate, leaving the business to those foolish enough to wish for it on its merits or demerits. There are always such competitors, and they may be left to stew in their own juice. But where a profit may honourably be worked in edgeways the trade may be worth having.

A Sprat to Catch a Whale. Let us take, for example, a workhouse, hospital, or municipal department, the year's contract for ironmongery in which is to be placed by competitive tender. It may be necessary to quote upon a profit basis of 10, 5, 2½ or even 0 per cent. to secure the order. If the extras which may be expected to accrue, and which are not covered by the schedule prices, promise to yield a reasonable, even if low, profit out of the whole contract, it is worth securing. There is always a little prestige attaching to a successful contractor under competition, and this is not quite a negligible quantity. Should the tradesman under such conditions charge fairly high prices for the extras, thereby getting "a little of his own back," he can scarcely be charged with either moral or commercial transgression.

A Case in Point. There are many cases where an apparent no-profit transaction is more directly remunerative. Let us suppose that a private individual is erecting a villa—an event which does not happen often in his lifetime. He is fastidious in his choice of grates, stoves, bell-fittings, chimneypieces and tile hearths. He probably goes the rounds of the local ironmongers inspecting stock and getting quotations. There is probably a certain make of kitchen range popular in the district, and one is certain to be included in the order. The ironmongers quote a low price for this stove, cutting the profit down to nearly nothing. The tradesman who makes a daring cut to a half-sovereign under cost price will secure the order. His fellows will wonder if he has developed into a philanthropic institution, and will predict his speedy appearance in Carey Street. But he may be the wisest man in the crowd. The purchaser is probably ignorant of the respective values of the other items in the bill he is mounting up.

Hearth tiles, which cost 7s. 6d. a yard, may be sold him for 20s. or 25s. a yard, if they please his fancy. A few chimney-pieces may be selected carrying something approaching 100 per cent. profit on cost, and the half-sovereign thrown away may return fifty times its value in net profit. The ability to profit by occasion such as this, to estimate its value, and to act accordingly, goes a long way to make the success of a modern retail ironmonger.

Stocktaking. Every business man should make a periodical inventory of his stock. Ironmongers are given to obey this rule less than other shopkeepers. There is some reason for their reluctance to take stock. It is no light undertaking. It is at the least a two or three weeks' job, and if things seem to be going well there is a great temptation to drive the old ship along without casting the log. But there is a double reason for taking stock. Not only does it indicate the value on the shelves, but it also gives a periodical opportunity to clear out old stock and sell it before its value has deteriorated further. The task of stocktaking may be simplified somewhat by following certain methods. For instance, wire netting may be weighed instead of being measured, and the measurement may be calculated from tables showing the relation of weight to length in the various widths, meshes and gauges. Oils may be treated in the same way. A system of stock taking of household and cabinet brassfoundery by weighing it is given in the "Ironmonger Diary" for 1903. It is approximately accurate, and while not good enough for an inventory for purposes of sale or purchase, is sufficient where the business is to remain in the same hands. By these and other devices the task of stocktaking may be materially lightened In any event, stock should be taken every year.



8. SHELVES PARTITIONED FOR EDGE TOOLS

Cheap Sales. The annual or semi-annual cheap sale has not yet become a general institution with ironmongers. A few firms have adopted this method of clearing off soiled or doubtful stock, and the fact that firms who have once gone in for this usually maintain it as a periodical event is the best recommendation for its value. One has only to attend an auction at which the stock of a very old-established ironmonger's is being realised, to be impressed with the mass of absolutely unsaleable stock which has accumulated. Much of it fetches the price of old metal, or a little more. The process of deterioration has been gradual. Had the goods been sold at cost price just when they began to go off, or at a little less a little later, their holders would have suffered far less loss. Not only would more hard cash have been got than was ultimately realised, but the room which things took up could have been devoted to more saleable goods. The ironmonger is, as a rule, far too loth to "cut his losses." Where a remnant might have been saved, he hangs on to the lot till all is gone. It is to be remembered in business that stock once deteriorated will never regain its original value, and no tradesman is more oblivious to this fact than the ironmonger.

Departments and Side-lines. There are many departments and side-lines to the ironmongery trade which are the subjects of special articles in this course, and which may therefore be passed with bare mention. They include agricultural implements, domestic engineering, bags and trunks, china and glass, cutlery and tools, cycles, guns and ammunition, fishing tackle, plumbing, baby-carriages, house furnishings, motor-cars, toys and games, and sewing machines. The suitability of a department or side-line depends upon premises, locality, competition, fashion, capital and taste, and upon these points every man must decide for himself.

Working Expenses. The working expenses of an iron monger's business are a very variable quantity. We noticed in the leading trade paper a few weeks ago that a prominent Liverpool ironmonger stated that it costs on an average 22½ per cent. to run an ironmonger's business, while a few weeks before another retailer not many miles away put the percentage as 10 per cent. The one was too low, and the other too high. It is evident that the framer of the former estimate had reached it by including in the sum interest on capital, or, at least, *managerial salary to principals.* This method of estimating is good and safe, and we believe that where high city rents have to be paid the ex penses *may sometimes be as high as* 22½ per cent. But in small businesses such as those we are considering it may be taken that 15 to 17½ per cent. of the turnover is swallowed in working expenses. Were the beginner to frame his prices upon the groundwork that expenses were 22½ per cent., he would probably starve for lack of trade. An old-established and a high-class business may flourish under a reputation for high prices if excellence and variety of stock be an accompanying feature, but the small beginner, whose stock, though good, cannot claim wide variety, would commit commercial suicide by attempting to build up a trade on high prices.

The Ironmonger's Workshop. Whatever may be said about the selling of iron mongery goods, it must be allowed that the trade is not prosecuted to its widest scope if the business does not include a working department.

Capital invested by an ironmonger in workshop equipment and material ought to yield much more profit than a similar sum spent upon stock. So much of the workshop turnover is labour, which involved practically no capital charge, being merely drawn upon as required, that it is much more remunerative than a ordinary merchant business. The materials also upon which workshop labour is expended—bar and sheet iron, tin plates, copper and brass, zinc and lead—are semi-raw materials, which cost much less in proportion to bulk than ordinary shelf hardware. Should there be two ironmongers near each other, one of whom has workshop facilities and the other has not, much merchant trade is caught in the net of the former on account of his ability to instal the ranges, heating and lighting apparatus, electric bells, pumps, and sanitary fittings which he sells, and from his ability to repair anything from a tin tea-bottle to a motor-car.

An Ideal Partnership. The ideal partnership for two young men beginning business together as ironmongers is found when one is skilled in buying and selling stock, and in window-keeping and office work, while the other is a practical man competent in one or more working compartments, and able, if he cannot himself do all classes of bench and fitting work, at least to supervise practically men who can, and to prevent the issue of badly-executed work and the waste which robs many an ironmonger of the profits which should accrue to him from his workshop department.

Should two young men such as we have indicated decide to run a double business of this nature, the most promising location for them is near a large and flourishing ironmongery concern without workshop facilities. Then, by pushing the working department for all it is worth, they may without difficulty alienate a good deal of the custom of the older establishment, as they have a powerful weapon of competition which the other has not at command.

Working Departments. Many considerations influence the nature of the work to be undertaken by the ironmonger. At the initiation of the enterprise the scope cannot usually be very wide. It is always well to have a main working department upon which others may grow with expanding trade as the need arises. Tinsmithing is a very frequent mainstay of an ironmonger's workshop. It has this merit—that slack times can always be employed in making for stock, and whatever may be the principal workshop output, it is always well to select something which can be made for stock. Such a practice has in it the germs of development into an important manufactory. Many large manufacturing concerns throughout the country have grown from small beginnings in an ironmonger's workshop.

Other possible workshop departments include domestic engineering, the repair of agricultural implements, agricultural engineering, smith work of various classes, sheet-metal work, electrical engineering, plumbing, foundry work, cycle and motor repairing. Many of these departments are considered in separate articles of this course, and it were idle repetition to enter into details of all of them here.

Text-book Aids. There are some text-books which the ironmonger will find useful guides in his workshop practice. The best practical handbook covering general work is "The Ironmonger's Workshop," the 5s. volume recently published by "The Ironmonger," of 42, Cannon Street, London, E.C.; and for the list of separate text-books devoted to specific branches the following may be recommended:

"Metal Plate Work," by C. T. Millis, M.I.M.E. (E. & F. N. Spon, Ltd.), 9s.; "The Sheet Metal Worker's Instructor," by Warn & Horner (Crosby Lockwood & Son, 7, Stationers' Hall Court, E.C.), 8s.; "Warming Buildings by Hot Water," by Frederick Dye (E. & F. N. Spon, Ltd.), 8s. 6d.; "Practical Electric Bell Fitting," by F. C. Allsop (E. & F. N. Spon, Ltd.), 3s. 6d.; "Telephones: their Construction and Fitting," by the same Author (E. & F. N. Spon, Ltd.), 3s. 6d.; "Wiring for Electric Light," by C. Metcalfe (Harper & Bros.), 5s. 6d.; "Lighting by Acetylene," by Frederick Dye (E. & F. N. Spon. Ltd.), 6s.; "External Plumber Work," by John W. Hart (Scott, Greenwood & Co.), 7s. 6d.; "Practical Sanitary Engineering," by Francis Wood (C. Griffin & Co., Ltd.), 8s. 6d.; "Construction and Working of Pumps," by G. C. R. Marks (J. Heywood), 3s. 6d.; "Hydraulic Rams," by J. W. Clarke (B. T. Batsford), 2s. 6d.; and "Modern Foundry Practice," by John Sharp (E. & F. N. Spon, Ltd.), 21s.

Workshop Economy. It is the intention, of course, that the workshop should be carried on at a profit. Though it may be made the most remunerative department in the whole business, it is the department in which money may most easily be lost. The lack of a good system of checking and pricing all work, and of seeing that every half-hour spent upon a job and every item of material are charged for in the final bill, often diminish the workshop profit considerably, sometimes even wiping it out altogether. Workmen need watching. So many bad and indifferent workmen are available that good workmen once engaged should be retained even at some inconvenience when business scarcely warrants retaining them. It is then that the value of making goods for stock comes to be appreciated.

Workshop accounts demand care. The filling in of the details of material on a job should be carefully verified, and only someone absolutely trustworthy and accurate should be trusted with this work. The omission to charge a half pound of solder on a job may seem a small matter, but if repeated half-a-dozen times a day for 300 days in the year means a loss of £40 a year. Careful checking by a system, even if it cost the wages of a man somewhat more expensive than an ordinary workman, is always a wise economy.

ELECTRICITY

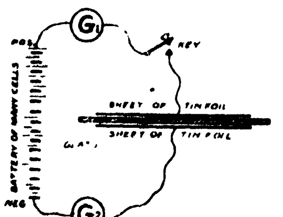
25

Continued from page 3423

By Professor SILVANUS P. THOMPSON

THROUGHOUT almost the whole of the preceding articles we have been dealing with electricity in movement, flowing as a current, since almost all of the useful effects due to electricity occur in consequence of its being in motion. We have now to consider certain particular effects or properties which belong to electricity *in the state of rest*.

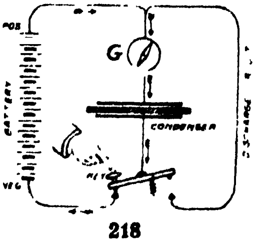
An Experiment. We shall first describe an experiment that is of some significance. Let us arrange a circuit as if we were trying to send a current through a sheet of glass, or of some other non-conducting substance. As the sheet does not conduct, no current will go through it—at least unless we employ so enormous an electromotive force (such as 100,000 volts or more) as to pierce a hole in the glass. It may seem absurd to try to send a current through a non-conductor; but the experiment is instructive. Procure a battery of a considerable number of small cells—50 Leclanché cells in series, or better still, 100. Have also a sensitive and quick-acting galvanometer, such as a Thomson mirror galvanometer, and a simple key, and let some sheets of tin-foil be also provided, and a large thin sheet of glass. This apparatus is then to be set up in the manner depicted diagrammatically in 217 Cut two sheets of tin-foil so that each is a little smaller than the sheet of glass, so that if laid down on the glass it would leave about ½ in. of margin all round. Lay one sheet of tin-foil down on a flat wooden table, place the sheet of glass over it, and the other sheet of tin-foil on the glass. Then join the battery to the two pieces of tin-foil with thin wires, connecting into the circuit the galvanometer G [217] and the key as shown in the diagram. The galvanometer may be placed at either of the positions shown. In fact, its particular position in the circuit is immaterial. All being ready, let contact be made by pressing down the key. It will be quite impossible to find any trace of current of a steady kind, for as a matter of fact, the glass sheet lies across the path and completely cuts off all current from flowing. And yet, if the experiment be very carefully made, and the galvanometer be sensitive enough, it will be found that when the key is first depressed there is a momentary disturbance of the galvanometer needle, indicating that on closing the circuit there is a transient rush of current; but it stops at once, leaving no permanent deflexion. In fact, what happens is this. The battery possesses an electromotive force by virtue of which it is always tending to drive a current through itself, though no current can flow until a circuit is provided. When the wires leading to the two sheets of tin-foil are made part of the (incomplete) circuit, on the pressing of the key there is a movement of electricity; for the battery is then able to move a small quantity of electricity along, drawing it out of one tin-foil (that connected to the negative pole) and driving it into the other tin-foil (that connected to the positive pole). It cannot produce a true circulation of current because the glass stops the way. In other words, the battery pushes a certain small quantity of electricity along the conducting path as far as it can go—that is, until it is stopped against the face of the glass plate, and at the same time it draws an equal quantity from the other side of the glass plate.



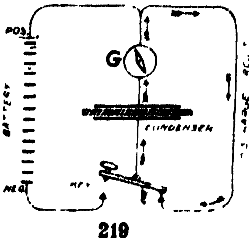
217

Charge and Discharge. The glass plate in the foregoing experiment is said to receive a *charge*. The word *charge* means a quantity of electricity at rest. The place where a charge is to be found is on the surface of a non-conductor. If electricity has been running *to* a surface of a non-conductor, and accumulates there, it is called a *positive charge*. If some electricity has been removed from a surface, so that there is a deficiency there, that surface is said to have acquired a *negative charge*. In the experiment above-described of charging a glass plate from a strong battery, the act of charging consists in producing a *positive charge* on one face and an equal *negative charge* on the other face.

A more convenient way to study the matter is to arrange the apparatus as shown in **218** and **219**, with a discharge circuit as well as a charge circuit, worked by a *Morse* key, the middle-point of which is connected to one of the tin-foils. The toe of the key, when pressed down by the spring below it, makes contact with the discharge



218



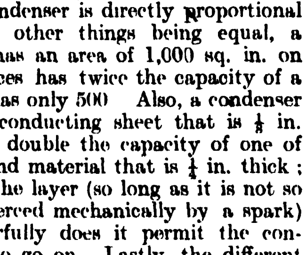
219

wire. When the handle of the key is depressed the discharge contact is broken, and instead the heel of the key makes a contact with the charging circuit, so that the battery can charge the sheet of glass. With this arrangement there will be observed in the galvanometer [G] a momentary movement of the needle, indicating a rush of current during *charge*, followed, when the key is released, by another movement of the needle in the opposite direction, indicating the rush of the current back, during discharge It will be found that these two rushes of current are equal.

Condensers. Any such arrangement of a layer of non-conducting material such as glass between two conducting coatings of metal is called a *condenser*, because it is thus able to condense electric charges upon its surfaces. If, in the experiment described, a sheet of glass has been taken that is small, only small quantities of electric charges can be condensed upon it, and the effects it produces will be small. Unless a battery of 40 or 50 cells be available, the galvanometer will scarcely detect any effect unless the sheet of glass has an available surface of 500 sq. in. or so.

The term *capacity* is used to indicate the electrical magnitude of a condenser. It is found by experiment that the capacity of a condenser depends upon three things: (1) its surface, (2) its thinness, and (3) its material. The capacity of a condenser is directly proportional to its surface; other things being equal, a condenser that has an area of 1,000 sq. in. on each of its surfaces has twice the capacity of a condenser that has only 500 Also, a condenser made of a non-conducting sheet that is ⅛ in. thick will have double the capacity of one of the same area and material that is ¼ in. thick; for the thinner the layer (so long as it is not so thin as to be pierced mechanically by a spark) the more powerfully does it permit the condensing action to go on. Lastly, the different kinds of non-conducting material have each their own specific quality; thus a mica plate has a greater capacity than a glass plate of equal size and thickness.

Large Capacity Condensers. In order to obtain condensers of large capacity it is necessary to use more than one sheet. For example, if we have 50 sheets of thin mica, each 6 in. long and 4 in. wide, we may arrange them to make one condenser having a large surface by piling them up on one another with tin-foil sheets between them in the following way. The tin-foil sheets are cut in the shape shown in **220**, each with a projecting lug, of such a size as to leave a margin all round except where the lug projects. One of these is laid down on a table with its lug towards the right, and a sheet of mica placed over it. On the mica is laid a second sheet, with its lug projecting towards the left; then another piece of mica; then a third tin-foil with its lug to the right; then another piece of mica, followed by a fourth tin-foil with its lug to the left; and so on with the whole series, alternate lugs projecting to right and to left. When completed, the pile is clamped together securely, and all the lugs of odd number are joined together to make one terminal, while all those of even number are clamped together to make the other terminal of the condenser.



220

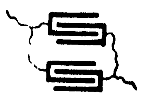
Dielectric Capacity of Materials. Faraday made a number of condensers of different materials, but all of the same size, to see whether they had equal capacities. One of these contained only air between the two metal surfaces, and as this was found to have a smaller capacity than the others air was taken as the unit for comparison of one dielectric with another. Faraday gave the name of *dielectric* to any material which will thus act as a condenser, meaning by the term that electricity can act inductively across the material, though no electricity passes through it. All dielectrics are non-conductors, but two different non-conductors that are equally effective as mere non-conductors may differ considerably in specific dielectric capacity. Air being then taken as the unit, the dielectric capacity of other materials run from wax, which is about 2, indiarubber and gutta-percha, which are about 2½, and glass, which varies from 2½ to 3½, up to 5 or 6 for mica. Glass is too brittle for most purposes, and air will not do, because it is too easily pierced by a spark, besides affording no mechanical support to the metal conductors. Mica has two advantages, in that it can be split very thin and yet remain strong, and that its specific dielectric power is high. But large sheets of it are expensive. If strong tissue paper, resembling banknote paper, be thoroughly dried and impregnated with pure melted paraffin wax it forms sheets that are excellent for condensers, and to which the necessary tinfoil coatings adhere readily. The condensers used in submarine cable service are usually made of paraffined paper.

Charge in Relation to Capacity. A charge being a quantity of electricity, the amount of it can be expressed in *coulombs*. The amount of charge that can be condensed in a condenser depends on two things—(1) on the capacity of the condenser; and (2) on the voltage used to drive the electricity into the condenser. Suppose we had a condenser of such a size that on applying an electromotive force of 1 *volt*, the quantity of charge that ran into the condenser at one side (as an equal quantity ran out of the other side) was one *coulomb*, then we should describe that condenser as having a capacity of one *farad*. But such a condenser would be impossibly large and expensive, and the practical standard of capacity is a condenser of only one-millionth part of the capacity named, and such a standard is described as having 1 *microfarad* of capacity. The quantity of electricity that runs in or out of a condenser can then be calculated by multiplying together the number that represents the capacity in *microfarads* and the number that represents the voltage of the battery, and then dividing the product by 1,000,000. Thus, if a battery of 120 *volts* be applied to a condenser having a capacity of 1·5 *microfarads*, the charge will be 120 × 1·5 ÷ 1,000,000 = 0·000180 coulombs.

Grouping of Condensers. Just as it is convenient in diagrams to use symbols for batteries and for galvanometers, so it is also useful to use a symbol for a condenser. This symbol [221] consists of lines drawn in such a way as to suggest the sheets of metal foil separated by a non-conducting space or layer.

221

Accordingly, two condensers *in parallel* with one another would be represented by **222**, in which the two + terminals of the two condensers are joined, and the two − terminals are also joined together, making virtually one large condenser. If, for example, one had a capacity of 3 *microfarads* and the other 2 *microfarads*, the two in parallel would have a capacity of 5 *microfarads*.

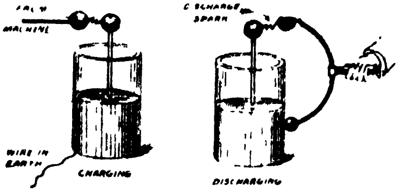


222

Fig. **223** represents two condensers joined *in series*, or, as it is sometimes called, *in cascade*. In this case the combination will act like a condenser of smaller capacity than either of them separately, for we have increased the total thickness in the amount of dielectric interposed across the circuit without adding to the area of either condenser. The equivalent capacity of the combination can be found by calculating the reciprocal of the sum of the reciprocals of the separate capacities. Thus, if the separate capacities of the two condensers are 2 and 3 *microfarads*, the joint capacity will be $1 \div (\frac{1}{2} + \frac{1}{3}) = 1 \div \frac{5}{6} = \frac{6}{5} = 1\frac{1}{5}$ *microfarads*.

223

The Leyden Jar. It is more than a hundred years since the property of condensers was discovered, and the form which the apparatus received was that of a glass bottle or jar, coated inside and outside with a conducting coating. The very first Leyden jar with which electric shocks were obtained was a glass phial partly filled with water, while the moist skin of the hand which held it formed the outer coating. Later, these jars were made up in the form shown in **224**, having inside each for convenience a metal rod, which passed down into the interior to touch the inner coating, and which was terminated at the top in a polished brass ball.



224

In old days these jars were charged by means of a *friction machine*, the sparks from which were sent into the brass knob, while the outer coating was connected to the earth. Such a jar cannot be charged if it stands on an insulating stand—for, as we have seen, in the act of charging as much electricity runs out of one coating as runs into the other. When a Leyden jar (or other condenser) has been charged, it can be discharged by connecting a conductor, such as a bent piece of wire, from the one coating to the other—that is, from the outer tin-foil to the knob. The instant that this is done the surplus from one surface rushes round to fill up the deficit at the other surface, there is a bright snapping spark, and the jar is discharged. If this discharge takes place through the human body a very unpleasant shock is the result.

Seat of the Charge. It was stated above that the seat of the electric charge is at the surface of the glass or other dielectric. The sheet-metal coatings are, in fact, mere conductors or electrodes that enable the electricity to flow to or from the surface whereon it is to rest as a charge. This is easily proved by taking a glass sheet and charging it by means of two loose sheets of tin-foil. If these are then carefully removed separately in such a way as not to make a circuit between them, it is found that they are not electrified. But if they are replaced, or if two other pieces of foil are placed upon the surfaces of the glass sheet, it will be found that the sheet will then give a spark when it is discharged.

Benjamin Franklin devised a dissectible Leyden jar, the metal covers of which could be taken off. With this he demonstrated that the charges reside on the glass, not on the metal coatings.

Energy of the Charge. It will, therefore, appear that the condenser does not really store any electricity, seeing that when being charged as much electricity runs away at the negative side as enters at the positive side. That which is stored in the condenser or Leyden jar is not electricity, but energy. Work has to be done in the process of charging, just as work has to be done upon a spring in the act of bending it. In the condenser as long as it remains charged, or in the spring as long as it remains bent, the work that has been done is stored up as potential energy, and afterwards that energy can be given out again. The condenser during discharge gives us back the electric energy that manifests itself by spark or shock. The bent spring during its recoil gives us back its energy as a visible motion. The energy given to the spring in bending it is equal to the product of the average bending force multiplied by the distance through which the spring has been bent at the place where the force is applied. This average force is equal to half the maximum force; hence, if *f* stands for the force and *d* for the displacement, the energy will be proportional to half *d f*. Similarly with the condenser: If Q represent the amount of electricity that has been displaced in or out during the charging, and V the electromotive force used in the charging, the energy of the charge will be represented by ½ Q V.

CENTRAL & SOUTHERN AFRICA

The Congo and Zambesi Basins. British Central Africa Protectorate. Portuguese East Africa. British South Africa. Cape to Cairo Railway. Islands

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

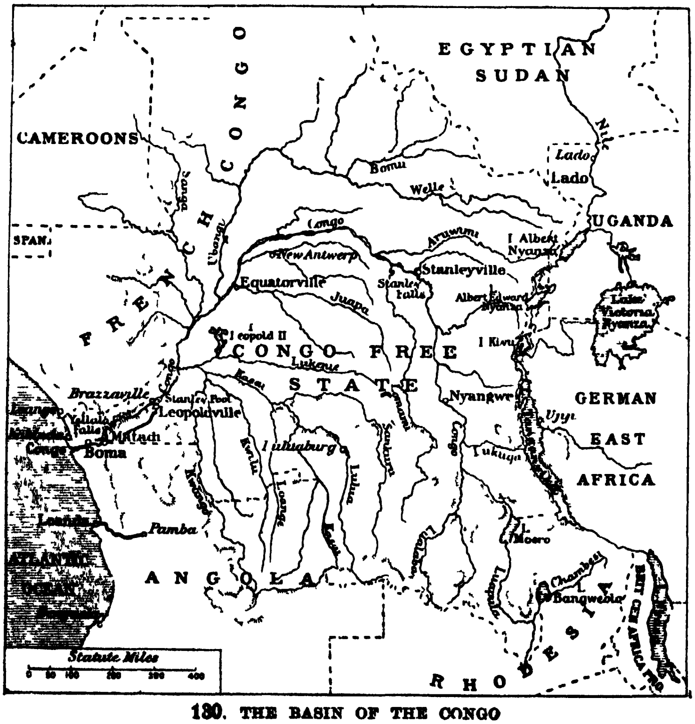
LAKE CHAD lies in a depression surrounded by higher ground, so that it has no outlet to the sea. It is a shallow, marshy lake, studded with many islands, and varies considerably in size in the wet and dry seasons.

The Cameroons and French Congo. Between the Niger and the Congo lie the German colony of the Cameroons and French Congo. The former rises from the steamy, swampy, mangrove-fringed, coastal plain to the grassy terraces of the plateau, reaching 12,500 ft. in the volcanic Cameroons Peak. The forests produce oil palms, rubber, kola nuts, ebony, etc. French Congo, which is broadly similar, extends north to the Sahara between Lake Chad and the frontiers of the Egyptian Sudan, and is continuous with the other African possessions of France.

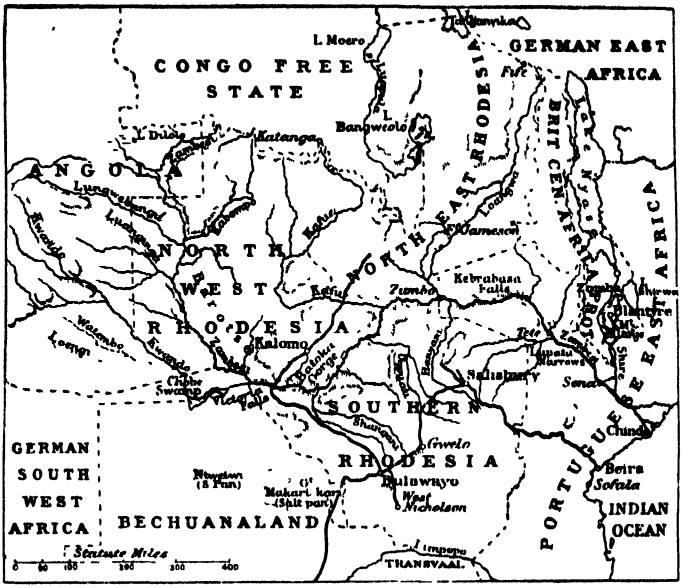
The River Congo. The basin of the Congo (3,000 miles) occupies most of equatorial Africa [130]. Flowing through one of the rainiest regions in the world, the volume of water carried down to the sea by the main stream and its innumerable tributaries is enormous.

The Congo rises as the Chambesi in the mountains south of Lake Tanganyika, and is already a great river when it enters the swamps of Lake Bangweolo, from which it issues as the Luapula, a river as wide as the Thames at London. It now begins to descend, falling 1.200 ft. before it reaches Lake Moero. Still descending rapidly after issuing from that lake it receives the great Lualaba from the south. Not far below the confluence the Lukuga enters on the right, bringing down at certain seasons the surplus waters of Lake Tanganyika, the long, narrow rift valley lake to the east, lying nearly 3,000 ft. above the sea, in a deep chasm shut in by forested mountains. At Nyangwe, less than half-way to the sea, the Congo, which has received innumerable tributaries from the mountains, forests and lakes of the surrounding region, is a mile broad and still descending rapidly. Almost on the equator it forms Stanley Falls, a series of seven cataracts with open water between, extending over a distance of 56 miles. The Aruwimi, which has risen quite near the Nile, comes in from the east, flowing through densely forested country. Between the Aruwimi and the Welle, which rises near it, the country is inhabited by agricultural tribes, who have many villages in the forest clearings, surrounded by plantations of maize, banana, millet, tobacco, etc. The main stream is now enormous in breadth and volume, often breaking up into parallel channels, which extend over several miles of country. In some maps this part of its course is shown as a long, narrow lake.

Forest Scenery of the Congo. Sir H. M. Stanley has vividly described the dense equatorial forest through which this network of rivers flows. "Some of the islands seem to be aflame with crimson colouring, while the purple of the ipomæa and the gold and white of the jasmine diffuse a sweet fragrance. These islands are not mere things of beauty; the tall palms are perpetual fountains of sweet juice which,



130. THE BASIN OF THE CONGO



131. THE BASIN OF THE ZAMBESI

when effervescing, afford delight to man. The golden nuts of other trees furnish rich yellow fat, good enough for the kitchen of an epicure. The lengths of calamus are useful for flooring and verandah mats, for sun screens on river voyages, for fish nets and traps, for field baskets, market hampers, and especially for the construction of neat, strong houses and fancy lattice work. That pale white blossom is the caoutchouc. For the enterprising trader there is a ficus, with fleshy green leaves. Its bark is good for cloth, and its soft, spongy fibre will be used in the future for paper. Look at the various palms crowding on each other. Their fibres, prepared by the dexterous natives, will make the stoutest hawsers, the strength of which no fibre can match. See that soft pale-green moss draping those tree tops; that is the orchilla, from which a valuable dye is extracted. I need not speak of the woods, for the tall, dark forest on bank and isles seems to have no end.”

The Lower Congo. Below Equatorville comes in the Welle, through similar forest country. The river gathers into a single narrower, deeper stream, and then widens out to the lake of Stanley Pool, shut in by white cliffs known as Dover Cliffs.

At the lower end of Stanley Pool, 1,100 ft. above the sea, the Congo begins its final rush down the last terraces of the plateau to the coastal plain. “It first precipitates itself with awful force down a five-mile slope, a succession of leaping waves, which from crest to crest might be about 300 ft. apart; then through a series of mad rapids, separated by short stretches of swift but steady flow, it is confined for 75 miles by the towering rock barriers of a cañon from 300 to 600 ft. below the level of the opposing summits of the cleft land; then for 88 miles it is tolerably safe for navigation; then comes another 60-mile rush, roaring cataracts alternating with noisy rapids, through the deep, rocky heart of the mountains, till finally the last plunge has been made down the Yellala Falls. A few miles below it leaves this sinuous and rocky gullet a navigable river for 110 miles, and flows by factories, villages, and towns to be presently vexed by the churning screws of ocean steamers.” The current is too strong for the formation of a delta, and the Congo enters the sea by a broad estuary.

The Congo Free State. Politically, most of this region belongs to the Congo Free State (officially entitled the Independent State of the Congo), under Belgian control. Rubber, ivory, palm oil, and other tropical produce are collected by natives and brought to Leopoldville on Stanley Pool, the centre of the trade with the interior. It is the terminus of a line 250 miles long, built from Matadi, below which the river is navigable, to avoid the rapids of the Lower Congo. From Matadi the produce of the Free State is forwarded to Boma, 60 miles from the sea, which is in regular steamer communication with European ports.

The Zambesi. The Zambesi (1,600 miles) is the shortest of the great African rivers [**131**]. It rises at a height of nearly 5,000 ft. in the Dilolo swamps, which at certain seasons also feed affluents of the Congo. In its relatively short, steep course to the sea the Zambesi receives many tributaries, which should be looked out on the map. As it cuts its way down the terraces of the plateau it is broken up into rapids, narrows, and cataracts, many of imposing beauty. Between these obstructions are navigable stretches, where the land is flat and the river flows between low, reedy banks, inundating the surrounding country in flood. Such is the Barotse region of the upper Zambesi, a grass land on which cattle are kept in vast numbers. The valleys both of the tributaries and of the main stream are skirted on both sides by rich forest, and the many islands are also richly wooded. The finest of the many grand cataracts of the Zambesi are the famous Victoria Falls, the grandest in the world. Above the Falls the river is a noble stream over a mile wide, flowing between walls of forest. It plunges abruptly over a rocky ledge into an abyss over 400 ft. deep, with an indescribable volume of spray and a thunder of sound. It then flows for 40 miles through the narrow, zigzag Batoka gorge. Just below the Falls the river is crossed by the railway line from the Cape.

There are navigable stretches of considerable length between the Victoria Falls and the last of the Zambesi cataracts, the Kebrabasa Falls. Between these and the Lupata Narrows are large deposits of coal, which will before long be of commercial importance. At the Lupata Narrows the river contracts to 1,000 ft., flowing in a gorge between high rocky walls richly diversified with vegetation.

North-West and North-East Rhodesia lie to the north of the Zambesi, the lower course of which is through Portuguese territory.

The Shiré Highlands. 150 miles from the sea the Zambesi receives on its left bank its most important though not its largest tributary. This is the Shiré, from Lake Nyasa, another of the deep rift lakes of Central Africa. The middle course of the Shiré, like that of all African rivers from the plateau, is broken by falls and rapids, which interrupt navigation for 60 miles. It forms an important route from the Indian Ocean to the British Central Africa Protectorate and the north-east of North-Eastern Rhodesia, British territory which extends to the shores of Lake Tanganyika.

British Central Africa Protectorate. The highest parts of the plateau, which rises in the south-east to Mount Mlanje, 9,600 ft., are grass lands. Elsewhere the vegetation is tropical in character. All the most valuable products of tropical Africa, including rubber and the oil palm, are found. The chief crops cultivated by British planters are coffee—a native of the region, though the cultivated plant was introduced from the Botanical Gardens of Edinburgh by Scottish planters—cotton, and even wheat. The country, though not very healthy, is developing. Steamers run on Lakes Nyasa and Tanganyika. The largest settlement is Blantyre. The administrative capital is Zomba.

Portuguese East Africa. The lower Zambesi, some two or three miles broad, crosses Portuguese East Africa, an unhealthy region, exporting rubber and other forest produce. The delta which begins 90 miles from the coast, is of the usual swampy character, subject to periodical floods, and held together by mangroves. The Chinde, with a port of the same name, is the only mouth practicable for large steamers. North of the delta is the territory of Mozambique, with a capital of the same name. South of the delta is the port of Beira, connected by rail with Salisbury and Bulawayo, on the Cape to Cairo line in process of construction. The busiest commercial town of Portuguese East Africa is Lorenço Marques, on Delagoa Bay.

Angola and German South - West Africa. South of the Congo the rainfall decreases rapidly, and the country gradually becomes an arid region, similar to that in the corresponding latitudes north of the Senegal.

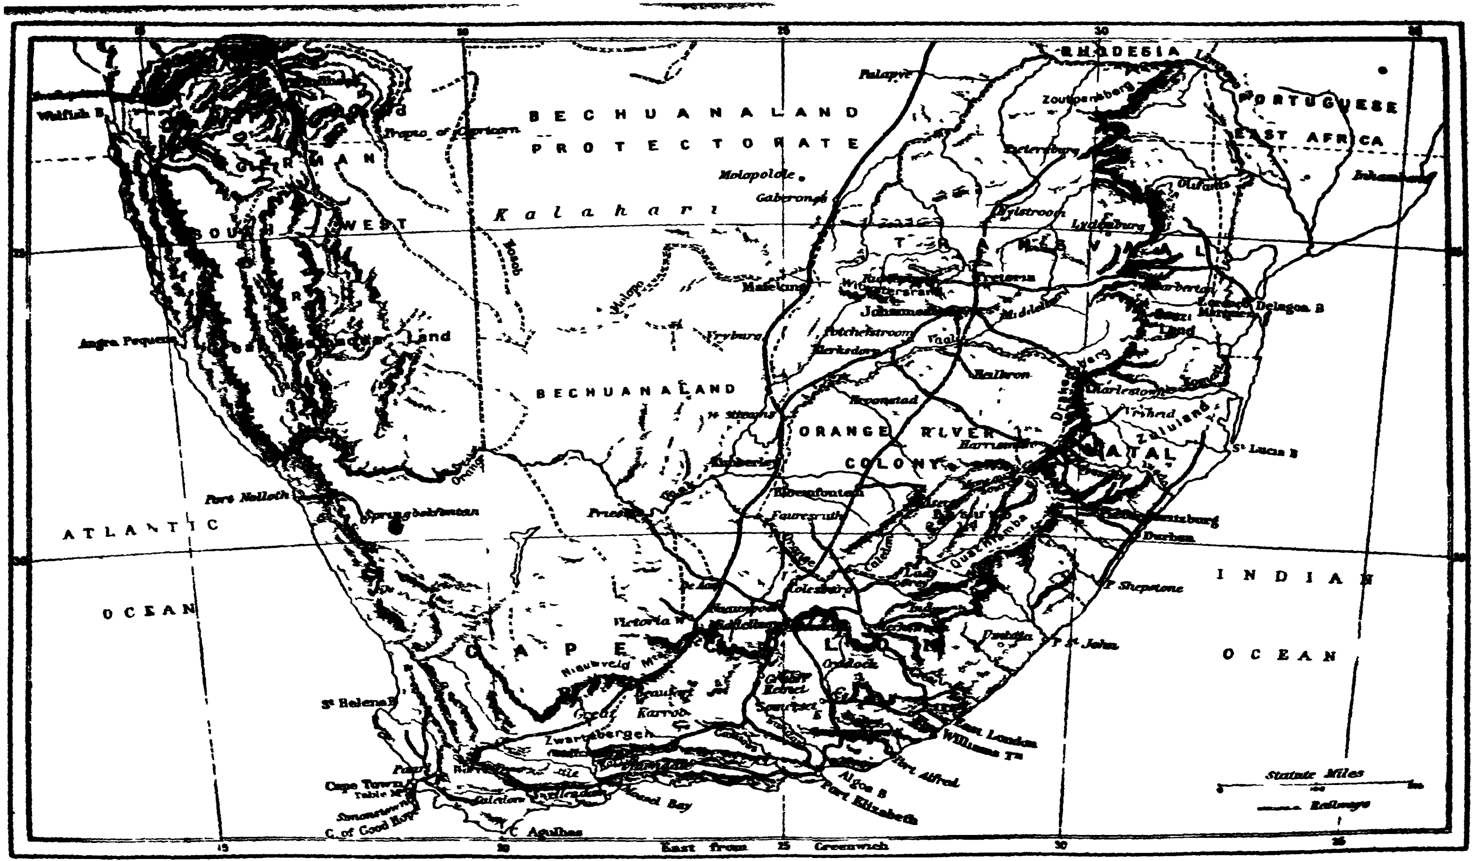
Angola, a Portuguese colony, rises from unhealthy coastal lowlands to the plateau, which is forested in the north, a savana in the centre, and arid in the south. Coffee is largely cultivated and exported from Ambriz, S. Paolo de Loanda, Benguela and Mossamedes.

German South-West Africa is an arid region of little economic value. The administrative centre is Windhoek, to which a line is built from Swakopmund near Walfish Bay.

British South Africa. The rest of Africa south of the Zambesi is British. It consists of Cape Colony in the south, Natal on the south-east coast, and inland the Orange River Colony, the Transvaal, the Bechuanaland Protectorate, Matabeleland, and Mashonaland.

South Africa consists of four well-marked regions—(1) A low coastal plain of varying width which is narrowest in the south-west, where the high rugged edge of the plateau comes down to the sea in Table Mountain, Cape Agulhas and other spurs. (2) Two series of ranges running parallel to the south coast, with the Little Karroo between them and the Great Karroo, beyond the inner ranges of the Zwartebergen. (3) Rising above the coastal plain and the Great Karroo the irregular margin of the plateau, which from below appears as continuous ranges of hills or mountains. The valleys which penetrate this margin grow narrower and steeper as the traveller ascends, and the spurs which enclose them become more mountainous in character. This high, irregular edge of the plateau is called the Drakenberg or Quathlamba Mountains in the south-east and east. Its finest scenery is in Basutoland, the Switzerland of South Africa, where Cape Colony, Natal, and the Orange River Colony meet. Here the land rises to 11,000 ft. in Mont aux Sources, from which flow the rivers Orange, Tugela, and a tributary of the Vaal. The precipitous edge of the plateau rises high above the undulating lowlands of Natal, and the rivers break their way down in cascades hundreds of feet high. (4) The immense interior tableland, flat or rolling, and diversified by isolated flat or pointed-topped hills or kopjes. It owes such beauty as it has to the sharpness and line of colour in the clear air, and to the wonderful atmospheric effects at dawn and sunset.

South African Rivers. South Africa lies in the lee of the trade winds in latitudes corresponding to those of the Sahara. Its climate is consequently very dry. Many rivers marked on the maps are dry except after rain, and fail to reach the sea. The longest river, the Orange-Vaal, from the Mont aux Sources, flows west to the Atlantic. The short Tugela from the same highlands, and the Limpopo, from the Witwatersrand of the Transvaal, flow east to the Indian Ocean. The Limpopo and Orange, though extremely shallow in the dry seasons, are never waterless, but their tributaries are often reduced to a string of pools. After rain they become impassable raging torrents for a few hours, to disappear almost as quickly. Add to this that all are obstructed by rapids in their descent from the plateau and flow in steep-sided valleys, and it will be seen that the rivers have contributed little to the opening up of the country.



132 BRITISH SOUTH AFRICA

NAWAB SALAR JUNG BAHADUR.

3585

Climate. If South Africa were as broad as North Africa it would be a desert like the latter. In the west, the Kalahari is actually a desert, though of less forbidding extent and character than the Sahara. Elsewhere the influence of the sea counteracts the aridity, and renders the rainfall over most of South Africa sufficient for stockkeeping; but the Karroos, shut in by mountain ranges, are very arid. In the south-west of Cape Colony the rain falls in winter, as in the Mediterranean, with which this part may be compared. Natal, like the east generally, has summer rains. The north-west is almost rainless. Everywhere the question of irrigation is important, especially for agriculture.

The proximity of the ocean reduces the summer heat of the marginal lands. Cape Town, in the latitude of Gibraltar, is cooler in summer and warmer in winter. On the tableland the range of temperature for the year and even for the day is great. The nights are cool for the greater part of the year. In the northern parts of the Transvaal, and in Rhodesia, the climate of the valleys is tropical, but the very high summer temperatures of the Sahara are never experienced.

Vegetation. The coastal plain is fairly well wooded, with small patches of primeval forest on the seaward slopes above. The higher part of the country is a vast area of grass land, passing into desert in the west, and into tropical forest in the valleys descending to the Limpopo and Zambezi. The few trees are thorny acacias or mimosas and eucalyptus trees introduced from Australia and found round most of the homesteads. After rain, the Karroos and veldt become beautifully green, but with prolonged drought the country takes on a brown and parched appearance. The vegetation of the Kalahari consists of thorny or succulent plants of the usual desert type.

The flowers of South Africa, and of the Cape Peninsula in particular, are extraordinarily beautiful. They include many heaths, and some of the loveliest ornaments of our conservatories.

The cultivated plants correspond with those of similar regions already described. In the areas of Cape Colony with winter rains, all Mediterranean plants are or might be grown. Maize, or "mealies," is the chief cereal everywhere in South Africa, but wheat is grown round the Cape and in the east of the Orange Colony. The production of wine is increasing. In Natal we find the products of monsoon lands. Tea is grown on the seaward slopes of the northern hills, and sugar, bananas, oranges, rice and tobacco are also cultivated. The Karroos and veldt are too dry for cultivation, except when irrigated, and are essentially a pastoral country.

Minerals. The mineral wealth of South Africa is enormous. The diamond mines of Kimberley, in Cape Colony, are the richest in the world. The deposits of gold in the Witwatersrand of the Transvaal are of incalculable value. Gold is also abundant in Rhodesia. The useful metals will become of more value as that of the gold and diamond mines decreases. Coal is found to some extent in all the colonies.

Occupations. At the present time the mining interest, helped by the introduction of indentured Chinese labour, is in the ascendant. It must, however, not be forgotten that mining tends ultimately to impoverish a country, not to enrich it. In its vast pasture lands South Africa has a more permanent source of wealth, and wool, hair and ostrich feathers may prove in the long run of more value than gold or diamonds. The veldt and Karroos are at present thinly settled, partly because the thinness of the covering of vegetation makes a great extent of pasture necessary. The future of agriculture is bound up with the question of irrigation. Manufactures hardly exist, and towns are few and small relatively to the vast area of the country. The chief disadvantages of South Africa are the dry climate, the absence of navigable rivers and timber, the scourge of locusts and the diseases of plants and animals, as well as the want of racial unity.

Peoples. Two kindred European races—the English and Dutch, both endowed with fine qualities, at present regard each other with suspicion. This is least marked in Cape Colony, where the mining interest is less prominent. Opposing economic interests, as everywhere else, count for more than community of race.

The native races of South Africa represent well-marked stages of economic development. The diminutive Bushmen depend chiefly on what Nature offers, and neither keep stock nor practise agriculture. The Hottentots are a pastoral people. The finest native race is the tall Kaffir, of Bantu stock, who possesses animals and practises agriculture. This race alone is likely to escape the destiny by which lower races disappear before the advance of the higher.

Cape Colony. This is our oldest South African Colony. It is chiefly pastoral, producing wool, hair, ostrich feathers, tobacco, and some wine and brandy. It has few good natural harbours, and no navigable rivers. Cape Town, the capital and chief port, is magnificently situated between mountains and the sea. Simonstown, in the vicinity, is a naval station. Port Elizabeth, on Algoa Bay, is built in a bare region, surrounded by low hills. East London is the port in this colony nearest the Transvaal, to which most of its imports go. Grahamstown is the chief inland centre in the east, and Kimberley, which owes its prosperity to the diamond mines, in the north.

Natal. Natal is more diversified in surface than Cape Colony, and has a hotter summer climate. The coastal regions are very fertile. There is a smaller proportion of waste land than in any other colony. Tea, coffee, bananas, and all manner of tropical produce are raised near the coast. Stockkeeping is the chief occupation up-country. Durban is the port, and Pietermaritzburg the capital. North of the Tugela, but included in Natal, is Zululand, containing some of the finest pasture land in South Africa and considerable stores of coal and gold.

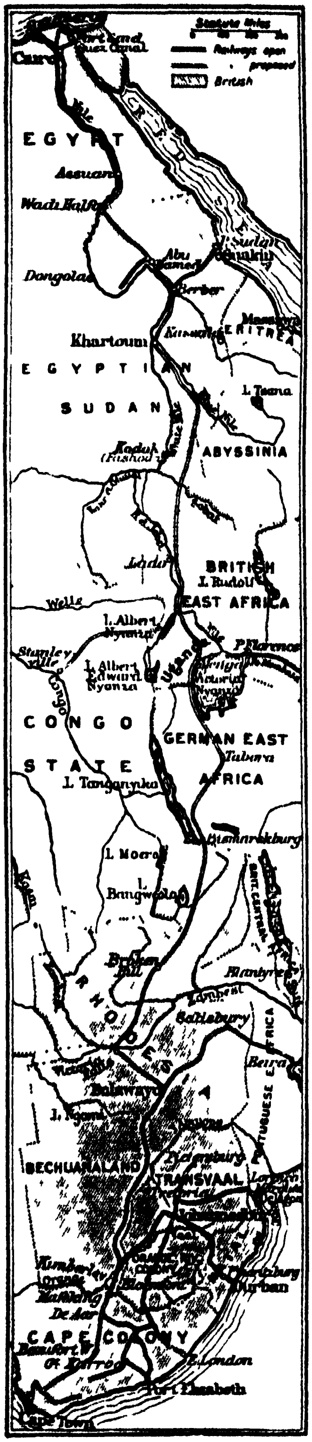
Orange River Colony. This is a grass land, engaged in cattle and sheep breeding, with agricultural land in the east, and diamond mines in the south-west. The only considerable town is Bloemfontein.

The Transvaal. The Transvaal is a grass land, with warm valleys opening to the Limpopo. These are well wooded, but unhealthy. Little land is yet under cultivation, though much is well suited to agriculture. Stockkeeping is the chief occupation on the thinly-peopled veldt, where the capital is Pretoria. The mining interest and dense population centres in Johannesburg, the largest and richest town, the middle of a belt of gold mines 50 miles long Coal is mined at several centres, and a rich diamond mine is exploited east of Pretoria.

Rhodesia. The greater part of Southern Rhodesia consists of undulating, grassy downs, or else low forest land, sinking to the dry Kalahari in the south-west, to the Limpopo in the south-east, and to the Zambesi in the north. Gold-bearing quartz reefs are numerous. Coal is mined at Wankie on the railway between Bulawayo and Victoria Falls.

The country is less dry than that to the south, as it lies in the belt of tropical summer rains. Below an altitude of 4,000 ft. fever is very prevalent. The development of the country is only beginning. The capital is Salisbury and the largest town is Bulawayo.

The Cape to Cairo Railway. In a country which has no navigable rivers, and where immense distances must be travelled through thinly-peopled and poorly-watered country, the construction of railways is essential to the development of the country A line has been built from Cape Town to the Zambesi, and will in due time connect with the railways of Egypt and British East Africa [183]. It climbs by the valley of the Hex River to the Great Karroo, which it crosses to Beaufort West. It then ascends to the High Veldt, and reaches De Aar Junction, whence branches run to Port Elizabeth, East London. and through Bloemfontein and Johannesburg to Pretoria and to Durban. From Pretoria a line runs to Lorenço Marques. From De Aar Junction the main line continues to Kimberley, to Fourteen Streams (where the direct line to Johannesburg now leaves it), to Mafeking, Bulawayo, and the Zambesi, and is now open to Broken Hill in North-West Rhodesia. From Bulawayo a branch goes by Salisbury to Beira, in Portuguese territory.



183. THE CAPE TO CAIRO RAILWAY

African Islands. The French island of Madagascar (230,000 sq. miles) is low in the west, and gradually rises to a plateau which is highest in the east and sinks in steep escarpments to the low eastern coastal plain, with its fringe of lagoons. The east has heavy summer rains, and is densely forested. The west is a much drier savana land. All forest products are important, especially rubber. Tropical produce of various kinds is cultivated on the plateau. The western savanas are inhabited by pastoral peoples. The mineral wealth is very great. Tamatave is the port, from which a railway is being built to Antananarivo, the capital, on the plateau.

Réunion (1,000 sq. miles) is also French. It is a beautiful volcanic island, richly wooded, and grows sugar, vanilla, coffee, and cacao on the plantations. The capital is St. Denis.

Mauritius (700 sq. miles), formerly the Isle de France, with its dependencies Rodriguez, the Admiralty Islands, the Seychelles, the Chagos Archipelago, and smaller islands, is a British possession. Mauritius is a volcanic island fringed with coral reefs. Port Louis, the capital, in the north-west, is the chief harbour, from which a railway runs across and almost round the island The sugar-cane is the most important crop, and coconut palms grow round the coasts Two-thirds of the inhabitants are coolies from India, but negroes, Chinese, as well as French and English settlers, live on the island.

Off the west coast are the Azores, Madeira and Cape Verde Islands belonging to Portugal, the Canary Islands, with the fine Peak of Teneriffe, belonging to Spain; and St. Helena and Ascension, belonging to Britain. All are volcanic. The Canaries and Madeira are famous for their fruits, wines, and vegetables.

UNDERCLOTHING

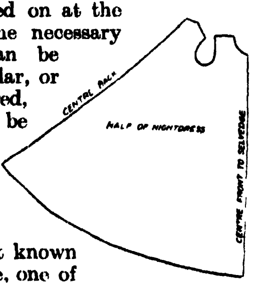
Cutting Out and Making Camisoles, Underskirts, Bed-room Wear, Negligées, and Dressing-Jackets

By AZÉLINE LEWIS

FIG. 41 illustrates a French nightdress pattern, cut all in one, which is particularly comfortable for flannel, as it fits somewhat closely at the back. This shape can easily be evolved from a bodice drafting.

The centre-front is placed to the selvedge, so that there is a seam at front and back. A piece will have to be joined on at the lower part to make the necessary width. The neck can be finished off with a collar, or in any way preferred, whilst the sleeve can be the same as the foregoing. This pattern also forms an admirable one for a simple dressing-gown.



41. NIGHTDRESS CUT IN ONE

Lastly, we have that known as the "djibeh" shape, one of the later novelties, the idea of which was taken from the Turkish djibeh, which has no fastening, the garment being slipped on over the head [42]. This style, however, always requires a quantity of embroidery on the front, the back always being plain. Fig. 43 gives an idea of the shape.

A to B is half entire chest measure; this pattern requires to be fairly roomy across the chest. A to C, half neck measure; A to D, one-third of same. The back neck is sloped down about 1 in.; C to E about 5 in., for shoulder; B to F, 8 in. Curve from E to F for front armhole. D to H, length of front; H to I, 28 in. for front lower edge. Slope and cut as shown, making back 2 in. less than front. The sides can be sloped out more if required.

42. DJIBEH

The shoulder can be placed to the fold or tucked to back. The edge, of course, must be embroidered and the neck drawn in by means of ribbon passed through buttonholed slots, as marked in the diagram.

The sleeves should be cut rather wider at the wrist than the usual shape, and they are finished off and drawn up in the same way as the neck part.

For the drafting of an Empire yoke the worker should refer to TAILORING, cutting this, however, a little shorter.

For a nightdress of average size, 5 yd. to 6 yd. of 36-in. material must be allowed.

Camisoles. The shape, style, and making of the camisole, or underbodice, are legion, but all with the exception of 46 are based on the bodice pattern, which may be utilised with one, two, or more side pieces and darts. The various portions are usually joined by a flat seam stitched at each edge, but in the more expensive and elaborate bodices the seams are united by veining or beading.

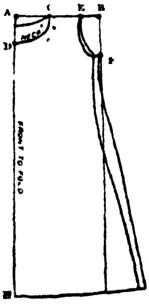
Fig. 44 depicts a bodice of fine cambric in which all the seams are whipped and united in the manner above-mentioned, which has a very charming effect, but which should not be attempted by indifferent workers, as it is so easy to get the pattern out of shape.

Fig. 45 gives an American shape, the charm of which is that it requires no fastenings. It can be cut from the bodice pattern, as shown by the broken line, the front being extended from the shoulder into a point at the waist, this point depending on the size of waist, as it only needs to extend beyond the under-arm seam. The making of this corset-cover is a very simple matter, and the trimming can be added according to taste.

Fig. 46 illustrates a drafting of a bodice cut all in one, in which the front seam comes on the cross. This, however, is a pattern better suited to slight than stout figures. It is made with or without an added basque, as preferred. For the drafting, take a piece of paper 1½ times the length of back, and wider than half of chest measurement, and fold it in half. Divide length into three parts, mark them respectively A, B, and C, and rule lines at right angles. C to D, quarter of waist measure; B to E, half chest measure. Rule a line from D through E to F. Fold paper at this line and mark G exactly under A. Open out again, draw a line from F to G, and mark A to H one-sixth of neck. Curve down ½ in. for back neck.

G to J, quarter of neck measure; draw line from H to J. B to I, half chest; draw line from G to I. G to K, quarter of neck; curve from J to K for front neck. Extend I to L for length of front; measure C to L, half of waist, and finish front. M is midway between C—L and D. Curve as shown by the broken line.

J to P, 4 in. to 5 in., as required for length of shoulder. H to O, the same. Lower the latter, raise the former ¼ in., and draw shoulder lines. M to N, length of underarm; curve from O and P to the point for armhole, as shown, hollowing out front a little more than back.



43. DJIBEH DRAFTING

For the basque, see Knickers

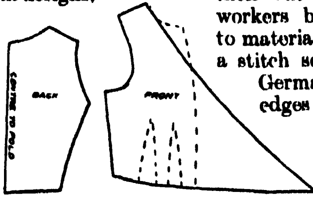
in Fig. 30, or cut to the same as the lower portion of bodice just drafted, making it a little larger. If tucks be required, extend fronts from K to L, the needed amount.

The sleeve can be any shape desired.

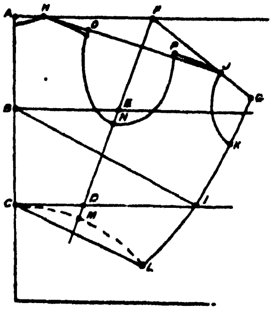
Many camisoles are made with full or tucked fronts, without darts, and for evening wear the shoulder straps are either of insertion and lace or ribbon, whilst very dainty corset-covers have been made from two hemstitched pockethandkerchiefs. These, however, are all fancy affairs, which the maker can easily evolve from a design or imagination.

Embroidery now forms, in many cases, the sole decorative finish of the more elaborate camisoles, the fronts being ornamented in some pretty design worked in satin stitch, and the edge in buttonholed scollops, small slots being worked at intervals to pass the ribbon through. For such bodices, fine linen is generally used.

44. CAMISOLE WITH VEINED SEAMS



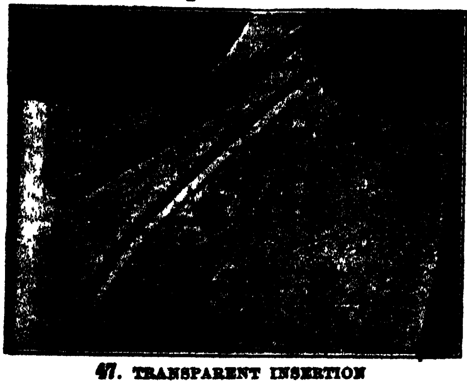
45. CROSSOVER CAMISOLE



46. UNDERBODICE CUT IN ONE

Transparent insertions arranged in designs, with and without tucked centres, also form an important part of fine trimmed underwear. The insertion must first be tacked on the garment in the required design, care being taken to keep the two sides exactly even, and to tack it fairly closely at each edge. Various stitches and methods are employed in the working of such trimming, so no hard-and-fast rule can be given. In the cheaper forms the insertion is merely stitched at each edge, and then cut away on the wrong side. This, however, is not satisfactory for fine goods, as the edges soon pull and fray away from the insertion and quite spoil the look of the garment.

When the insertion is tacked on the right side, cut the material through the centre of the design on the wrong side (using short, blunt-pointed scissors), snipping well any curves to make these set well, as in embroidery, then turn down the cut portion to the edge of the insertion on the wrong side, and oversew firmly and very closely together on the right side. In some of the Irish work the two edges are sewn together by means of satin stitch, forming a raised edge, and then cut away afterwards. Again, some workers buttonhole the edges of insertion to material, whilst others unite the two by a stitch somewhat similar to that in the German seam, and others whip the edges on the wrong side. The method, however, is not important, provided the result be neat and strong, and the above directions give as good a result as any. Use very fine embroidery cotton or Harris's lace thread, No. 80 or 100, the latter being excellent for the purpose. Fig. 47 shows the method above-described for transparent insertions: (*a*) the insertion sewn on and material cut through on wrong side; (*b*) the insertion sewn on and edges neatened.



47. TRANSPARENT INSERTION

From ½ yd. (or less) to 1½ yd. of 36-in. material is usually required for a corset-cover.

Petticoats. As the majority of petticoats are now cut on the lines of a good skirt, being either 3 or 5 piece affairs, we have only included the drafting of a plain gored one intended for flannel, but which can be easily lengthened or have a flounce added for an underskirt.

Front Width. A to B, one-sixth of waist; A to C, 1½ in.; C to D, length, plus 4 in. (giving two tucks 1 in. deep) for tucks and 2 in. for hem; B to E, ½ in. more than C to D.

Side Gore. A to B, half of waist, less 2 in.; A C, one-twelfth of waist measure; C to D corresponds with B to E of front width, and B to E the same

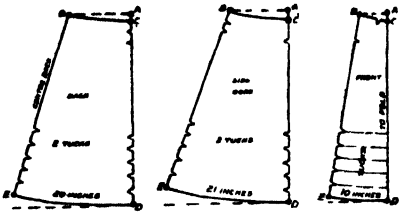
Back Gore. A to B, half of waist, plus 1 in.; C to D and B to E are the same as in the preceding gores [48].

Yoke Band. See Diagram 30, making it, however, a little more pointed in front.

This petticoat, if made of flannel, must have the seams herringboned, whilst the lower edge can be festooned [21], or it can be finished off with a lace or scolloped frill, or one composed of lace and ribbon.

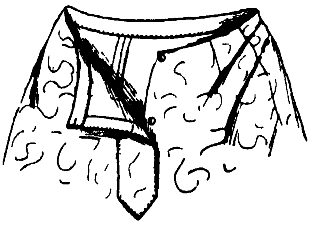
For the drafting of other gored skirts, see DRESSMAKING, also for the shaped flounce, if this be desired.

Princess Pattern. This can be drafted from a bodice and skirt, but full directions for the drafting of a Princess dress are given in TAILORING, which can be simplified for a petticoat—*i.e.*, made with only one side piece, also shorter and less full.



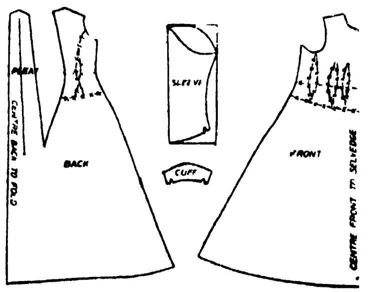
48. GORED FLANNEL PETTICOAT

Many jupons are now made with top of closely-fitting material and removable flounces, the latter being secured to the foundation by buttons and buttonholes, or by ribbon passed through slots in both flounces and foundation. For the slots, see CHILDREN'S CLOTHING.



49. WAISTBAND OF PETTICOAT

Fig 49 illustrates the method of finishing off the waist part and placket-opening of an ordinary petticoat. The strip for neatening the waist must be cut on the cross to set well. In some cases, this is piped to make it stronger, but the cord must be very fine or it will make a ridge. The average quantities for petticoats are 3 yd. of flannel, and 4 yd. to 6 yd. of 30-in. goods for an underskirt, with one or two plain frills, but an elaborate silk one will need 7 yd. to 9 yd. In calculating for such petticoats, the necessary quantities of which vary very much, it may be some guide to reckon 3 yds. of 30-in. material for the upper part, and then add on what may be required for the flounces. Directions for calculating the quantities were given in DRESSMAKING.



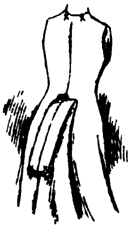
50. WATTEAU DRESSING-GOWN

Bed-room Wear and Negligées. Under this heading we may include dressing and bed jackets, and various styles of morning and dressing gowns.

As in all other classes of garments, the shape and variety is infinite, and it would be impossible to deal with all, but the student who has followed the course should be able to construct any design she wishes by the aid of the diagrams given and a bodice pattern.

As the dressing-gown with a Watteau pleat at back is always more or less a popular shape, we have selected this as an example.

No. 50 gives the diagram, which, as will be seen from the broken lines, is cut from the bodice pattern, the pleat being added at the back, as well as the required length from the waist. The broken lines and crosses indicate the portions which are not to be cut out.



51. WATTEAU PLEAT

52. COMBING WRAP

The sleeves, of course, can be made of the prevailing shape, and if a double-breasted garment be desired, extend the right front as much as may be liked beyond the fold of centre, which should be carefully marked.

The Watteau pleat should have the two edges carefully seamed up on the wrong side, opened and pressed, and then be turned inside out like a bag, and pressed with the seam even with the centre fold.

No. 51 shows the pleat made and ready to be secured to the back neck, as shown by the two crosses, when it will be sewn in with the neck-band or collar. It should be drawn a shade tight, *i.e.*, not allowed to hang slack, which will keep the pleat out well in the shape at the lower part; but, of course, it must not drag in any way. For such a gown, 4 yd. to 5 yd. of 44-in. goods will be needed, without turnings.

A yoke dressing-gown can be cut on similar lines to the night-dress shown in Diagram 40, allowing, of course, extra fulness at front and back, and sloping out the side seams. The neck of yoke may be rounded if wished, or it may, of course, be made in pointed style, whilst for the cutting of an American yoke full directions were given in DRESSMAKING.

A "Kimono" shape can be evolved from No. 50 by making the fronts a little wider and sloping off from the shoulder to about the waist part. The back may be shaped slightly, but the garment beloved in the Land of the Rising Sun is innocent of any shaping and fulness.

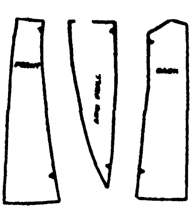
Tea-gowns. The tea-gown forms a class in which elaboration and trimmings have quite put into the shade its original idea and meaning of a simple, loosely-fitting robe to be donned in the intimacy of one's private circle.

The Empire yoke and style makes up very charmingly for such gowns, and is capable of much ornamentation. For the drafting of an Empire yoke or bodice see TAILORING, where full directions are given. The skirt part may also be cut as there shown, adding on the length and fulness required.

If the skirt part be preferred gathered at the top, all that is necessary is to add some inches more at centre back and front.

This style will form an exceptionally graceful gown with the neck part finished off with a fichu of soft silk, net, lace or muslin, and frilled elbow sleeves, whilst one or more frills could finish off the skirt edge. For other and more elaborate styles, the worker should consult the current fashion papers.

Dressing Jackets. Here again the variety in make and style is infinite, but the majority of dressing jackets are made either in sacque or yoke form, with or without collars, as preferred, and these, we think, the worker will be able to manage for herself with the aid of the preceding diagrams and explanations We have, however, in 52 selected a combing wrap of charming simplicity of make and arrangement, capable of being made into either a fascinating shoulder covering and adornment, or as an addition to the wardrobe for indoor wear.

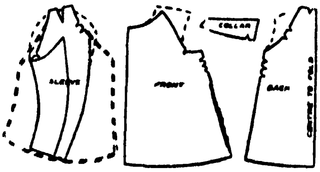


53. COMBING WRAP

As will be seen, it consists of three parts—front, back, and armhole frill—the latter taking the place of sleeves, as the sides are open and the garment is merely passed over the shoulders [53].

54. DRESSING SACQUE

For a combing wrap, cambric, muslin, or flannel can be employed; but for the second-named purpose, oriental-patterned silk would be the most suitable, edged with a fold of plain cross-cut silk, satin, or velvet. About 2 yd. of 36-in. material should suffice for this wrap, in which there are only two seams and no fastenings.



55. DRAFTING OF DRESSING SACQUE

Diagram 55 gives a drafting of a jacket, either for combing purposes or for invalid use, the armhole seams extending to the neck, which makes for ease in slipping on, an important matter in the case of invalids. If necessary, the jacket need not be joined at the underseams, but only at the armholes to the neck, so that it can be slipped round the shoulders and fastened by buttons and buttonholes or ribbons, the sleeves being drawn up like those of the "djibeh" style, or left loose [54].

The broken lines show the variation in this pattern from the ordinary shape, so that it could be cut like the other garments from a bodice pattern. By following these broken outlines the ordinary sacque shape would be obtained, but for elderly people or invalid use the Raglan shape (shown by the firm line) is infinitely preferable. The double broken lines show the full sleeve sketched; the thick line the plain Raglan sleeve, which is better for invalid use. If made of cambric, the seams should be of the French variety, but if of flannel they must be herringboned down quite flat. About 2 yd. of 36-in. material will be required for this jacket.

An excellent shape for an invalid night-dress is the "djibeh" shape, made to fit closely at the neck and fastened at the shoulder, the upper part of sleeve level with this being left open and fastened when on by buttons and buttonholes, or tapes and ribbons. If necessary, one side seam could also be arranged to fasten in the same way [42 and 43].

As it has already been pointed out, the whole beauty of this class of work depends upon the fineness and excellence of the needlework. It is practically impossible for an indifferent worker to produce dainty and attractive lingerie.

BISCUIT MAKING

How the Materials Used are Prepared. Shaping and Baking Wafers and Confectionery. Ship and Dog Biscuits

By CLAYTON BEADLE and HENRY P. STEVENS

THE dainty and attractive articles of food called biscuits, in the form in which they are known to-day, are essentially modern innovations, and the industry connected with their introduction and also of the machinery necessary for their manufacture are essentially English.

The Biscuit Industry. The term *biscuit*, spelt in various ways, can, however, be traced back for many centuries. The origin of the name, according to Gibbon, the historian, has reference to the practice of twice baking bread in a special manner when it was required for very long voyages, or for military campaigns.

The method of baking the goods as indicated by the name has not, however, been preserved to any large extent. Some few well-known biscuits, notably the *rusks* of various kinds, are still twice baked. The only other instance of a double treatment in cooking is in the case of *cracknel* biscuits, where the material is first boiled and then baked.

Previous to about 1830, biscuits of a certain character had been known and were appreciated amongst the élite of society. These biscuits, however, having to be made entirely by hand, were comparatively high in price and were consequently the luxury of the few. The introduction of machinery, with the consequent enormous increase of production, together with free import of the raw materials necessary for biscuit manufacture, have contributed to the popularity and cheapening of these articles of diet.

Machinery. Biscuit-making machinery is in its essence but an application of the old world method of mixing flour and other ingredients into a dough, rolling it out, cutting it into shapes, and baking it. Some modifications have been made in the machinery from time to time, but possibly in no other industry have fewer alterations been made; in fact, in the works of Messrs. Peek, Frean, who have been good enough to give us the benefit of their opinion on many important points, are many machines which have been in continuous use for thirty years or more. They are doing as good work now as when first introduced, and could not be improved upon by any machines of more recent make.

In the dry store-room of a large biscuit works, which may be regarded as the starting point, certain raw materials, such as eggs, coconuts, almonds, raisins, sultanas, and currants, are sorted and freed from dirt, stalks, husks, etc.; to some of these we will make detailed reference.

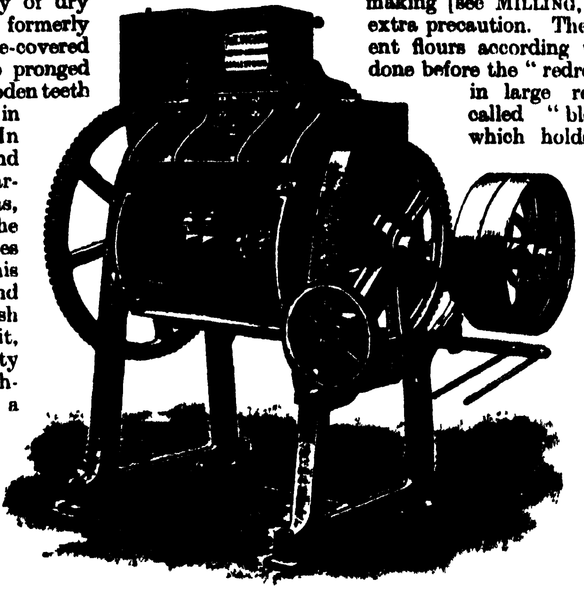
Eggs. In a large factory some hundreds of tons of eggs are used in the course of a year, 100 eggs weighing from 16 lb. to 18 lb. When proper care is exercised, each egg is broken individually by hand, just as a cook breaks an egg on the side of a basin. After each has been examined to see that it is quite fresh, the yolk and white are thrown together into gallon pans. Each gallon is then further tested by an overseer to see that no musty eggs have been overlooked by the girls whose work it is to test them. One musty egg would spoil a whole mixing, hence the necessity of examining every egg. The mixed white and yoke is then passed through a sieve to remove any particles of egg-shell, etc., into a whisk holding two gallons, when, after whisking, it is ready for use. The egg-shells are burnt as they are useless. Attempts have been made to utilise the albumen adhering to the egg-shells, but without success, on account of the attached dirt contaminating the extracted albumen. Such extracted albumen, although unfit for human food, might find useful application in other directions. When the yolks and whites have to be separated, large eggs, such as turkey eggs, are, by preference, used. This separation is done by hand, exactly as a cook does it—namely, by breaking the shell and tipping the yolk from one shell to another, in such a way as to allow the white to run off into a basin. The yolk is used for rich cakes, and the white for such goods as macaroons, while the whole egg is used for ordinary qualities of biscuits.

Milk. Milk is also used to a very large extent, and to ensure its absolute purity, every delivery is examined by the resident analytical chemist.

Coconut. Coconut from which the oil has been extracted before shipment, by means of pressure after grinding, arrives at the works firmly pressed into wooden tin-lined cases. The agglomerated lumps are broken up and passed through automatic shaking sieves of different meshes, so as to separate it into three different grades of fineness to be used for different kinds of biscuits.

Almonds. Almonds are first filled into a large basket of wire gauze and plunged for five minutes into a cauldron of boiling water. After removal they are fed on to a travelling belt, which carries them to a chute and drops them between a pair of rubber rollers, set just the right distance apart to squeeze the almonds so as to make them jump out of their husks as can be done between the finger and thumb. They then pass through a pair of wooden rollers to remove those husks which have escaped the first pair. The skinned almonds then fall on to a tray, while the husks, being comparatively light, are winnowed by means of a fan in the opposite direction. The almonds are then hand-picked to remove any husk still adhering, and then dried at a temperature of 100° F. The manner of slicing now to be employed will depend upon the purpose for which the almonds are to be used—whether for flavouring or for ornamenting cakes, etc. They can be either cut crossways, lengthwise, or cut or split along the seam in the narrow or broad way of the almond, or merely ground up. The cutting machine consists of a wheel which revolves against fixed knives passing into grooves in the wheel. This wheel is fitted with numerous recesses, into which the almonds are fed by hand while it revolves. The cut almonds drop into boxes beneath. When used for confectionery, the almonds are not husked, as the presence of the husk in the cakes is beneficial, giving a peculiar and agreeable flavour. Such almonds are largely obtained from Majorca and Valencia.

Sultanas. Sultanas arrive at the works pressed together in cakes; the cakes are broken up and the separated sultanas mixed with a small quantity of dry flour. They were formerly "dressed" in a gauze-covered trough, in which two pronged stirrers fitted with wooden teeth moved to and fro in opposite directions. In this way the flour and stalks, etc., were separated from the sultanas, and fell through the wire bottom and sides of the machine. This flour was used over and over again for fresh quantities of fruit, until it became too dirty for further use. Without admixture with a dry substance, such as flour, it was not possible to remove mechanically these impurities on account of the sticky nature of the sultanas. They were then hand-picked and sorted to free them from any stones which may not have been removed in the husking machine. This was done by girls, who passed the sultanas over a tray covered with perforated zinc, when any stones present were detected by grating on the metallic surface. This elaborate process was considered necessary to completely cleanse the fruit, and to ensure that no gritty matter or impurities found their way into the confectionery.



1. BRAKE MACHINE (T & T Vicars)

Currants. These come into the works in cases, half cases and quarter cases, containing 1 cwt., 56 lb. and 30 lb. respectively. The modus operandi, until recently, was to fill them into a "dresser" consisting of a slowly revolving cylinder covered with fine parallel wires, inside which a brush revolved. The currants travelled down this wire into a second "dresser," while the stalks, which were removed by this treatment, fell through the wire. In the second dresser the currants met with a jet of water, whereby they were thoroughly washed, and then passed on to a rocking sieve which struck the surface of water with a peculiar oscillatory motion, that caused the currants to travel forward, but deposited the stones, which fell between the crevices, and the dirt between the wire meshes. The currants were then dried by means of a centrifuge.

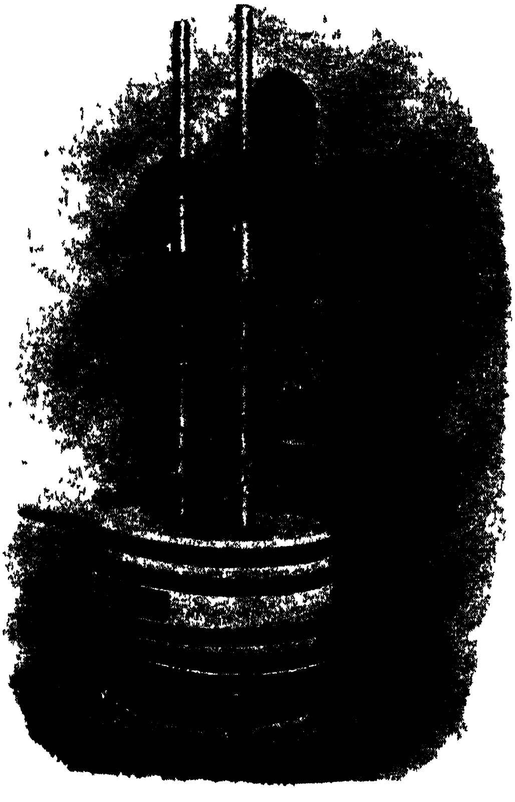
As a simplification of the above, sultanas and currants are now washed in the same machine. The cleaning is done in a semicircular sieve suspended in a tank of water, through which the beaters work backwards and forwards and thoroughly remove the dirt; the semicircular sieve is then tipped up and the contents dropped into a centrifuge.

Flour. Flour as received from the millers is "redressed" before being used for biscuit making [see MILLING, page 3078], as an extra precaution. The blending of different flours according to requirements is done before the "redressing," sometimes in large revolving cylinders called "blenders," each of which holds the contents of about ten sacks of flour. The most up-to-date flour-blending machine consists of a fixed cylinder [see 12, page 3395], round the bottom of which a revolving knife moves and cuts off an equal quantity from each of the compartments into which the cylinder is divided. The blending and sifting of the flour is then continued. The redressed and blended flour is then taken to the mixing-room to be made into dough.

The Mixing-room. In this department the major ingredients of the different biscuits are weighed, measured, and mixed. The flour, sugar, etc., are filled into large hoppers capable of holding two bags of flour besides the other ingredients. When the hopper is full, a trap in the bottom is raised by means of a cord, and the contents shot down into *drum mixers* situated in the room below, where the liquid ingredients, such as milk or water, are added. The mixers [1] consist of iron drums through which a square shaft passes. This shaft is provided with arms in the shape of loops. These, however, get worn to a sharp edge by constant friction. When the drum has been filled with the charge, a large cover is drawn up over the "man-hole" by means of a hand wheel. The agitator is then made to revolve until the mixing, which takes an hour, more or less, according to the constituents, is complete. The contents of the mixer are then emptied into a wooden truck. There is another form of mixer called a *soft dough mixer* [2]. This consists of two vertical shafts side by side and fitted with blades disposed in corkscrew fashion. These shafts revolve in the same direction, and thus give the dough a grinding and thorough kneading. The dough to be mixed is filled into large wooden tubs, which are then run underneath the mixer, the knives of which are lowered and set revolving.

Rolling. The machine-room and bakehouse comprise the department in which the actual making of the biscuit takes place. The dough is first put through the *brake*, which consists of an endless felt travelling between two iron rollers [3]. The motion of the rollers can be reversed by means of gearing, and the roll can be raised or lowered by means of a hand wheel. On this machine the dough is rolled into a sheet of any desired thickness by being made to pass to and fro under the roll, which is gradually lowered. The dough is kept well dusted with flour to prevent it sticking to the roll.

The dough is next taken to the *cutting machine*, of which the latest type is shown in 4. It is placed on an endless travelling felt, and dusted over with flour to prevent it sticking to a roll under which it next passes. There are usually two pairs of these rolls, the first of which presses the dough to, say, twice the thickness required for the biscuit, and the second to the actual thickness. The practice of brushing or spreading the flour with light brushes by hand has been superseded by a revolving brush.



2. SOFT DOUGH MIXER (J. Baker & Sons, Ltd., Willesden)

Cutters. The dough then passes on to another endless felt [4, far end], which moves forward in jerks, and in this way is carried under the cutters which stamp the shape of the biscuit out of the dough. The number of biscuits stamped out at one operation varies from 6 to 80, according to size. The "scrap"—namely, that portion of the sheet of dough between the cut biscuits—passes on to a separate felt up over a roll, whence it is caught on a tray, taken back to the "brake," and used again. The biscuits deprived of their scrap are conveyed on the felt, whence they are transferred to travelling iron trays carried under the felt on chains. The biscuits fall in regular lines on to these trays, and if for any reason a row of biscuits has to be removed from the felt, the motion of the tray can be arrested till the next row is ready to fall on to it, when it is allowed to proceed. If this were not done the trays would not receive a regular charge, and consequently the biscuits would not be evenly baked in the oven.

Spraying. In certain cases, as with ginger nuts, each tray, as it is filled, is lifted off and passed by means of a band under a hood, where the atmosphere is charged with a fine spray of water. Biscuits so sprayed are seen to possess a fine film of moisture on their surface, which imparts to the biscuits a gloss when baked. From this machine the trays of biscuits pass through the ovens.

The Ovens. The trays are now laid on travelling chains provided at equal intervals with spikes that catch the edge of each tray and carry it forward through the oven at a uniform speed, which can be regulated to suit the baking. The ovens are now constructed 50 ft. long, and are heated by producer gas generated in the works [5]. The time taken by the trays to pass through the oven varies with the class of biscuit. With ginger nuts, the time is about twenty-five minutes. With this particular kind of biscuit, one cutting machine supplies two ovens and turns out about 35 cwt. per diem. Each tray takes 84 ginger nuts.

Sugaring. Biscuits are sugared from a long rectangular box which stretches the whole width of the machine. The box is mechanically shaken up and down, causing the sugar to fall through in a regular shower on to the dough passing under it. Biscuit fingers are made and cut out much like ordinary biscuits, but they are carried off on wire trays instead of on the ordinary iron ones. As they leave the cutter they are thin, but slightly rounded on the top and nearly flat underneath, so that when baked the expansion of the upper surface causes them to curl up and to assume the shape of a spill. A somewhat peculiar process is in the above instance ingeniously made use of to assist in forming the biscuit into shape.

3. HARD DOUGH BRAKE (J. Baker & Sons, Ltd.)

Chocolate Fingers. Biscuit fingers are sometimes coated with chocolate by hand. They are laid on wire trays divided into partitions into which they fit. Each tray holds twelve. The trays are then dipped into liquid chocolate, and immediately on removal briskly shaken to remove any excess. By inverting the trays, the fingers fall on to sheets of paper, on which they are conveyed to the racks for drying. These processes are now performed mechanically. Chocolate should be stored at constant temperature, otherwise it gets streaky. The temperature of the store-room in which this class of goods is kept is maintained at about 70° F., to prevent the chocolate from "streaking off." The temperature should never rise above this. The chocolate used for confectionery, such as *fingers* or *wafers*, is prepared by mixing pure chocolate with a small amount of *cocoa butter* in the proportion of about 1 cwt. of chocolate to 20 lb. of cocoa butter.

4. HARD AND SOFT DOUGH GAUGING, CUTTING, STAMPING, AND PANNING MACHINE (J. Baker & Sons, Ltd.)

The "Vanessa" biscuit is prepared on a machine somewhat on the following lines: After the two colours of dough, one white and the other chocolate, are put into the hoppers, plungers which work between the hoppers are raised and lowered by means of cams, and force exactly the right amount of batter to the

5 TWO-PAN TRAVELLING OR CHAIN OVEN (J Baker & Sons, Ltd)

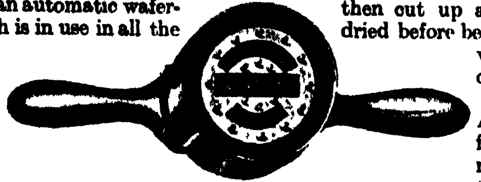
trays which pass underneath The white and chocolate coloured doughs are pumped simultaneously upon the pan

Fairy Cakes. Here the dough is deposited, in rows, from a similar machine to the above, on to a "spun pan,' which consists of a tin plate in which a number of small hollows have been shaped out by an ingenious process of "spinning" (hence its name) Each of these numerous hollows provides a mould for a fairy cake The pans are smeared with a mixture of butter and flour to prevent the baked cakes from sticking. When the pans have been used, they are cleansed by being pressed against revolving brushes moistened with water, and after smearing with butter and flour, are ready for further use. With the "drop machine" there is no waste or scrap, as the exact amount of stuff required is delivered for each biscuit or cake

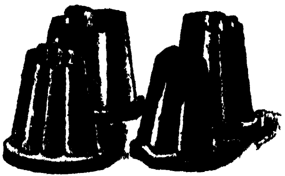
6. CONTINUOUS BISCUIT FORCER

Colonial Biscuits. Colonial biscuits are made from dough on the "Rout" press. In a similar manner are produced "Cable" and "Twist" biscuits, and, with special "dies," the "Rose, "Café," "Ring," and similar biscuits. Colonials are formed in strips about ¾ in wide, and have a rough upper surface, caused by the rucking up of the surface as it passes from the die of the nozzle These strips pass under a "cutter," which cuts them into 3-in lengths Here, again, there is no waste or scrap. When the trays carrying these biscuits emerge from the oven, they are lifted out and placed on racks for a few minutes to cool, and are then tipped into boxes ready for packing A continuous biscuit forcer to work by hand, used for Queen's and Rout biscuits, is shown in 6 Hand biscuit cutters [7] are made round, oval, or fancy shapes, plain or engraved, with name for the use of those who make up their own biscuits, where hand kneading and the rolling-pin take the place of processes already described These cutters are made to cut, print, and eject, like a machine cutter; also fancy biscuit cutters [8], for rich and soft doughs, are made in strong tins of various sizes and designs.

Plain Ice Wafers. Probably the most important of special biscuits is the sugar or ice wafer. We illustrate here an automatic wafer-making machine [9], which is in use in all the largest factories in different parts of the world. This biscuit, so great a favourite with those who eat ices, is made of a mixture so thin as to be a batter instead of a dough. This batter is held in a tank at the side of the machine. A series of pumps distribute the batter in measured quantities upon silver-plated and highly engraved plates; these plates run in pairs, and as soon as the batter has been placed on the lower plate of the pair the top half closes and locks. The batter so held between the plates is carried round a chamber, which is heated by gas stoves. When the complete revolution of the machine has been effected, the plates unlock and the sheet of baked batter drops out. This sheet is made up of 32 of the finished wafers, and these are cut out from the sheet by means of rapidly revolving saws. All these operations are carried out automatically.

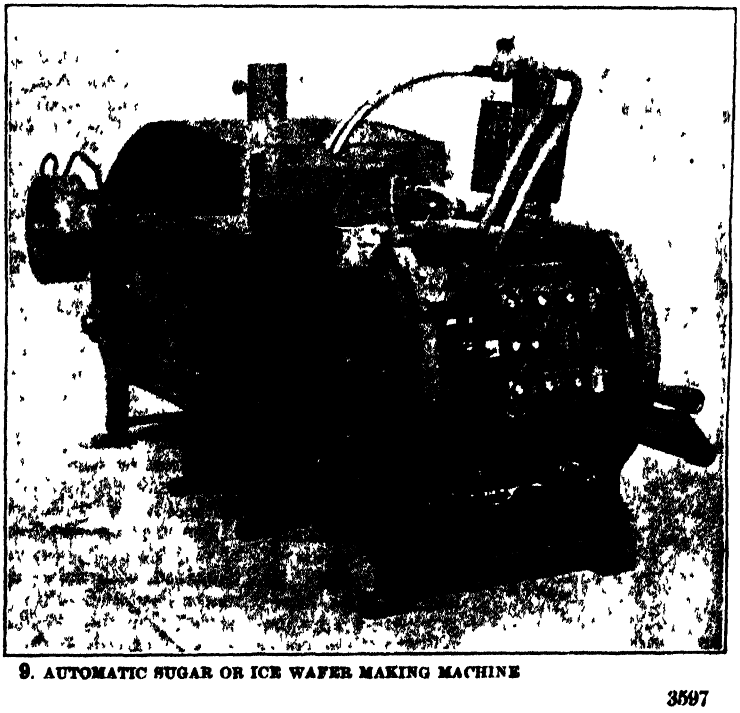


7. HAND BISCUIT CUTTER



8. FANCY BISCUIT CUTTERS

Cornets. These are wafers shaped like cones, made on a machine somewhat similar to that used for plain wafers, but the plate consists of cone-shaped moulds, 24 in number, and the cover is fitted with a similar number of cone-shaped spikes which fit into the moulds. The moulds are filled with the batter by means of a special device which delivers into them exactly the right quantity of stuff, thus saving any waste. When the moulds have been filled the cover is clamped down, turned over, and passed on as before, the next plate coming round to be emptied. From it the cones or "cornets," which are either in the moulds or sticking to the spikes, are removed and packed in boxes. One plate takes five minutes to travel round the machine. About 9,000 a day per man are turned out. These wafers are largely sold to itinerant ice-cream vendors.



9. AUTOMATIC SUGAR OR ICE WAFER MAKING MACHINE

Windsor Wafer. The Windsor Wafer or Sugar Vanille consists of two plain ice wafers between which is sandwiched cream. The cream is put in between the sheets of wafers, which are then cut up and dried. If they were dried before being cut, bits of the wafer would chip off, and thus cause a loss.

Artificial Bananas. Among the various forms of confectionery now made is an imitation banana. This is flavoured with a concoction to give it the taste of a banana. It is shaped and coloured like a banana, and when broken is soft, like that fruit. Large quantities are shipped to Jamaica, Batavia, and Egypt.

Hand-made Biscuits. Cakes, even in large factories, are made by hand, though this method is rapidly dying out. There is also a certain class of biscuit, such as macaroons, which are sometimes made by hand, although generally on a drop machine. The shape of the biscuit is cut out of the dough by a hand cutter and then put on to an iron tray. When a sufficient number have been cut, the tray is put into an oven to bake, the tray simply lying on the floor of the oven. Its position is occasionally changed with the aid of a long wooden pole—technically called a *peel*—shaped at the end like a spade. When sufficiently baked the trays are taken out, and the biscuits are allowed to cool and are then tipped into boxes.

50 ft 2 pan Travelling Oven
Revolving Pan Rack

10. THE ARRANGEMENT OF A SWEET BISCUIT FACTORY

Packing. Most biscuits and small cakes are packed in tins holding about 9 lb. of biscuits. Each tin is put on to a travelling belt, which carries it to a hoist that conveys the tin to the floor above, where it is labelled. The tins are then put into a hot chamber to dry the labels to prevent them rusting the tins. Tins used for export are hermetically sealed. A certain class of goods, such as "Quaker Oat Biscuits," are packed in cardboard packets called "boxets." These boxets are waxed inside, and the biscuits are wrapped in waxed paper before being placed in the box. The life of a biscuit tin is about five or six journeys. The tins are well scoured out every time they return to the works.

Refrigerating Plant. This is an essential part of a large factory. It is used for cold storage of butter and lard, for ice making and milk cooling. [See FOOD PRESERVATION.]

The complexity of the work of a large biscuit factory may be judged from the fact that one large firm may turn out 250 varieties. We give, in **10**, the general arrangement of a small sweet biscuit factory.

Ship and Dog Biscuits. The method of manufacture of ship biscuits, as in the works of Messrs. Spillers & Baker, who have the latest installed plant, is conducted somewhat on the following lines.

A selection is made of specially milled flours of a description and quality suitable for the biscuit required, ship biscuits being usually made in several qualities, some for cabin and some for crew use. The mixture and blend having been decided upon, the various flours are put through a set of automatic mixers, which blend them thoroughly together. This mixed flour is then caught off from these mixers in sacks, each one being carefully weighed to ensure the exact quantity of flour being used for the next process. A charge of from 5 to 10 cwt. of the mixed flour is then shot into a dough mixer. Fixed above is a tank connected with a supply of pure water, and by means of a gauge the desired quantity of water for the weight of flour is added. The mixture is kneaded into dough in from 15 to 30 minutes, and discharged on to an iron table immediately below, near which is fixed a brake, through which the dough is rolled backwards and forwards until a sheet of the required thickness is produced. The other processes of preparation for the oven being similar to those described above.

A Special Oven. The oven, which differs in some respects from that used for sweet biscuits, consists of a number of iron plates, which, being connected together and worked on tumblers, are made to traverse the whole length of the oven. The most approved size for up-to-date ovens is about 8 ft. wide and 44 ft. long. The length of time the biscuits take to pass through the oven can be adjusted by means of a ratchet-wheel and pawl at the front end, and they take from 15 to 30 minutes, as more or fewer teeth are taken by each upward motion of the pawl. The heat in the oven is regulated by an elaborate arrangement of flues and dampers, and as the ovens for this kind of biscuit are usually what is termed "direct heat ovens," a smokeless fuel, such as coke, has to be used; the consequence is that the heat produced is very much more intense than that in ovens fired by other methods, and has the effect of rendering the biscuits so baked capable of withstanding changes of temperature and keeping a considerable time. But because of this direct heat, ovens so constructed require very much more careful manipulation and closer attention, as the heat is apt to vary more than in "indirect heat" ovens.

By properly regulating the heat, and also by previous calculation, the biscuits, on reaching the end, are thoroughly baked They are conveyed by elevators to a drying floor in order to cool and to get rid of any superfluous moisture that may be contained in them. After being stored on this floor for sufficient time, they are packed in barrels or bags for delivery where required. This final drying operation is not required in the case of sweet biscuits.

The method employed for the manufacture of dog biscuits is on similar lines to that just described, with the exception, of course, that the materials used are different. Great care has to be exercised in the selection of suitable flours and meals, and also in the addition of the cooked meat considered necessary for the dog's dietary.

Biscuit Making concluded

HOW, WHEN, AND WHAT TO EAT

Continued from page 3481

Digestion and Diets. Meat Food. Regularity. The Three Meals. Influence of Mind on Digestion. Meal-time should be Cheerful

By Dr. A. T. SCHOFIELD

SOME time ago the United States War Department made experiments with a view to reducing the weight and bulk of the soldiers' rations without impairing their nutritive value. It was soon known, however, that the experiment had resulted in failure. A report on the subject has now been issued from which some interesting details may be gathered. A company of the 7th Infantry, it appears, was detailed to make the experiment. The company was furnished with condensed rations, consisting of coffee, soup, bread, and bacon. The coffee and soup were in small tablets, which, when placed in boiling water, were ready for consumption in two minutes. The bread was in small, flat cakes, the weight and hardness of a brick, which, when moistened, swelled out like a sponge. The bacon was compressed, and needed only to be warmed in a frying-pan. The soldiers started out with 10 days' rations, but the campaign was brought to an abrupt end after four days of 15-mile marches. The food not only failed to satisfy hunger or give strength, but seemed to irritate the stomach.

Suitability of food largely depends upon its digestibility, as well as upon its chemical composition. Thus, it would seem that, from one point of view, pork and milk contain about the right proportion of carbon and nitrogen, and yet the one is a most unsuitable article of diet, the other the best we have. As a rule, the nitrogen in vegetables is not so easily absorbed as in meat.

Force Derived from Various Foods. With regard to the proportion of body and mind work derived from various foods, an attempt has been made to give a table showing the percentage of force that food gives out as heat, as physical force, and as mental energy. This is as follows, but must be taken as merely approximate :

PERCENTAGE TABLE

Foods.	Heat Force	Physical Force	Mental Force
Rice	82	5	½
Prunes	78½	4	4½
Wheat	66½	14½	1½
Oats	51	17	3
Beans	40	24	3½
Ham	32	35	4½
Yolk of egg	30	—	2
White of egg ..	—	13	3
Cheese	28	31	4½
Potatoes	16	1½	1
Mutton	14	21	2
Beef	14	19	2
Milk	8	5	1
Chicken	2	21½	3
Herring	1	16	5

The rest is water

This table gives the relative cost of foods :

COST OF SUFFICIENT FOOD TO SUPPLY THE AVERAGE DAILY FORCE NEEDED

	s.	d.		s.	d.		s.	d.
Codfish	5	0	Butter	1	7	Beans	0	6
Mutton	3	6	Cheese	1	6	Rice	0	5
Lean beef	3	0	Fat pork	0	9	Bread	0	4
Milk	2	3	Potatoes	0	7	Oatmeal	0	3½

This, of course, gives no idea of relative suitability or digestibility, and no one could live exclusively on any one article named, excepting milk and bread. Let us take a more general survey of the principles and practice of dietetics.

Importance of Proper Food. There can be no doubt as to the importance of the subject when we learn that in this country alone over 2,000 lives a week are lost through bad and improper food. Indeed, this is too low an estimate when we remember that food includes drink, and hence alcohol. It is sufficient, however, for us here to know that the misuse of food (including drink) is by far the chief cause of disease, death and misery in the English race, and that " proper food " is the first and foremost of the five laws of health.

Food is necessary, as we all know, to repair the waste of the body, and in its widest sense includes not only solid and liquid, but the gas we inspire from the air, under the name of oxygen. While, however, we have ultimately no control over the *amount* of oxygen we inspire, nor any choice of gases, we can and do adulterate the air as much as lies in our power, to our own cost But our powers for evil over what we breathe are small and insignificant when compared with the wide powers and complete control that we have over the food we eat. One would think that the human race, when it became civilised and educated, would long ago have settled the question of food and drink, and have discovered the best and most economical way of repairing the system. *What* to eat or drink, *when* to eat, *how* to eat, should long ago have been questions so settled by experience and authority.

Repair of Waste. We require a good deal of food—for, as we have shown, we perish at a faster rate when we are alive than when dead, wasting to the extent of about one twenty-fourth part daily. We thus lose over a ton a year, and the important question is, how best the loss is to be made good.

This rate, however, is not even throughout life, and for the first twenty-five years we have to consider not only how to replace the daily loss, but how to build up the body and what material to use.

As regards quantity of food, the best and simplest rule seems to be: From the ages of 1 to 25, as much food as is wished, provided it be wholesome and given at stated intervals; from 25 to 55, as much food as will keep the body at the same weight for these 30 years; from 55 to 75, a gradually decreasing amount of simpler food, so that weight is slowly lost, or at any rate, not gained. In the first third of life we seldom eat too much; in the last third we very often do so.

The difficulty in writing on dietetics is to avoid being too explicit, and yet to give directions that are of real value. We shall try not to be too exact as to details, but very definite as to principles.

Digestion and Indigestion. When the digestive system is "in order" its great characteristic, like that of all other body systems, is that it performs all its work unconsciously. So perfect is its mechanism that we do not know or feel we have either stomach or liver, although both may be hard at work, and the former in violent motion for hours together. But once indigestion begins, this delightful unconscious calm vanishes, and we are only too painfully aware of the internal troubles.

In nearly every case this is our own fault, and is brought on through gluttony for food or excess in drink. Gluttony is a great vice, but being personal and harming no one but ourselves, it escapes censure, save when leading to excess in alcohol. An old German proverb says, "As a man eateth, so is he." It is true that our food influences our character, but it is equally true that our character affects our eating, and that the wise, self-governed man is far less likely to suffer from dyspepsia than the self-indulgent one.

Moderation the Motto of Health. Personal habits leading in this direction to ill-health are easily formed, and should be carefully watched. Small habits of excess are easily acquired, and are then so difficult to break.

We do not wish to lay down many rules, but say emphatically that "moderation in all foods" is the motto of health. This habit formed in youth is a powerful safeguard against many ills, and prevents much physical unhappiness.

We will first look at the question, "*What we should eat*," on which many opinions are held.

The natural query is, "Shall we exclude any ordinary staple food such as meat from our dietary, and if so, what?"

Our answer for those whose digestion is in order and who desire to keep it so, is "No. Let all ordinary food be eaten in moderation." But there are many who exclude "butcher's meat" and eat "white" meat only, others who forswear all meat, but eat other animal food such as milk, eggs, butter, etc., and are miscalled "vegetarians." Others, again, rise above these and eat vegetables only. A superior class still exists on fruits, but the highest and smallest class of all consists of those eccentric beings who are kept alive by nuts and seeds only, including, very largely, apple pips. To such heights of faddism or depths of imbecility does dieting extend, and in every stage there are men and women ever ready to demonstrate, in their own persons, that every conceivable energy and grace is produced by their particular diet, and to hand you convincing manuals that prove this.

Dietaries should be Shunned by the Healthy. All dietaries should be shunned by the healthy; their adoption is a confession of weakness, and even the weak should use diet tables as little as possible.

When we remember how different are people's temperaments and idiosyncrasies, and that what agrees with one so often disagrees with another, we see the difficulty, if not the folly, of laying down general dietaries. Dr. King Chambers writes: "Some cross off their dietaries everything that has ever disagreed; better to add to it everything that has once agreed." This advice goes rather too far, but it is on the right side.

After infancy, therefore, when the full digestive powers are established, diets do generally more harm than good, save in special diseases. Even if some food is found to disagree it is better to eat less of it than to cut it off altogether. We must remember, too, that cooking can render the same food digestible or indigestible.

The question to ask respecting any article of diet is, "Do you like it?" and "Does it like you?" If both questions can be answered satisfactorily, there is no doubt on the matter; if the first only, try the food in moderation and well cooked before you decide to give it up.

No doubt, not only gout but many smaller ills come from a wrong diet, and if a person suffering from any of these is told by a responsible physician that they are caused by any article of food, he should heed him and not use it; but we are speaking of the healthy, and of the self-dieting of dyspeptics.

Eating too Much and too Little. But "What to eat" embraces also what amount to eat, and we would touch on this, for it is most important. We think that most people who can afford to do so eat too much.

The rule we have already laid down of living by the scales rather than by the appetite is a golden one. Let the weight be fixed and never exceeded or lessened by half a stone. This is not only the way to keep in order, but to prolong life and to avoid many diseases.

Dr. Mortimer Granville says that there is "More danger from excess of food than from infection; and there can be no doubt that excess of animal food is a great and crying evil in the English people and produces an amount of dyspepsia and other troubles wholly preventable by eating half the amount. In this country we consume about four times the amount of meat of any other country in Europe."

Eating too much does not strengthen the body, but exhausts it with the labour of digestion and the evils of the undigested residue. Among the aged this is a common error, mainly due to friends and relatives who are continually urging the old man, whom Nature has wisely deprived of his teeth, to eat more and to live better; whereas his health and happiness depend on eating less and living more plainly.

While we thus speak against over-eating in the healthy and wealthy, we see plenty of evils arising from starvation among the rich.

Many eat too little for various reasons, even when otherwise in health; and this soon leads to the nerves or some other part being out of order. A false idea of refinement, or some slight dyspepsia or over-fatigue, leads to semi-starvation, and very soon nervous signs follow, showing the nerves are no longer in health.

So far, we fear, we have spoken in a very vague way for those who, as we have said, love exact rules. We will try to be a little more exact in speaking of one or two articles of diet.

Meat and Vegetarian Diets. Of meat we eat far more than the French or Germans. No doubt we require rather more than they do; but the excess over what we really require is enormous, and not only represents great waste but needless disease.

There is no storehouse in the body for excess of meat food as there is for fats and starches; and the result is that if the excess passes a certain point the meat becomes poison, and uric acid is produced.

For light workers meat once a day is enough. Butcher's meat three times a day is an excess for anybody in this country. The recent researches of Professor Chittenden tend to show that a far greater limitation of meat diet may be beneficial.

The bulk of the diet should be what is called—but is not—vegetarian; that is, farinaceous and vegetable foods, milk, with eggs, etc. In growing youth and early manhood too much care cannot be taken that the food is digestible; and above all, artificial and pre-digested foods should be avoided; for hard digestive work in moderation strengthens the stomach, whereas little or no work certainly weakens it. Thus, "meat teas" which are hard to digest are not bad for young people.

Bread the Staff of Life. Bread is the staff of life, and no attention should be paid to dyspeptic faddists who claim to have discovered rather late in the day that it is the source of much disease. It contains the meat and vegetable principles as no other food really does, and can be eaten in such a variety of forms that none need tire of it. White bread well made is the most nutritious and generally useful; for the weak and for children wholemeal bread is splendid, while Hovis bread is of real value as compared with other breads, on account of the amount of fat it contains, making it nearly equal to bread and butter. Italian pastes, such as macaroni, are exceptionally nutritious, and indeed no dish can surpass in food value macaroni and cheese, which is, perhaps, for its bulk, the most nutritious dish that can be made; but it does not follow that it is particularly easy of digestion.

We have already pointed out that the old idea that force is gained principally from meat diet has proved to be erroneous, and it is now shown that muscular force is principally obtained from the carbohydrates — the starch and sugar foods. These two can be eaten in excess with much greater safety than meat, as we have shown. Sugar itself is a most valuable muscular food and must be mentioned here. As a rule, it is taken plentifully in all farinaceous food, for all starch is changed into sugar. The advantage of sugar is that it requires no change. It exists in large quantities in some vegetables such as beetroot, in some fruit such as grapes, and also in chocolate and other artificial foods. If half a pound a day is eaten, from 15 to 20 per cent. more work can be done. Hackenschmidt, the great wrestler, gets nearly all his force from sweets, chocolates, etc. Seventy-two lb. per head is used in Great Britain, 52 lb. in America, 25 lb. in France and 17 lb. in Germany. Sugar creates no uric acid, and does not in itself produce gout. Two lumps of sugar eaten daily, will increase the weight 14 lb. in one year.

When to Eat. The next point to consider is "*When to eat.*" As to this, we may certainly say, "*At fixed times.*" Food eaten at irregular times is much more apt to disagree than if taken at fixed hours. This is truest in early and late life, but holds good all through.

A baby may suffer from birth from capricious feeding, and without fixed hours soon becomes a burden to itself and to others; whereas if fed every two hours in the day, and every four hours at night *by the clock*, it would be in health and perfectly easy to manage. It is astonishing, too, how soon a child becomes accustomed to fixed habits, and what an untold blessing these are; and this refers not only to eating, but to all habits necessary for the health of the individual.

Regularity of Meals. Perhaps we may be allowed to point out here the great misery that has resulted to, and is still experienced by, thousands whose digestive systems in some part of their course are out of order, solely from a culpable neglect on the part of parents in forming a daily habit in their children, and thus rendering constant medicine wholly unnecessary.

The advantage of regular meals is that the digestive organs themselves learn to expect these meals, and get ready for them if they are taken at fixed hours.

The interval between meals should never be less than four hours, and is better if not over six. It is most important that a fresh meal should not be taken until the last is digested. The neglect of this rule is a common cause of dyspepsia. The burning question of the number of meals in the day is by no means easy to settle.

We have been recently invaded from America by a no-breakfast agitation, which, though not so much needed here as in the States, raises a very important question. In America breakfasts have run to such an excess as to become veritable banquets.

No breakfast at all may suit some, but the folly is to think of this or any similar device as a universal panacea.

Three Kinds of Breakfast. Three sorts of breakfast remain for those who take any; they may be summed up as the *English breakfast*, the *plain breakfast*, and the *French breakfast*, each admirably adapted for certain cases.

The man or woman who has to do hard physical work before lunch, and especially in the open air, does well to eat a hearty breakfast, allowing, say, an hour afterwards before beginning work.

The man or woman who has light physical or mental work to do, and whose forenoon is spent more within doors, does better with the plain breakfast, with perhaps an egg and some marmalade; or with the still lighter "French breakfast."

The general consensus of hygienic wisdom lays down that the principal meal when the man's work is over by one o'clock is the lunch or early dinner; while all-day workers do better with a light lunch and a more substantial dinner. Where there is hard labour all day, practically two substantial meals, or dinners, are needed. The principal meal, at any rate, should be eaten, if possible, when the chief work of the day is over, and, let us repeat, must always be eaten at leisure. Quantity is the point in early dinners, variety in late dinners; for the digestion at that hour cannot deal with such large quantities of food as earlier in the day, and variety stimulates the appetite. Light tea is best taken as now, between four and five.

The Evening Meal. One last point remains as to when to take food, and that is with regard to the interval between eight or nine p.m. and eight or nine next morning. Though this long fast may not be a common cause of dyspepsia, it is certainly a common cause of wakefulness and nerve troubles, and many a slight nerve case has been cured by providing a meal between these hours.

If the evening meal at eight be plentiful, and if the night be spent in sleep, nothing is, as a rule, required till breakfast next morning. But this turns on two "ifs," either of which may fail. Sometimes the dinner is at six or seven, and very little may be eaten; in this case some sort of supper at ten or eleven is needed. Again, the night may be wakeful, and the person sick from hunger, and yet no food can be had till breakfast-time.

This should never be. Food of some sort that is palatable when cold should always be accessible, so that an impromptu meal can be taken with some milk when required; while those who always have their evening meal early, and often eat little at it, should, as we have said, as a fixed custom have a light after-supper about four hours later, and if any part of it can be hot so much the better for digestion. There is really no necessity for walking a mile after this supper. If a brief interval be allowed before retiring to rest, the meal will not only give no trouble but will probably act also as a mild hypnotic.

How to Eat. The third and last point is "*How to eat.*" Now, all things may be lawful, but all are certainly not expedient, for while there may be no sin in eating all that is set before us, there is often suffering if we do.

Sir Henry Holland's three rules for eating were:

1. Never to fill the stomach to repletion.
2. To eat slowly.
3. To allow no mind strain at meals.

These may not sum up all that is needful to keep the digestion in order, but they are wise and good as far as they go.

The first rule may be put in another form, perhaps more refined: "Always rise with an appetite."

The reason of this is that when we have really eaten enough the hunger is often not wholly appeased *at the time*, because the food has not yet had time to digest. Therefore, even if we rise "with an appetite," it soon disappears as the food becomes assimilated.

Over-eating of animal food is more serious than that of other kinds, for in this case, sooner or later, gout is almost sure to supervene.

The next rule is to *eat slowly*. This all may do; and if they cannot, they should eat only the lightest food when in a hurry.

The third point is most important—"*no mind strain at meals.*" The same simple meal that will perfectly agree with a man in ordinary circumstances may cause violent dyspepsia if eaten under severe mind strain or shock. Even if done once, the bad effects are felt; and, if continued, chronic dyspepsia is the sure result.

Influence of Mind on Digestion. We must impress this point—that to keep the digestion in order heavy meals must never be eaten when the mind is agitated or strained. At such times the simple and wise course is to live on light food until the mind is relieved. The neglect of this simple precaution often begins the fatal reaction that culminates in a nerve attack. The attack of dyspepsia reacts on the mind, which becomes more nervous and strained; this weakens the stomach still more, and the process goes on till the system is impoverished and nervous debility ensues; and then, indeed, when the fatal circle is established, it is seen too late how much better and easier prevention is than cure.

The connection of stomach and brain, of digestion and thought, is very close. Good blood supply and nervous energy are as necessary for one as for the other, and the two cannot be fully working at the same time. It is, therefore, always advisable that a meal time should be a season of relaxation and of cheerfulness.

If this advice is needed for those in health, it is still more important for dyspeptics. A man who is liable to indigestion, and who eats a full meal when in a state of mental tension, may bring on a sharp attack of gout by so doing.

Continued

AN AGE OF DISCOVERY

The Wars of the Roses. Warwick "the King-maker." Murder of the Little Princes. Introduction of the Art of Printing. Discovery of a New Continent

By JUSTIN McCARTHY

ONE of the most important events in the course of English history was the outbreak of the Wars of the Roses. These wars were carried on in maintenance of the rival claims of the houses of York and Lancaster to the English throne. The Lancaster family were descended from John of Gaunt, Duke of Lancaster, fourth son of Edward III., while the York party were the descendants of Roger Mortimer, grandson of Edward's third son. The Lancastrians adopted the red, and the Yorkists the white rose, as their emblem, and thus this prolonged contest, which lasted some thirty years, came to be described in history as the Wars of the Roses.

The Wars of the Roses. We read that in these wars perished 12 princes of the blood royal, more than 200 nobles, and more than 100,000 of the aristocracy and their dependents. It is not necessary to follow minutely the story of these wars and to recount the victories now of the one side and now of the other. Nothing could well have been more barren, so far as the prosperity of the country was concerned, than those trials on successive battlefields of family claims which seem to readers of the present day to rest on merely technical questions as to the law of succession. Even where it was shown that the immediate and direct line of succession had been broken, it was argued on the other side that on the death of a sovereign, the existing constituted authorities charged with the welfare of the realm had always claimed, and on several occasions exerted, without opposition, the right to designate for the throne one of the royal princes not actually next in the line of succession

The record of these wars is sickening and ghastly to a degree which the stories even of civil wars cannot often equal. The rival parties do not seem to have behaved towards each other with any regard for the common laws of war as prevailing between rival countries. The Yorkites and the Lancastrians acted on the principle that in such a struggle each party, when it had won a victory, was honourably free to act towards the conquered leaders as if they had been mere mutineers, for whose breach of discipline any punishment might properly be inflicted.

The King-maker. The wars began in 1455, but the actual dispute had been going on since 1449, when Richard Duke of York publicly claimed the succession. One leading figure in those wars was that of Richard Neville, Earl of Warwick, the famous "King-maker." When the war broke out, Warwick rendered great service to the Yorkites at the battle of St. Albans, and was, indeed, the main instrument in obtaining the victory After this he took the leading part in the struggle. He had more in him of the statesman than of the soldier, and it does not appear that mere love for soldiering had brought him to the battlefield. He was shrewd, astute, foreseeing, had a gift of political intrigue and political mastery, and was unscrupulous as to the means by which he accomplished his end. There were victories and defeats on either side, but Warwick effected a bold stroke by marching on to London with Edward, son of the Duke of York, and proclaiming him King Edward IV. Soon after the Yorkites gained a signal victory at Towton, and for the time the struggle seemed to be at an end.

The young King made himself very popular by his courage and his winning manners. Indeed, at that time, London was well inclined to welcome any sovereign whose coming to the throne brought with it the promise of restored peace.

Edward later on made many enemies by his licentious tendencies, and Warwick, among others, turned against him. Edward found that there were strong forces opposing him, and he left England and took refuge in Flanders while he was gathering new strength around him to meet his enemies. After six months he came back to England, and with his brother Clarence, who had recently taken his side, encountered his opponents at Barnet, April 14th, 1471, where Warwick the "King-maker" was surrounded and killed on the battlefield.

Tewkesbury. The result of the battle was a victory for Edward, and by a subsequent victory at Tewkesbury a few weeks later he brought that chapter, at least, of the war to an end. Edward behaved with extreme cruelty to some of his captured enemies, and the latter part of his career illustrated in very striking fashion the general character of those lamentable Wars of the Roses. On April 9th, 1483, he died suddenly. When his life ought to have been only at its prime it was prematurely brought to an end by the excitement of politics and war, and probably even more by dissipation. His successes were made for him by others, his faults and failures were his own.

He was succeeded—at least nominally succeeded—by his son Edward V., who was then little more than twelve years old. He came at once under the influence of his uncle, Richard, Duke of Gloucester, the youngest brother of Edward IV. Richard, Duke of Gloucester, is one of the most remarkable, and one of the most odious figures in English history. He is, perhaps, best known not through history, but through the drama. Shakespeare in his "Richard III." has made for us a terrible picture which is as living as life itself, and even if every fact and incident in that great drama is not a literal reproduction of the truth, his character of Richard may be taken to be a fair representation of the real man.

Richard was born on October 2nd, 1452; on the defeat and death of his father, the Duke of York, he was sent abroad for safety, but after Edward IV. had won the throne he returned to England and was made Duke of Gloucester. He took a conspicuous part in the York and Lancaster struggle during its later developments, and is accused of having sanctioned, or even promoted, some of the worst crimes—the judicial murders of leading opponents during that war.

The Murder of the Little Princes. After the death of King Edward, Richard was appointed Protector of the Realm and guardian of Edward V., then only thirteen years old. He became practically ruler of England for the time, and the Queen-dowager was induced to put under his guardianship also her younger son, the Duke of York. The two boys were put into the Tower of London with the avowed object of keeping them safe. They were afterwards murdered there, it was generally believed, by the orders of Richard. Richard the Protector had Earl Rivers and Lord Richard Grey, the uncle and the stepbrother of young Edward, arrested on a charge of treason and brought to a trial which ended in their execution Richard now seemed to be absolute master of the state, and he was invited by the Parliament to accept the crown. This invitation, entirely in accordance with Richard's own ambition and schemes, was promptly accepted by him, and he was crowned king.

Bosworth. In the meantime the feeling of hostility to Richard and his deeds was spreading throughout the country, and some of the most powerful nobles began to turn against him. Henry Tudor, Earl of Richmond, was then the most important representative of the House of Lancaster, and the friends of this powerful nobleman began to organise a scheme to dethrone Richard and make Henry Tudor king. The attempted movement failed, and its principal leader, one of Richard's earlier supporters, the Duke of Buckingham, was put to death for the part he had taken in the projected rising. Henry, Earl of Richmond, had no ideas of abandoning his hostility to King Richard because of any temporary check to the movement in his own favour, and on August 22nd, 1485, he encountered Richard at the famous battle of Bosworth, in Leicestershire. The battle was a complete defeat for Richard, who was deserted at the last moment by some of those who had, up to that time, supported him. Richard lost his life on the battlefield.

There was a story widely credited for a long time that Richmond was actually crowned on the battlefield as King of England with Richard's own crown, which was found when the fight was over not far from the spot where Richard had fallen, but the story is probably only another illustration of the romance of history.

Richard III. was a man of distinct and remarkable capacity who might, under other conditions, have made a great name for himself and have been a benefactor to his country. Intellectually and in education, an education in great part self-acquired, he was in advance of most of the English princes of his time; but his ambition, impatience, and his recklessness of all moral restraint, illumined only with a lurid light that chapter of history which encloses his reign.

With the death of Richard III. the Wars of the Roses ended. Henry Richmond became without further struggle the successor to the English throne. His father, Edmond Tudor, belonged to a celebrated Welsh family, was the son of Owen Tudor, who bore a name distinguished in the history of Wales, and of his wife, Queen Catherine, the widow of Henry V. Henry VII., soon after he had come to the throne, married Elizabeth of York, eldest daughter of Edward IV., and by this marriage the red and white roses became united.

Introduction of Printing. A new chapter of wider significance and more enduring influence in the history of the world than any associated with the rivalries of states or the fortunes of contending armies, was opening about this time. This was the chapter which tells of the discovery of the art of printing. Up to this period authorship of whatever kind had to address its public through the form of manuscript. Books had been made up of letters written with the hand on pages of parchment, paper, or even of leather, but the only medium of communication between the poet, the historian, the romancist, and the outer public was the character traced by the human hand. It is said that a sort of block printing, the impressing of words on paper or parchment through the medium of wooden carvings representing the words, was discovered in China some five centuries after our Christian era, and practised there for some time. There is evidence of similar inventions and applications having been made the subject of experiment at later periods in European countries, and of having been practised there with some success.

The idea might have come into almost any mind, at any period since works of literature came to be composed, that there might be some mechanical process for reproducing on parchment or paper the text of the author in a form at once more legible and more capable of rapid multiplication than could be accomplished under any conditions by hand. But the art of printing, as it is understood in modern days, seems to have come into use in different parts of Europe at about the same period in the world's development—during the fifteenth century. The name of William Caxton will always be identified in England with the earliest practical application of the art of book printing.

Caxton. Caxton was born in the Weald of Kent, about 1422, and was in his boyhood apprenticed to a London mercer, afterwards Lord Mayor of London, who seems to have been a kindly protector to the young Caxton. When the mercer died, in 1441, Caxton went over to Bruges, became one of a company of English traders who had settled there, and in the course of time rose to be a governor of the company or association. It was while in Bruges that his attention was attracted to some experiments going on there and in other parts of the Low Countries, as well as in Germany, for the construction of a system of mechanical printing—the reproduction of words and sentences by means of a stamping process which should make the reproduction capable of infinite repetition. It may be that the attention of Caxton was originally drawn to the importance of some such process of rapid and multiple production not merely by the interest he always took in the reading of books but also by the fact that during a great part of the time which he spent in the Low Countries he was engaged as copyist to a family of high rank. His attention was soon caught by the efforts going on for the introduction of some method of providing reading matter for the public otherwise than through the toil of the human hand.

The First Printed Book. Caxton made up his mind that his best business in life was to become a producer of books, not merely in the capacity of an author but in the capacity of one who supplies the public with books almost any number of which can be produced within a limited space of time, and can be read without straining the eyes of the student. In the preface to his first printed work he tells of the trouble it cost him to copy with the pen: "My hand weary and not steadfast, mine eyes dimmed with overmuch looking on the white paper. Therefore I have practised and learned at my great charge and dispense to ordain this said book in print after the manner and form as ye may see, and is not written with pen and ink as other books be, to the end that every man may have them at once, for all the books of this story here emprynted as ye see were begun in one day and also finished in one day."

This first book printed in the English language was printed in Bruges under Caxton's instructions; but after he had made England his home, and had taken service as a kind of household manager and secretary with Margaret, Duchess of Burgundy, sister of Edward IV., he brought out the first English book actually printed in England—"Dictes and Sayings of the Philosophers," published in 1477. Caxton now set up a printing press at the sign of the Red Pale, in the Almonry at Westminster, and although he was now growing old—he died about 1491—he threw himself into his new work with an energy which would have done credit to youth.

Development of Printing. The public seems to have been taken at once with the opportunity thus offered of having an almost unlimited number of copies of some popular work put into circulation at the same time. England cannot claim to have been the first to bring out printed books, but she may claim to have been the first to make the printing of books a regular institution, and to have found for them a steadily increasing public.

Caxton was a lover of literature, and he gave to the world printed versions of all the English poetry then to be had, foremost amongst which was his edition of Chaucer's "Canterbury Tales." He collected and printed the poems of Gower, he gave to his readers a version of the Æneid, taken from a French translation, and some of the writings of Cicero. Caxton's own tastes led him to a pure and simple English style, free from the pedantic affectations delighted in at that time by writers who had not yet recognised the fact that a new epoch was arising for the English language as well as for the English people. He made translations of his own, and he helped to put together many books which had to do with the trade and commerce of the time. Many of the productions of his printing press are still preserved, either in complete copies or in treasured fragments, kept as heirlooms in families or carefully guarded in public institutions. The printing art spread rapidly over a great part of Europe. There were printers busily occupied during the days of Caxton at Rome, Venice, and Milan, while France, Germany, and the Low Countries became occupied at a very early period in the great new movement. A new world of letters was beginning to grow up, and the clearest practical evidences were given that humanity was no longer content to live intellectually on the bequests consigned to it by the ancients. Science was also beginning to makes its existence known—science, that is to say, as we understand it now, the study of actual realities, and the discovery of systems founded on careful calculation and comparison of figures and facts, and not the mere theories and exalted speculations of gifted philosophical imaginations.

Invention of Gunpowder. Not very long before the discovery of the art of printing—indeed, almost about the same time—another art had been discovered which had a very different effect on the whole subsequent history of mankind from that wrought by the use of printing—the art of making gunpowder. The invention of gunpowder is generally believed to have been the birth of one of the closing years of the fourteenth century. There are, indeed, some theories that it was in use long before that time in China and in Hindostan, and it is certain that Roger Bacon, who died in 1292 or 1294, mentions in one of his treatises the existence and the use of such a composition. But the uses of gunpowder as the great weapon of war had only come into recognised and universal application a short time before the printing press had created a new era for literature, for science, and for popular education.

The earliest effect of this new ingredient in the making of war was to render the sovereigns and nobles more powerful than they had ever been, and to give, for the time, a lessening chance to any popular efforts towards the resistance of tyrannical and oppressive laws and forces. When the weapons to be used in war were only made of iron and steel, the peasant insurgent could use his edged and pointed weapon, however rude its construction, with much the same effect as the knight could use his burnished sword blade or polished lance-head. But the making of gunpowder required science and skill, large capital, and the employment of scientific artificers, and was not to be accomplished by sufferers from oppression who belonged to the humbler classes. There came a time, indeed, when gunpowder was made to serve the cause of popular revolution as it had served the cause of dynastic and feudalistic oppression, when it became the servant of plebeian uprising as readily as that of patrician down-trampling.

Christopher Columbus. The discovery of that vast region which we still call the New World belongs to this period. Christopher Columbus was born in Genoa, in 1447, and was brought up by his parents to the business of a wool-comber. He soon developed a passion for the life of the sea, and at fourteen years of age he became a sailor. The vessel on which he was engaged had many fights with roving galleys belonging to Tunis, and the young man underwent several perilous adventures. As the result of one of these, he had to escape on a plank from shipwreck, and was flung ashore on the coast of Portugal. He settled in Portugal for a time, and there became possessed with the belief that a new way, and the best way, for reaching India would be by sailing westward. He formed elaborate plans for an expedition with that purpose. He submitted his project to King John II. of Portugal, later to Henry VII. of England, and still later to Isabella, Queen of Castille His plans were at first rejected, but Columbus was persevering, and pressed them again and again, and after seven years of alternating hope and despondency he succeeded in securing the patronage and support of Ferdinand and Isabella—then rulers of Spain His plans were accepted in April, 1492, and on August 3rd in the same year Columbus, now an admiral, set out on his voyage of discovery in command of a small vessel, the Santa Maria, with a crew of fifty, accompanied by two smaller boats. In his first voyage he came upon the Bahamas, and afterwards reached Cuba and Hayti. In his second voyage he came upon Dominica in the West Indies. These voyages were disturbed by many wrecks, and he found it hard to keep up in his crew the nerve and the patience needed for such adventures.

Discovery of America. After many quarrels with his associates and a long illness he returned to Spain in deep depression, but not yet content to abandon all his hopes. He organised a third expedition, the result of which was the discovery of the South American continent. His last great enterprise was a voyage in which he found his way to the south side—the Gulf of Mexico. Columbus had discovered North and South America, won for himself an undying fame, and opened out an entirely new world for all explorers and settlers. The fame he acquired was not the fame which he had sought, and it might almost be said that he became, in spite of himself, the greatest discoverer of new realms that humanity had ever known.

We shall have to trace the growth of North and South America, and especially the manner in which the northern continent came to be one of the most important and powerful among the states of the world, the shelter and the home of people from all regions of the earth, and how it gave to the republican principle of government its most enduring illustration since the birth of Christianity. Columbus settled in Spain after his great discoveries, where his most powerful, enlightened, and generous supporter was Queen Isabella. But the greatness and importance of his discoveries made enemies for him there, because ambitious nobles and others believed that Columbus was bent upon a career of self-aggrandisement at the expense of all opponents.

Columbus died on May 20th, 1506, at Valladolid, little more than a year and a half after the death of his patroness and friend Queen Isabella, and at the time of his death he was suffering severely from the injustice and persecution employed against him by the Spanish Government. It is a characteristic illustration of how Columbus failed to have early justice done to his career that the two great continents which he discovered should not have recognised him in their established name. We have North America and South America—the name of each continent taken from that of Amerigo Vespucci—a Florentine who was a provision contractor at Cadiz. During the early part of Columbus's career Amerigo Vespucci had contracted to supply him with provisions for some of his expeditions, and later on he made a voyage to the New World on the track of Columbus, on the strength of which he afterwards claimed to have been the first to discover the continent.

The First English Settlement in America. That New World remained for a long time mainly an exploring ground for Spanish colonisation, and the names of Cortes and Pizaro will always be associated with certain parts of it. There were many French conquests and colonisations there—and, indeed, most of the states of Europe sought for settlement on its territory. The first English settlement in America was accomplished by Sir Walter Raleigh, at Rowanoak, Virginia, which was called after the Virgin Queen Elizabeth. The discovery of the New World, and the opening it gave to the enterprise of Europe come appropriately in this chapter because they bear testimony to the spirit of practical and scientific discovery and inquiry which forms so impressive a characteristic of the whole period. The struggles going on about the same time between rival states in Europe did not prevent European sovereigns from encouraging adventurers and explorers of every kind to seek out territory in the newly-discovered world, and to annex new dominions to the seignorial possessions of European crowns. The two great American continents give evidences of the rush which was made upon them by foreign invaders, but while North America came more and more into affinity with England, the continent of South America was from first to last the colony of various states on the continent of Europe.

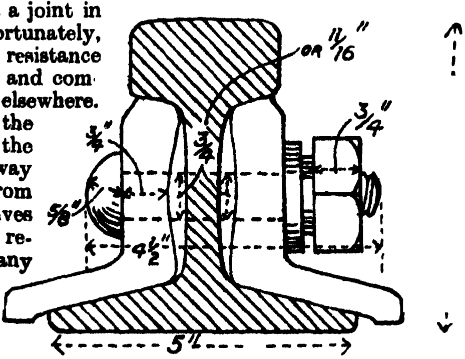
RAILWAY CONSTRUCTION continued from page 3437

By R. W. WESTERN

Rail Joints. The simple expression *rail joints* comprises what has always been, and still is, one of the main difficulties of making a satisfactory railway. The forms of joint are innumerable; none is perfect. A common form is shown in section in 51.

To understand the requisites for a good rail joint it is necessary to have a clear idea of the mechanical action of the loaded wheel passing along the rail. The rail is bent concave upwards between the sleepers between which the wheel is at the moment, and concave downwards both in front and behind, but particularly in front. The action will be better understood in detail by the light of the theorem of three moments. Thus, as an engine moves over the line it is accompanied by a wave in the rails which subjects the upper and lower flanges alternately to tension and compression. When this wave reaches a joint in the rails, it reaches, unfortunately, a place at which the resistance offered both to tension and compression is less than elsewhere. Consequently the rail, the immediate support of the wheel and flange, gives way unduly at this spot, and from the very fact that it gives way, this spot, of course, receives heavier jolts than any other part. There is a popular belief that the shock which is often distinguished in a railway carriage as the wheels pass over a joint, is due to the gap provided for the expansion of the rail on a rise in temperature. This, however, is not the case. Similar gaps filed in the head of the rail away from the joint cause no appreciable shock as the engine passes. The jolt at the joint is due to the weakness inherent in the joint, and until the perfect joint is discovered the jolt is inevitable.



51. COMMON FORM OF RAIL JOINT

The *stiffness* and *moment of resistance* of a rail at the joint should be the same as elsewhere. This condition has been the aim of all designers of rail joints, and it must be the object of all whose business it is to see that rail joints are made and maintained that these conditions are as nearly perfect as circumstances permit.

Provision for Joints. The joint is supported by placing the sleepers on each side of it closer together than the others. In light railways the joint may be placed on the top of a sleeper. This method cannot be used on heavier lines, as the weakness of the joint causes pressure at this point to be less distributed than elsewhere, and the sleeper over which the joint is placed is soon knocked out of level.

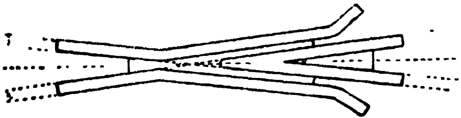
The plan of making the rails *break joint*—that is to say, placing the joint of one rail half-way between joints of the other—is sometimes practised.

Care must be taken that the proper odd lengths of rail are used in curves, as otherwise the sleepers will come to be unevenly distributed, producing an ununiform road-bed. Thus, if there be a sleeper at each joint and five between, the effect of the joints in the inner rail being displaced forwards on rounding a curve is to bring the sleepers under the first part of the next rail nearer together, and this defect continues after the curve is passed and until corrected. The advantage of making the rails to break joint is the increased resistance which is thereby given to any lateral displacement of the line.

In general, the joint sleepers in the case of a suspended joint should be a distance apart equal to six-tenths of the distance apart of the intermediate sleepers. A *suspended* joint is a joint placed between two sleepers, which are called *joint sleepers*. The advantage of longitudinal sleepers in facilitating the design of a good rail joint will now be understood.

Testing of Rails. Rails are generally tested at the works where they are rolled, those responsible for the quality of the material used for the railway stipulating for facilities for overlooking the whole process of manufacture. Both chemical and mechanical tests are required to establish the value of a steel rail. The suitability of the metal chiefly depends upon the quantity it contains of various metaloids—carbon, phosphorus, silicon, and sulphur. The effect of these substances upon the properties of steel may be studied in another section. For the present purpose it is sufficient to say that sulphur should be absent, phosphorus should not exceed 1 per cent., silicon should not exceed ·2 per cent., carbon should exist in quantities between ·33 and ·45 per cent., a rather larger proportion being allowed for heavy rails, but not more than ·55 per cent. in any case.

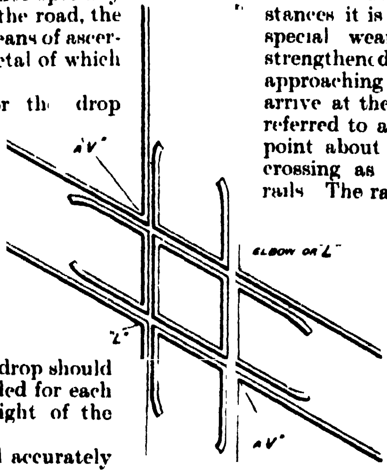
A high proportion of carbon renders the rail very much harder, and therefore more resistant to wear, but at the same time it renders it brittle, so that a high proportion of carbon is suitable only for strong, well-built roads, over which a great deal of heavy traffic passes without much shock. From this it will be seen that a high carbon steel is not suitable for new construction at all, since, however carefully built, a recent construction is always liable to irregular settlement, and new roads seldom have very much traffic to deal with at first. The presence of nickel adds to the durability of a rail, and nickel steel rails have been used for this reason on curves over which a heavy traffic passes, but the advantage here conferred has to be carefully balanced against the extra cost of introducing the nickel. The inspector for the railway is usually furnished by the manufacturer with an analysis of the steel made each day from drillings taken from a test ingot.



52. A FROG

Mechanical Tests. The mechanical tests include the ordinary determinations of elastic limit, ultimate strength and elongation at rupture, but in default of these or in addition to them it is very common to resort to the drop test. Where rails are not specially rolled for the construction of the road, the drop test furnishes a ready means of ascertaining the quality of the metal of which they are composed

The Drop Test. For the drop test the rail is placed on solid supports 3 ft apart, and a ton weight is allowed to drop upon the rail midway between the supports The total length of the rail should not exceed 6 ft., or the weight of the overhanging portions will add to the resistance of the central part. For rails of 50 lb. weight to the yard the drop should be 14 ft , and 1 ft. may be added for each increase of 5 lb. in the weight of the rail per yard



53. LARGE ANGLE CROSSING

The rails should correspond accurately to the prescribed weight. Variations in section should not exceed $\frac{1}{32}$ in.; variation in length should not exceed $\frac{1}{4}$ in. The holes for the bolts at the joints must be accurately placed, and must be clean—that is, free from burrs.

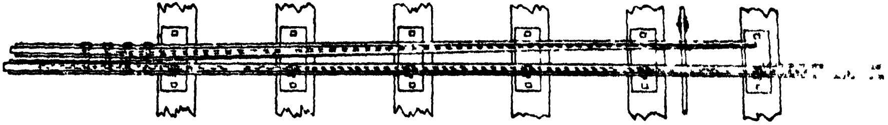
Rails must show no irregularity on top, but be perfectly smooth; the ends must be cut precisely at right angles and all burr removed. It is convenient if the name of the manufacturer be rolled in raised letters on the side of the web of the rail, together with the date, and it is sometimes provided that the number of the "blow" shall be stamped there, so that if a number of rails from one blow prove defective, the remainder may be identified. The *heat treatment* of steel should be studied in the article on metallurgy, as the future useful service of the rail greatly depends upon it. Rails being *the* essential things about a railway, it is impossible to know too much about them.

Points and Crossings. The advantage of constructing the tyres of the wheels of rolling-stock with flanges in order to guide them along the rails is accompanied by the drawback that, whenever it is desired to transfer rolling-stock from one set of rails to another, the continuity of the latter must be broken. Gaps set in the rails to permit the passage of wheel flanges are called *crossings*.

The Frog. A diagram is given [52] of the gaps provided at the place where two lines of way first come into contact; it is often referred to as a *frog*. The point in the middle where the dotted lines are seen to cross each other is the centre of the crossing It will be seen that the two rails approaching each other from the left meet in a point which is not extended to the centre of the crossing, but rounded off before this is reached. There is danger lest the flanges of wheels passing from right to left should strike this point if it be advanced too close to the centre of the crossing Under any circumstances it is a place that is subjected to special wear, and must be fixed and strengthened with special care. The rails approaching each other from the right arrive at their minimum distance apart—referred to as the *throat* of the frog—at a point about as far from the centre of the crossing as the termination of the other rails The rails then increase their distance apart, and pass on each side of the opposing rails, forming a guide for the outer side of the flanges of the wheels of the rolling stock, and are finally splayed out to avoid any danger of being struck by the flanges of wheels coming from the other direction.

The Angle. The inclination of the two sets of rails to each other is the *angle of the crossing;* it is commonly referred to by number; the number is half the cotangent of half the angle.

Clearance. Lines may cross each other at any angle. In order to understand the provisions which should be made to enable this to be done with safety, it must be remembered that the flanges are upon the inner sides of the wheels and project about an inch beneath the level of the top of the rails, also that the distance between the side of the flange in contact with one rail and the side of the flange in contact with the other rail is rather less than the gauge of the railway—that is to say, there is always some play or *clearance* between the rails and the wheel flanges. When two lines of way cross at a large angle, as is shown diagrammatically in 53, a jolt as the wheel passes over the gap cannot be avoided. When, however, as in 52, the crossing is made at a small angle, the jolt is very greatly diminished, if not entirely obviated. The effect of the acuteness of the angle of crossing is to bring the gaps in the rails into the form of an elongated parallelogram; and since the breadth of the tyres of the wheels is always made greater than that of the top of the rails, the wheel will have already reached the new rail before it has entirely left the old.

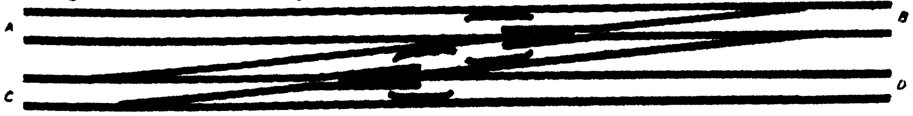


54 RAILWAY POINT

Guide Rails. It will be seen in 53 that additional rails are provided inside the usual rails to guide the wheels by confining the movements of the flanges on their outer sides. This has already been referred to in 52 The effect of these is to provide that at the moment when one wheel is passing a gap, and therefore not so completely under the guidance of its flange as at other times, the other wheel fixed to the same axle is provided with a rail on each side of its flange, so that any tendency to movement from side to side is sufficiently opposed.

55. SECTION OF RAILWAY LINE SHOWING POINTS

Switches and Points. One means of diverting a train from the track upon which it is running to another line of way has been sufficiently described in the account which has been given of the contractor's or temporary railway. These contractor's crossing and *stub* switches have been constructed with elaboration for permanent use, but have not been found satisfactory. On the permanent way the diversion of rolling stock is now universally accomplished, in the first instance, by means of a switch and completed by an *elbow* or "L," a gap in the rail, of which an example will be seen in the centre of 34. The *points* or *switches* are names given to pointed rails that can be switched aside so as to be passed by the wheel flanges either on one side or the other, according to the position of the points. An illustration of a point, together with the *stock* rail or ordinary rail with which it is associated, is given in 54. The points are well illustrated in the photograph [55]. The length of the switch, often called *tongue* rail, is usually about 15 ft. At the thick end it is pivoted, and here its cross-section is the same as that of the stock rail; its distance from the stock rail at this end must be sufficient to allow the flanges of the wheels of the rolling stock to pass between. At the other end it is pointed, and the movement of the pivot is to enable this end to be moved, either away from the stock rail so that the flanges of the wheels can pass at this end also, or close against it, so that the point comes between the wheel flange and the stock rail, thus diverting the wheel and causing it to roll upon the switch

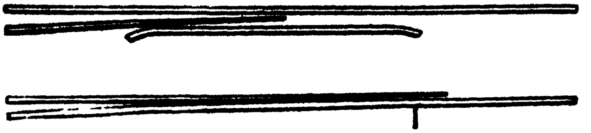


56. ORDINARY CROSS-OVER ARRANGEMENT OF RAILS

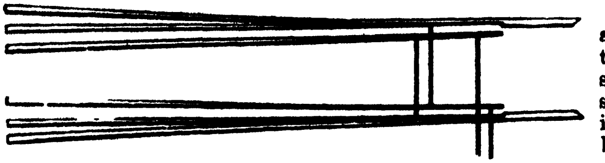
Cross-over Road. Fig 56 shows diagrammatically the very ordinary arrangement provided for crossing from one to another of two parallel roads The position of the frogs and switches and the guide rails will at once be recognised The photo [55] also contains several illustrations

Trailing Points. It will be seen [56] that trains passing from A to B come upon the point rails at the *heel* or pivot end first Thus, whatever the *position of the points*, the direction of the train could not be affected by them, and the pressure of the flanges of its wheels would tend to press the point rails into their right position and retain them there.

Facing Points. On the other hand, trains passing from B to A would come upon the

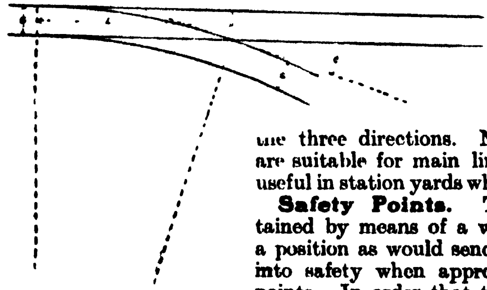


57. THE MOST SIMPLE SYSTEM OF POINTS



58. THREE-THROW POINTS

point rails, point first. Thus, if these were not in the right position the train would go wrong, and if, while the train were passing, the points where changed in position, the train would be broken in two, by the latter part of it being differently directed to the first. Facing points are, therefore, very much more dangerous than trailing points, and should be avoided wherever possible. Thus, if 56 be taken to represent a double line of way, the direction of traffic would be from A to B and from D to C, and not the other way about under any avoidable circumstances.



59. TURN-OUT FROM MAIN LINE

Locking-bar. In places where facing points cannot be avoided, the mechanism by which the points are shifted is best connected with a bar called a locking-bar, disposed on the inner side of one of the stock rails so as to be locked or fixed in its position by the flanges of the wheels so long as a train is passing or standing over the points. The points, being immovable while the locking-bar is fixed, are kept in one position, whether right or wrong, until the whole train has moved by. The mechanism by which the points are moved is simple in principle but exceedingly complex in application. It consists essentially of a series of links and elbows or bell cranks, such as are arranged by the bell-hanger about the domestic house. Since movements must be provided in both directions, rods must generally be used instead of wires, and the levers are usually connected with the signalling apparatus in such a way that the position of the points is known by the position of the signals.

Interlocking. The details of the mechanism by which these effects are produced and controlled from the signal-box are various and complicated, especially at crowded junctions, where there are often many acres of ground covered with crossing and branching lines of way. In these situations electric methods are now being introduced.

Varieties of Points. Points are not necessarily provided with more than one tongue. Thus, in 57 is shown diagrammatically what are still called points, though only one is, in fact, a movable point. It will be seen that the movement of this switch at the bottom of this figure will suffice to change the direction of a pair of wheels coming from the right, so that on reaching the fixed point at the top of the figure the flange of the wheel on that rail will already have been brought into the right position to pass it, whether on one side or the other. In 58 three-throw points are shown diagrammatically. Here more than one set of points are introduced at the same spot, and a train coming from the right may be sent in any one of the three directions. Neither of these devices are suitable for main line traffic, but are often useful in station yards where the space is confined.

Safety Points. These are points maintained by means of a weight or spring in such a position as would send a train or engine, etc., into safety when approaching them as facing points. In order that the train or engine, etc., may be sent in the alternative direction, someone must lift the weight or release the spring. There are many situations where this device is useful; it is often provided for sidings lest

60. CROSS-SECTION OF CULVERT

the trucks therein be blown by wind or otherwise brought on to the main line by accident

Design. Points and crossings are critical parts of the permanent way; they are subject to special wear, and must be specially designed and supported The great majority of railway accidents are due directly or indirectly to defects in their parts. The approximation of the sleepers has already been shown in 34 The actual dimensions of the metal contained in the frogs and switches depend upon the section of the rail in use, the gauge of the line, and other circumstances A junction or crossing may have to be effected at very different angles

One line may be straight and another curved, or both lines may be on the curve, and they may be curving in the same or in the opposite direction, introducing trigonometrical problems of some complexity.

A Turn-out. In 59 the simple case of a turn-out from the main lines is exhibited diagrammatically Here G represents the gauge of the railway in feet, R the radius of the curve by which the turn out is effected, and A the angle of the crossing; L, the distance in feet between the springing of the curve from the main lines and the centre of the crossing, is called the *lead* The following relations are immediately obvious:

$$L = G\cot\frac{\theta}{2},$$

$$R = \frac{G}{1-\cos\theta} - \frac{G}{2}$$

The two rails of the line turning out of the other have, of course, radii of curvatures differing by G, the width of the gauge separating them R is the radius of curvature of the centre line

A convenient form for expressing the lead is $\sqrt{(R_1+R_2)G}$, in which R_1 and R_2 are the radii of curvature of the two rails respectively

In the foregoing, it is assumed that the points are placed at the springing of the curve and are themselves curved to the proper radius, also, that the lines of the frog are also curved. These conditions rarely obtain except in street railways when curves are sharp, consequently, in careful work the fact that these portions of the turn-out are straight lines must be taken into account. It is, perhaps, well to point out that considerations of space have caused the curves in 59 to be drawn very much sharper than they would be made upon the main lines of an ordinary passenger railway.

61. CROSS-SECTION OF CULVERT

Weight of Rails. The proper weight of rails for a railway may be calculated from the following formula:

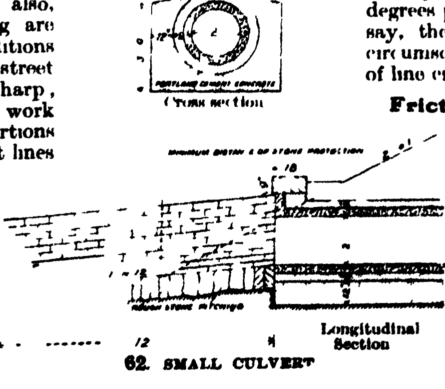
weight per yard (linear) $= 17\,(E + .0001\,EV^2)^{\frac{2}{3}}$

where E is the maximum load on one wheel in tons and V is the maximum speed in miles per hour

Thus, if the maximum load on one wheel were 10 tons and the maximum speed 40 miles per hour, the rails should weigh 87 lb per yard, or about 75 tons per mile of single line

Curves. The curves of a railway are described either according to the length of the radius of the circle of which they form part of the circumference, or according to the angle at the centre of the circle which is subtended by a chord 100 ft in length Thus a 6 degree curve would be, approximately, the same as a curve having a radius of 955 ft, and a 15-chain curve would be, approximately, the same as a 5 deg 44 min curve The amount of curvature is usually referred to as so many degrees per mile of line – that is to say, the total number of degrees circumscribed divided by the length of line circumscribing them

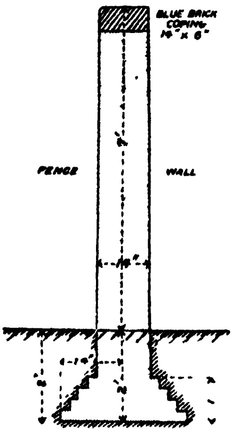
Friction on Curves. The extra wear and resistance to traction due to curvature is of course greater on a sharp curve than on a comparatively flat curve, but the length of the latter is proportionately greater, so that the aggregate effect of the curvature is governed by the magnitude of the sum of the central angles



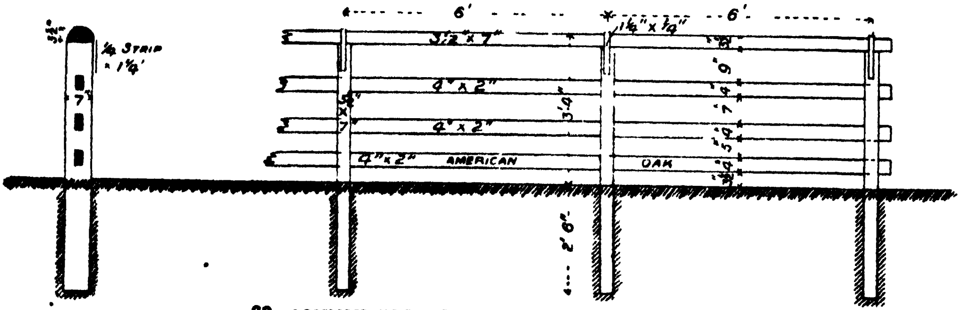
62. SMALL CULVERT

of the curves about which the rails are turned. Curvature to the amount of 600 degrees per mile would have the effect of doubling, approximately, the resistance to traction; it would indeed offer about the same resistance to traction as an incline of 1 in 100, and be very much more objectionable—first, because the resistance would be the same both ways; secondly, because the wear would be much more both on rails and wheel tyres.

The interaction of tyres and the rails will be best understood by referring back to 37. The surface of the former, which comes into contact with the top of the latter, is called the *tread*. This is always shaped in the form of a cone. The coning is slight, and not sufficient to be very obvious, but, were the surface of the treads to be extended, a double cone would be formed, having an apex on the outer side of each wheel and in line with the axle. Hence, when running upon a straight portion of the line of way, the wheels will tend to take a central position, with each flange clear of the rail. When running upon a curve, the flange of the wheel on the convex side of the curve will be scraping against the side of the wheel, except so far as this is modified by *superelevation*, which will be explained later. The effect of the wheels being fixed to the axle and thus necessitating the slipping of one of them an inch for every degree of curvature, has already been dealt with in treating of the wear of the rails and length of the rails This effect is in some degree modified by the coning of the heads, since the portion of the tread in contact with the outer rail is rather larger in diameter than the portion of the tread in contact with the inner rail, and will therefore move further than the latter during a given number of revolutions. Thus on a curve of about half a mile radius there would be little or no slipping from this particular cause. There remains, however, another result of curvature of the line, and by no means the least important. All road carriages have a *locking* arrangement, as it is called—that is to say, the axle upon which the two front wheels are attached, and to which the shafts, or, in a motor-car, the steering-gear is fixed, is movable about a vertical axis. It is sufficient to point out here that the absence on railway trucks, etc., of anything equivalent to the locking apparatus of a road carriage, causes on curves exactly the same amount of scraping and friction with the road as would result from turning a corner with an ordinary four-wheeled vehicle when the locking was jammed fast. While passing round a curve the carriages of which a train is composed form angles with each other, and on any change of curvature or reversion to the straight the buffers of the carriages—when lightly coupled—grind against each other.



64. SECTION OF WALL



63. COMMON TYPE OF POST AND RAIL FENCE

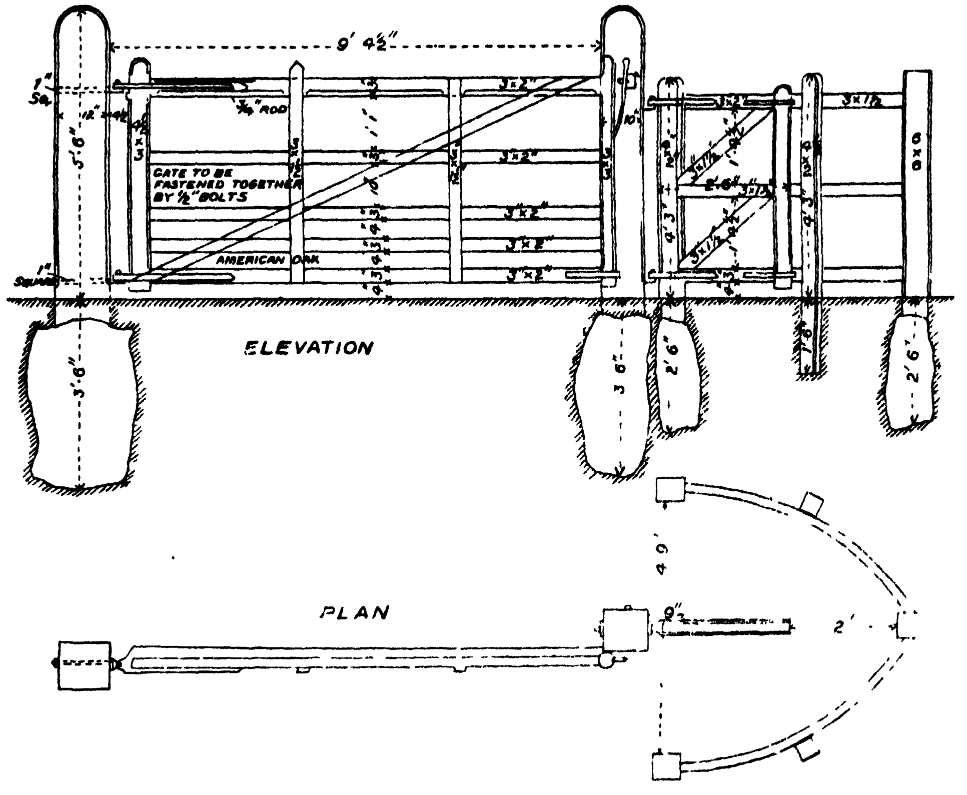
In modern railway design, the numerical results of the effects of curvature upon the capital and annual expenditure is carefully calculated.

Superelevation. According to the first law of motion [see Physics], a train will continue to move on in the same straight line until acted upon by a force sufficient to divert it. On reaching a curve in the line this force is supplied by the pressure of the outer rail of the curve on the flanges of the outer wheels of the train, save as hereinafter explained. It is, of course, undesirable that all the pressure should be provided by pressure on one side of one rail, when by raising the level of the outside rail of the curve sufficiently above that of the inside rail of the curve the needful pressure would be exercised by both rails, and upon their upper surface.

The outer rail of the curve should, therefore, be raised sufficiently that the component of the force of gravitation in a plane parallel to that of the rail-tops shall suffice to divert the path of the train to the degree required by the curvature. The amount by which it is raised is called the *superelevation*. If all trains moved round a curve at the same rate the superelevation could be calculated to fulfil perfectly the conditions above set out, so that the wheels would pass with their flanges equidistant from the rails, as before explained. However, all trains do not move round a curve at the same rate, so a compromise must be adopted according to the traffic conditions. The application of elementary mechanics will show the superelevation for a line of standard gauge to be $\cdot 4\frac{V^2}{R}$ in feet, where V is the speed of the train in miles per hour and R the radius of the curve in feet. Of course, on curves with an up grade the average speed, and therefore the superelevation, will be less, and where trains are to pass in both directions another compromise must be effected so that superelevation only partially counteracts one source of friction upon curves.

Transition Curves. So far, it has been assumed that the curves of a railway line are throughout the arcs of circles. Now, a circle is a curve of uniform curvation; immediately a train or, rather, a pair of wheels, enters upon a circular curve, it begins to turn, and continues to turn at the same rate until it passes out of that curve. The superelevation ought, therefore, to be as great at the beginning as at any other part of a circular curve. This is seen in the form of the expression for it already given. $\frac{\cdot 4 V^2}{R}$ depends only upon the speed and the radius of curvature. But the outer rail cannot be suddenly raised 4 in. or 5 in., as the case may be, at the tangent point where the curve begins, or similarly depressed at the end of the curve. The superelevation must, therefore, begin before the curve and be increased upon the curve, being there too much and here too little, and causing a lurching of the train very unfavourable to steady running.

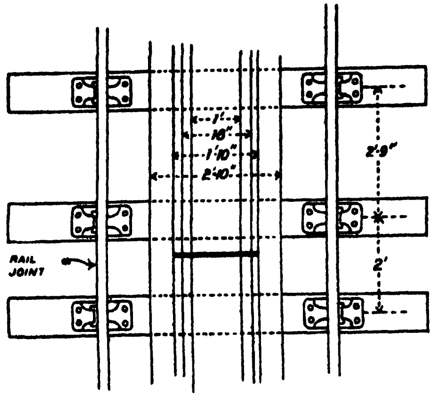
Obviously, therefore, the right thing to do is to begin the curve at tangent point with a circle of infinite radius for which the superelevation would be nothing, and continue it by reducing the radius of curvature and at the same time increasing the superelevation, until the desired radius of curvature and its proper superelevation were gradually attained. The mathematics involved in such procedure is complicated, and though tables have been computed by the help of which transition can be made in this manner, it is more usual to introduce a short cubic parabola between the circular curves and the straight portions of the line wherever required for the safety of the service, or for the comfort of the passengers.



65. GATE AND WICKET FOR LEVEL CROSSING

See the articles on Surveying for the means to be adopted to lay out a cubic parabola.

Waterways. The bridging of rivers and brooks is dealt with in another article. It remains, however, to treat with exceptional rainfall. This is not conspicuous in our favoured islands, but most countries at intervals of 10 years or 20 years (or oftener in the Tropics) are subject to storm-bursts, etc., when water appears in places which are at all other times dry, in quantities sufficient to demolish long stretches of railroad unless provision has been made to deal with them. To this end the character of the rainfall, the soil, and the area drained must be examined. The question to decide is: How much of the rain falling on one side of the railway must pass it to the other side and in what time? An inch of rain in 15 minutes is, of course, a very different thing to an inch of rain in an hour, since the latter has four times as long to run away. A porous soil will soak up a lot of rain, whereas a clay soil will allow nearly the whole of it to run off; and the same thing will occur on porous soil if a storm-burst occurs after a rainy period when the soil is saturated. If the drainage area stretched away from the railway a long distance, the water from it will arrive in more manageable amounts than if it were all within a short distance of the railway.



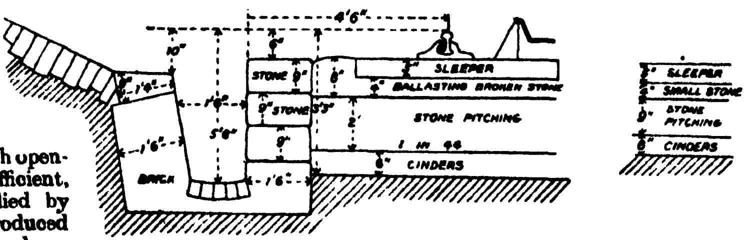
66. PLAN OF RAILWAY WATER TROUGH

Area of Opening. The first rough idea of what area of openings through the line will be needed to carry off flood water may be gained by applying the formula

$$A = C\sqrt[4]{S^3},$$

where A is the number of square feet required for the openings, S the area drained in acres, and C a constant quantity; to be taken equal to 1 or ·7 for steep, rocky localities, ·3 for rolling country, and ·2 or less where the drainage area stretches away from the line a distance five or six times its width.

If, then, the area drained were 10,000 acres of ordinary agricultural land the number of square feet of opening required would not be less than 200 ft. or more than 700 ft. This is a very wide margin in which to exercise judgment. In order to narrow it down it will be of great assistance if there are other roads near by the openings in which it may be examined and compared. If such openings have proved sufficient, the value of C implied by their size may be introduced with confidence in the above calculation. Marks left by the high water of previous floods should be carefully sought; in default of similar structures to go by, they will often serve as a guide to the maximum of water to be dealt with.



67. SECTION OF RAILWAY WATER TROUGH

Culverts. The openings in the line to allow for the appearance of exceptional floods like those for the bridging of small perennial streams, are called *culverts*. Cross-sections of these are shown in 60 and 61. It will be seen that they are of brick, and substantially built, with a strong arch above to transmit the pressure from above, and an invert arch with concrete foundations to distribute the pressure over the earth below. In spite of the latter precaution it will frequently be found that the culverts in a high embankment have been bent downwards in the middle by pressure of the superincumbent earth. Smaller culverts may be built in the manner shown in 62, where the end elevation and longitudinal section as well as the cross-section is shown. Culverts, particularly a culvert of circular section, as this is, may be permitted to run full or even with a *head* as a level of water higher than the height of the inside of the culvert on the up side is called. In general, however, it is best to make the culverts sufficiently large to prevent flood water "backing up" agains the railway bank.

Points about Culverts. It is in all cases important to preserve the embankment near the openings of culverts from the erosion of the water entering or leaving them. Thus, wing walls are often provided like those attached to ordinary bridges, but on a smaller scale. In 62 the culvert is shown provided with a flat face, and a channel of stone pitching sloped at 1 in 12 and 12 ft. long, is built at the down end to carry away the water rapidly and safely. The culvert itself should have a slope of 1 in 20. Cast-iron pipes are also useful for small culverts, and those too defective to carry water under pressure are often good enough.

A culvert may sometimes be economically roofed with old iron rails placed contiguously. Indeed, there are a great many uses about a railway to which old sleepers and iron rails may be put.

The earth on each side behind the walls of a culvert must be rammed hard and not tipped loosely over it to be consolidated by time and the weight of more earth on the top. Thorough ramming, as described, will relieve the culvert itself of much pressure and serve to sustain it against the tendency to curl beneath the weight of the bank as it settles. If the crown of a culvert be allowed to approach too near formation level, there is sure to develop a bump which will be very perceptible as an engine passes above it, and which once established is most difficult to cure. The crown of a culvert should, therefore, be kept 3 ft. or more below the formation level.

Fencing. A well-grown hedge forms the most economical fence where the soil, etc., is suitable, but it takes some time to grow. Supplemented by barbed wire to prevent trespass it makes a very satisfactory boundary. Innumerable other forms of fencing are in use. A common type of ordinary post and rail fence is shown in 63. When a wall is necessary, the dimensions given in 64 are necessary and sufficient.

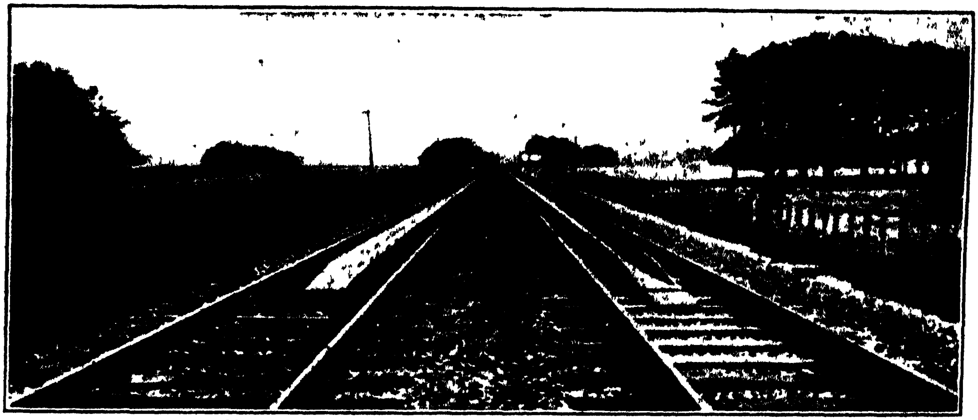
It frequently happens that gates must be provided in the fence to enable farmers' carts, etc., to cross the line. A common example is shown in 65, in which a side wicket is introduced for foot-passengers. It will be noticed that the gate-posts are squared only above ground and the timber beneath is left in the rough. This gives the post a better hold on the ground, and provides a better defence against decay. The wood under ground should also be charred. If the timber below ground is not left rough, charring will weaken it unduly, and the post in this case should be creosoted, as sleepers are. A stout fence may be constructed of old sleepers where these are available. The sleepers of a standard gauge railway being 9 ft. long permit of a fence 5 ft. 6 in. high, 3 ft. 6 in. being under ground. Old rails may also be turned to account in like manner, though there are generally other more useful purposes to which they may be put.

Water Supply. The water consumed in locomotive boilers is a very variable quantity, and depends chiefly upon the work done by the engine. On down grades it will be small, on up grades it will be high, and heavy trains will involve a consumption greater than light trains, by an amount roughly proportional to the difference of weights, supposing that the same length of line is under consideration and the speeds are about equal. Fifty to one hundred gallons per mile are the usual limits, and stations for water supply should be provided at intervals not greater than 16 miles for the lightest traffic, and as close as 10 or 8 miles on roads over which the traffic is heavy. The general question of water supply may be studied in another article.

Track Troughs. On lines where a quick service is necessary, and long distances must be accomplished without a stop, troughs containing water are placed upon the sleepers between the rails. Passing trains are fitted with a scoop which enters the trough while moving and lifts sufficient water to enable the engine to proceed. Illustrations of such a trough are given, the plan in 66, and half-section in 67. The accompanying photograph [68] shows graphically the section of a railway line with two water troughs. Such troughs are usually placed in cuttings where a natural supply of water can be obtained by gravitation.

By the action of the scoop a great deal of it is spilt over the line, and special means must, therefore, be taken for the drainage of the permanent way in these places. The half-section in 53 shows how this may be accomplished. Two feet of stone pitching is provided beneath the ballast, and 6 in. of cinder below the stone pitching where the troughs are placed, while at the side is shown the diminished thicknesses provided for other parts of the same cuttings. Since the surface of the water in the troughs is necessarily level, the rails are made to slope from the commencement of the trough, so that the scoop enters the water automatically. It is made to leave the water by the same means. As to the quality of water required for locomotive boilers it does not differ from that required for other steam-using purpose.

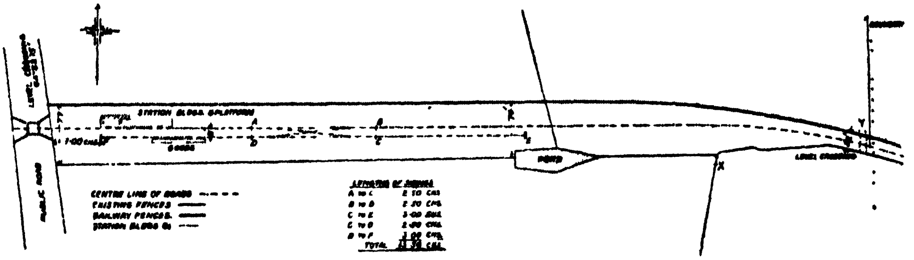
Water Tanks. The water tank on the tender of a locomotive may contain 10 or 20 tons of water, and tanks by the wayside from which the former are to be supplied must be dimensioned accordingly. They should be placed 8 ft. 6 in. from the centre of the nearest track, and about 12 ft. above the level of the rails. It is sometimes necessary



68. SECTION OF RAILWAY LINE WITH WATER TROUGHS

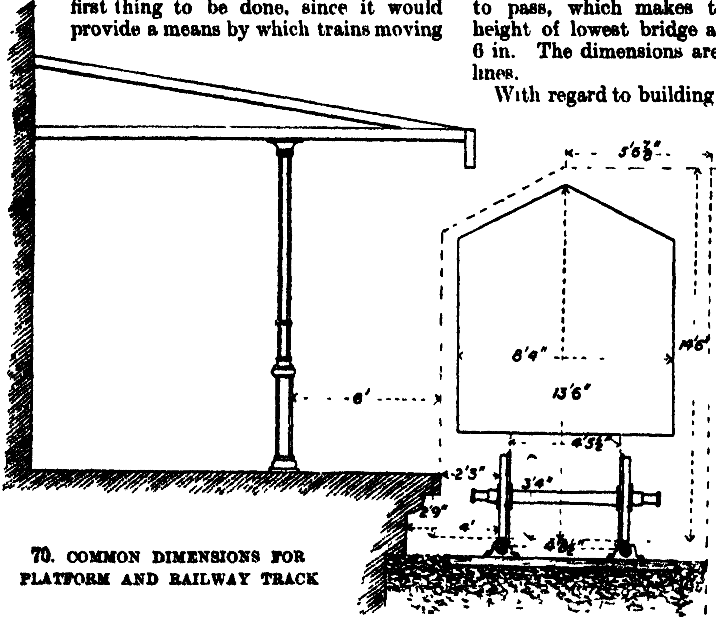
to provide for the injection of steam to prevent freezing, but this applies with most force to the water troughs described.

Stations. Large stations are usually situated in large towns, where the arrangements are always determined to a considerable degree by the configuration of the available ground.



69. A TYPICAL SINGLE LINE ARRANGEMENT AT A SMALL RAILWAY STATION

In **69** is shown the arrangement laid out for a wayside station of a single line of standard gauge railway that is in many respects typical. The sidings c e and *d f* are long enough to accommodate trains of 15 or 16 trucks, and land is provided to enable extensions to be made when and if they are warranted by future increase of traffic. The siding *c e* might be extended in the direction from *c* to *e* to twice its length, and another junction with the main line then made. This would probably be the first thing to be done, since it would provide a means by which trains moving in contrary directions upon the main line might pass each other with less delay; 11 ft. is the usual distance between the centres of adjacent lines of rails. The width of land taken up, therefore, suffices for two more sidings on either side of the lines of rails shown. The platform is most conveniently made 3 ft. high, measuring from the ballast, though it may be less.



70. COMMON DIMENSIONS FOR PLATFORM AND RAILWAY TRACK

Platform Structures. No structure upon the platform should be less than 11 ft. from the centre of the contiguous line of rails. Other distances commonly observed are given in **70**. Here it will be seen that the ordinary width of rolling-stock for a standard gauge railway is 8 ft. 4 in., and its height above rail level 13 ft. 6 in. One foot is allowed between this height and that of the lowest structure under which it should be permitted to pass, which makes the least *headway* or height of lowest bridge above rail level 14 ft. 6 in. The dimensions are shown by the dotted lines.

With regard to buildings and other structures at the side of a line, none should approach nearer than 7 ft. to the centre of a line on which passengers are carried at heights above rail level between 12 ft. 6 in. and 11 ft., or, in the case of a goods line, nearer than 5 ft. 6 in. between the same heights. With other gauges and different rolling-stock these measurements will, of course, be modified, but the illustrations afford a concise notion of what has been found necessary and sufficient on lines of the English standard.

LIGHT RAYS & LIGHT PRESSURE

Rays of Light and their Characteristics. Magnetism and Light. Radiation Pressure. The Weight of Light on the Earth

Continued from page 3473

By Dr. C. W. SALEEBY

THE area which is affected by lupus, when exposed to ultra-violet light, slowly but with practical certainty heals. In marked contrast with the most successful results that can be obtained with ordinary surgery, the diseased tissue is replaced by a soft, pliable scar that can scarcely be distinguished from the original skin with which it is continuous, and that does not contract, whereas an ordinary scar by its contraction produces great deformity. While emphasising the splendid results which have been attained by the employment of ultra-violet light in the treatment of lupus, it is our duty to observe that this light has completely failed to exercise any favourable influence upon cancer, or upon various other morbid states of the skin. In this respect ultra-violet light has proved to be very much inferior to the Röntgen rays.

The Rays of Radiant Heat. We already know that just as there are rays beyond the violet so there are rays below the red. These, indeed, are none other than the rays of radiant heat. When sunlight is spread out into a spectrum, these rays also are sorted out into their places. If we place a highly sensitive thermometer in various parts of the spectrum, in succession, we can precisely ascertain their heating power. We find that the greatest heating power is exercised by a part of the spectrum considerably below the red, and that from this point onwards the heating power steadily diminishes, until at the violet end of the spectrum it has practically vanished altogether. The reader will compare these statements with the practical application of the Finsen treatment.

We clearly understand, of course, that these infra-red rays are related to the red rays just as a C on the piano is related to a D or an E above it. They are in every respect as real as the visible rays. The essential difference between them, from our point of view, is merely that our retinæ are so constructed that we can see the one kind but are blind to the other. In proof of this we may note that, just as there are Fraunhofer lines in the visible spectrum, so there are absolutely identical lines in the infra-red part of the spectrum—lines or gaps where there is no radiation at all, and the explanation of which is identical with that of the gaps the presence of which can be detected by direct vision.

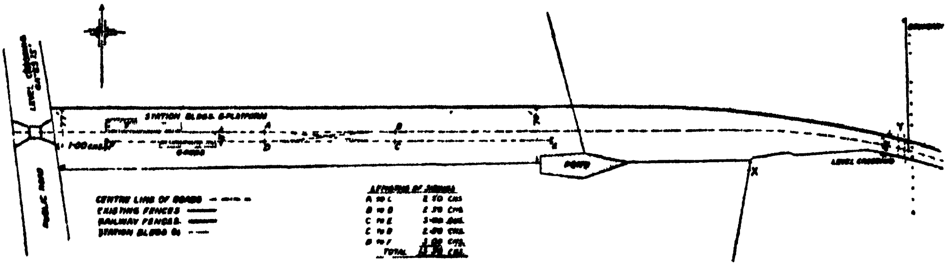
Light and Magnetism. Further aspects of spectroscopy are discussed in considering the chemistry of the stars [see CHEMISTRY]. Meanwhile, however, we must briefly consider a special aspect of spectroscopy which depends upon the relations between light and magnetism. In discussing this subject there is no choice but to use certain phrases the meaning of which cannot positively be understood until magnetism itself has been studied, but we shall reduce their employment to the smallest possible limits.

The relations between magnetism and light are of fundamental importance, and in considering the most important of them we cannot do better than quote freely from the words of Professor J. J. Thomson. He points out that "the first relation between magnetism and light was discovered by Faraday, who proved that the plane of polarisation of a ray of light was rotated when the ray travelled through certain substances parallel to the lines of magnetic force. This power of rotating the plane of polarisation in a magnetic field has been shown to be possessed by all refracting substances whether they are in the solid, liquid, or gaseous state."

It was natural that, having made this great discovery, Faraday should seek to see whether a magnetic field influenced the nature of the light emitted by any luminous body; but Faraday's apparatus was not adequate to bring him success. Ten years ago, however, a great advance was made by Professor Zeeman, of the University of Amsterdam. He found that spectral lines characteristic of lithium and of sodium were decidedly broadened if the flames containing salts of these substances were placed between the poles of a powerful electromagnet.

"Rays of Light in a Magnetic Field." Zeeman found that "in a strong magnetic field, when the lines of force are parallel to the direction of propagation of the light, the line (characteristic of cadmium) is split up into a doublet, the constituents of which are on opposite sides of the undisturbed position of the line, and that the light in the constituents of this doublet is circularly polarised, the rotation in the two lines being in opposite directions." On the other hand, "When the magnetic force is at right angles to the direction of propagation of the light the line is resolved into a triplet, of which the middle line occupies the same position as the undisturbed line: all the constituents of this triplet are plane-polarised, the plane of polarisation of the middle line being at right angles to the magnetic force, while the outside lines are polarised in a plane parallel to the lines of magnetic force." It is not possible here to go into the mathematics of this subject. Professor Lorentz has gone very far to explain the Zeeman effect, and his explanation is entirely in accord with the modern view of the structure of matter [see CHEMISTRY]. The interpretation of Zeeman's observation leads us to believe, first of all, that the bodies which produce the luminous vibrations which the spectroscope analyses to provide for the injection of steam to prevent freezing, but this applies with most force to the water troughs described.

Stations. Large stations are usually situated in large towns, where the arrangements are always determined to a considerable degree by the configuration of the available ground.



69. A TYPICAL SINGLE LINE ARRANGEMENT AT A SMALL RAILWAY STATION

In 69 is shown the arrangement laid out for a wayside station of a single line of standard gauge railway that is in many respects typical. The sidings *c e* and *d f* are long enough to accommodate trains of 15 or 16 trucks, and land is provided to enable extensions to be made when and if they are warranted by future increase of traffic. The siding *c e* might be extended in the direction from *c* to *e* to twice its length, and another junction with the main line then made. This would probably be the first thing to be done, since it would provide a means by which trains moving in contrary directions upon the main line might pass each other with less delay; 11 ft. is the usual distance between the centres of adjacent lines of rails. The width of land taken up, therefore, suffices for two more sidings on either side of the lines of rails shown. The platform is most conveniently made 3 ft. high, measuring from the ballast, though it may be less.

Platform Structures. No structure upon the platform should be less than 11 ft. from the centre of the contiguous line of rails. Other distances commonly observed are given in 70. Here it will be seen that the ordinary width of rolling-stock for a standard gauge railway is 8 ft. 4 in., and its height above rail level 13 ft. 6 in. One foot is allowed between this height and that of the lowest structure under which it should be permitted to pass, which makes the least *headway* or height of lowest bridge above rail level 14 ft. 6 in. The dimensions are shown by the dotted lines.

With regard to buildings and other structures at the side of a line, none should approach nearer than 7 ft. to the centre of a line on which passengers are carried at heights above rail level between 12 ft. 6 in. and 11 ft., or, in the case of a goods line, nearer than 5 ft. 6 in. between the same heights. THE area which is affected by lupus, when exposed to ultra-violet light, slowly but with practical certainty heals. In marked contrast with the most successful results that can be obtained with ordinary surgery, the diseased tissue is replaced by a soft, pliable scar that can scarcely be distinguished from the original skin with which it is continuous, and that does not contract, whereas an ordinary scar by its contraction produces great deformity. While emphasising the splendid results which have been attained by the employment of ultra-violet light in the treatment of lupus, it is our duty to observe that this light has completely failed to exercise any favourable influence upon cancer, or upon various other morbid states of the skin. In this respect ultra-violet light has proved to be very much inferior to the Röntgen rays.

The Rays of Radiant Heat. We already know that just as there are rays beyond the violet so there are rays below the red. These, indeed, are none other than the rays of radiant heat. When sunlight is spread out into a spectrum, these rays also are sorted out into their places. If we place a highly sensitive thermometer in various parts of the spectrum, in succession, we can precisely ascertain their heating power. We find that the greatest heating power is exercised by a part of the spectrum considerably below the red, and that from this point onwards the heating power steadily diminishes, until at the violet end of the spectrum it has practically vanished altogether. The reader will compare these statements with the practical application of the Finsen treatment.

We clearly understand, of course, that these infra-red rays are related to the red rays just as a C on the piano is related to a D or an E above it. They are in every respect as real as the visible rays. The essential difference between them, from our point of view, is merely that our retinæ are so constructed that we can see the one kind but are blind to the other. In proof of this we may note that, just as there are Fraunhofer lines in the visible spectrum, so there are absolutely identical lines in the infra-red part of the spectrum —lines or gaps where there is no radiation at all, and the explanation of which is identical with that of the gaps the presence of which can be detected by direct vision.

Light and Magnetism. Further aspects of spectroscopy are discussed in considering the chemistry of the stars [see CHEMISTRY]. Meanwhile, however, we must briefly consider a special aspect of spectroscopy which depends upon the relations between light and magnetism. In discussing this subject there is no choice but to use certain phrases the meaning of which cannot positively be understood until magnetism itself has been studied, but we shall reduce their employment to the smallest possible limits.

The relations between magnetism and light are of fundamental importance, and in considering the most important of them we cannot do better than quote freely from the words of Professor J. J. Thomson. He points out that "the first relation between magnetism and light was discovered by Faraday, who proved that the plane of polarisation of a ray of light was rotated when the ray travelled through certain substances parallel to the lines of magnetic force. This power of rotating the plane of polarisation in a magnetic field has been shown to be possessed by all refracting substances whether they are in the solid, liquid, or gaseous state."

It was natural that, having made this great discovery, Faraday should seek to see whether a magnetic field influenced the nature of the light emitted by any luminous body; but Faraday's apparatus was not adequate to bring him success. Ten years ago, however, a great advance was made by Professor Zeeman, of the University of Amsterdam. He found that spectral lines characteristic of lithium and of sodium were decidedly broadened if the flames containing salts of these substances were placed between the poles of a powerful electromagnet.

"Rays of Light in a Magnetic Field." Zeeman found that "in a strong magnetic field, when the lines of force are parallel to the direction of propagation of the light, the line (characteristic of cadmium) is split up into a doublet, the constituents of which are on opposite sides of the undisturbed position of the line, and that the light in the constituents of this doublet is circularly polarised, the rotation in the two lines being in opposite directions." On the other hand, "When the magnetic force is at right angles to the direction of propagation of the light the line is resolved into a triplet, of which the middle line occupies the same position as the undisturbed line: all the constituents of this triplet are plane-polarised, the plane of polarisation of the middle line being at right angles to the magnetic force, while the outside lines are polarised in a plane parallel to the lines of magnetic force." It is not possible here to go into the mathematics of this subject. Professor Lorentz has gone very far to explain the Zeeman effect, and his explanation is entirely in accord with the modern view of the structure of matter [see CHEMISTRY]. The interpretation of Zeeman's observation leads us to believe, first of all, that the bodies which produce the luminous vibrations which the spectroscope analyses are negatively electrified. Secondly, the properties of such bodies closely correspond to those of the negatively electrified particles which constitute what are still called the *cathode rays*, and which we are now beginning to know as *electrons*. "Thus we infer," says Professor Thomson, "that the cathode particles are found in bodies even where not subject to the action of intense electrical fields, and are, in fact, an ordinary constituent of the molecule [the atom]."

Light Under Magnetic Force. But the Zeeman effect will teach us far more than this, though such a confirmation of the corpuscular theory of matter is obviously of the greatest value. It is found that magnetic fields influence light in a far more complex fashion than that hitherto described. Spectral lines are sometimes split up into sixes and nines as well as threes. This indicates that the lines in question must be due to the vibration within the atom of systems consisting of more electrons than one. This, of course, entirely coincides with the doctrines which we have advanced in the course on Chemistry, where it is shown that within the larger atoms there are sub-atoms, or systems of corpuscles, such as those which give rise to the helium atom when the radium atom disintegrates. Writing a year or two ago, Professor Thomson says: "Thus the behaviour of the spectrum in a magnetic field promises to throw great light on the nature of radiation, and perhaps on the constitution of the elements." Writing also about the same time, Dr. Knott said: "The general explanation of the phenomenon follows at once from Maxwell's electromagnetic theory of light, taken into conjunction with the obvious hypothesis that, in the molecules whose vibrations are the source of the radiation, there are electrical vibrations which will respond to a magnetic force brought to bear upon them."

Spectral Lines and the Theory of Matter. Professor Thomson predicted that the recent discoveries as to the relations between magnetism and light would help us to understand the constitution of the elements. This prediction has been abundantly verified. Ten years after his original discovery, Professor Zeeman was asked to show some of his famous experiments, and offer the most recent interpretation of them, before the Royal Institution. He then pointed out certain facts which we may here quote. He said that "the study of the spectral lines affords a most cogent support to the electronic theory of matter. Furthermore, it has long been known that in the spectra of many metals there occur certain series of related lines which show a correspondence in the various groups of metals. The lines which belong to different series show the difference between them by the fact that they always behave differently under the influence of magnetism, but the fundamental relation between lines of one series, occurring again and again in related elements, is shown by the fact that these lines behave similarly to one another under the influence of magnetism. We have already seen that some lines are separated into triplets, some into sextets, or sixes, and some into nonets, or nines. Now it is the fact that, in a group of elements, corresponding series of spectral lines show the same degree of resolution, whether into threes, sixes, or nines." In a word, the more intimately we study the Zeeman effect the further proof do we find of the relation between the elements, and the more nearly do we come to understand in what that relation consists. In short, we may say that the magnetisation of the spectral lines affords one of our very best clues to the inner structure of the atom.

The latest statement of the Zeeman effect, in the words of the discoverer himself, may thus be briefly summarised: Certain spectral lines are divided into three in a magnetic field when the lines of magnetic force are at right angles to the direction of propagation of the light. Of these three, the middle component is plane-polarised in one direction, and the two outer components in a different direction. If the lines of force are parallel to the direction of propagation of the light, similar lines are split up into only two components, which are circularly polarised in opposite directions to each other. Hence, it may be argued that, in a gas which is emitting light, the ethereal vibrations arise from negatively electrified corpuscles, the size of which corresponds to that suggested by the study of the cathode rays.

Charge and Mass. We have used the loose and popular term "size," but what physicists are really attempting to measure is the ratio of the electromagnetic charge of the electron to its mass. If for the electromagnetic charge we use the symbol e and for the mass the symbol m, then it is the value of $\frac{e}{m}$ that the physicist seeks to estimate. In the course on Chemistry we have discovered the great and important complication which is introduced by the movement of the electron. Lastly, we may repeat in the most recent words what has already been said.

In the spectra of many metals there occurs a number of related lines which are called *series*. All lines of one series are broken up by the magnetic field in the same way, whether into threes, sixes, or nines. Not only so, the extent to which the lines are broken up, the degree of separation between their constituents, is the same in all lines of a given series. The reader is, of course, able to understand that the splitting up of these lines in the spectrum is merely an indication of the production of waves of varying frequency or wave length. All that the spectroscope does is to sort out into a band all the vibrations that pass through it in proportion to their frequency. The splitting up of the spectral lines is thus merely an indication of the fact that a magnetic field is able, under certain conditions, to alter the vibration frequency and wave length of part of the light produced — this being doubtless accomplished by the influence of the field upon the oscillation or rotation of the electrons within the atoms of the luminous substance.

All the Facts Consistent. As we have seen, corresponding series of spectral lines in different elements—elements forming groups in Mendeleef's table of the Periodic Law—show the same type of resolution of the lines constituting the series, and show the same amount of separation of them. Hence it is inferred—and this is most important—that all the lines constituting a series of spectral lines are produced by one oscillating or rotating system of electrons within the atom, and therefore that the number of series of lines in the spectrum of any "element" indicates the number of oscillating or rotating systems contained in the atom in question; and, lastly, that in a group of related elements the oscillating systems giving rise to corresponding series of spectral lines are identical.

It is of some interest to notice that the amount of separation (due to a magnetic field) of the components of a spectral line is proportionate, as might be expected, to the strength of the magnetic field. This fact, curiously enough, affords a service for the student of magnetism. The most accurate means, and by far the most delicate, of measuring the strength of a magnetic field is to be found in measuring the effect of that field in resolving the spectroscopic lines in the light of some element made luminous for the purpose.

The Countless Number of Spectral Lines. We are in the middle of a subject which is of the greatest inherent difficulty, and which is still further complicated by its newness, and also by the number of its relations to other subjects. One of these is so very interesting that we must try to elucidate it—its interest consisting in its bearing upon the corpuscular theory of matter. Professor J. J. Thomson has lately laid down the proposition that the number of electrons constituting the atom of any element is strictly proportional to the atomic weight of that element; and, furthermore, that the actual number is not a large multiple of the atomic weight. Now, if this be so, as several lines of argument would appear to show, how is it that the spectra characteristic of various elements seem to display no limit to their complexity? How is it that the number of spectral lines is limited only by the measure of dispersion—the more complete our arrangements for dispersion being made, the greater being the number of spectral lines, while no signs of any limit can be detected? If we are to assume that each new spectral line demands the existence of another electron in the atom, we cannot possibly accept the proposition that the number of electrons in the atom is only a comparatively small multiple of the atomic weight.

Significance of the Spectral Lines. But Professor Thomson asserts that we cannot deduce the number of electrons in the atom from the number of spectral lines which we see when the light produced by the atoms of any given element is analysed. He assigns reasons for believing that a very large number of spectral lines do not indicate at all the internal structure of the atom, but depend upon the formation of new systems of electrons—of a more or less temporary and unimportant character—between certain of the electrons within the atom and their surroundings. On this theory it may be possible to explain the apparently infinite number of spectral lines.

We have still before us the great subject of colour and of the relations of various colours, as also the fascinating but exceedingly difficult study of colour vision. Then, also, we must discuss, in very considerable detail, the subject of polarisation, to which some allusion was made when we were discussing the history of our knowledge of light. Thereafter there will remain for our study various forms of ethereal vibration, such as the Röntgen rays, our knowledge of which is comparatively new, but which are of the very greatest importance and interest. Meanwhile, however, we must return, as briefly as possible, to a subject which is now coming to take a very important place in physics, and which is of the highest philosophic interest, since, though it may be studied experimentally in the space of a few cubic inches, it has to be reckoned with as a factor in the causation of many of the most stupendous phenomena of Nature.

Light as a Carrier of Momentum. When we discussed gravitation and the ether, we made some reference, apparently out of place, to the pressure of light. It was pointed out that this pressure exercised by light against any surface upon which it falls is really no more than an instance of a still more general phenomenon called *radiation pressure* We observed that light must exercise a pressure if it be of the nature which Clerk Maxwell demonstrated. It was further noticed that the figures for radiation pressure which Clerk-Maxwell arrived at, *à priori*, have lately been demonstrated to be practically correct in consequence of the *à posteriori* or experimental demonstration of radiation pressure by Lebedew and by Professors Nichols and Hull [see page 938]

The reason why we had to discuss radiation pressure in that place was that it is a universal or practically a universal force which, in its measure, is opposed to gravitation, since it acts in precisely the opposite direction. We commented upon the fact that radiation pressure compels us to modify our statements both of Newton's first law of motion and of his law of gravitation.

Radiation Pressure and a Moving Body. Here we must make some brief further reference to the subject; in the first place, because it is properly a part of the subject of light, or, rather, of radiation in general, and also because the work of Professor Poynting, to which we alluded on page 939, has since been discussed by himself at the Royal Institution. Experience has taught us that we are right in assuming that doctrines and speculations are fit for wide diffusion when they have reached the status of exciting an invitation to lecture in the famous theatre in Albemarle Street.

What is probably the most important contribution of Professor Poynting to the subject has been already referred to. It is the observation that a moving body, whether small or great, which is emitting light—or any other form of radiant energy—tends to crowd upon the waves in front of it, while those behind it tend to be thinned out. The consequence is that the radiation pressure is greater in front of the body than behind it, and constantly acts as a break upon its motion.

Direction of Light and Sound Waves. Now, this case is, after all, only the latest illustration of a theory which goes by the name of *Döppler's Principle*, and plays an important part in many branches of physics. In describing it we cannot do better than quote the authoritative words of Professor Tait. The reader will see from them how this principle is applicable to waves of many different kinds:

"When a steamer is moving in a direction perpendicular to the crests of the waves, she will encounter more of them in a given time if her course is towards them than if she were at rest; while, if she be moving in the same direction as the waves, fewer of them will overtake her in a given time than if she were at rest. The same thing is true of sound waves. When an express train passes a level crossing at full speed, the pitch of the steam-whistle is higher during the approach to and lower during the recess from the listener at the gate than it would be if the engine were at rest. The successive sound-pulses are emitted at the same intervals as before, but from points successively nearer to or farther from the listener. Hence, more or fewer reach his ear in a given time. The principle is precisely the same as that of Römer's observation of the frequency of eclipse of Jupiter's satellites. The number of light waves which reach the eye per second is increased if the source is approaching, and diminished if it be receding."

Applications of the Principle. Döppler's Principle is usually described under Acoustics, and the usual acoustical illustration has been quoted above; but we have deferred its discussion until this place because it is of far greater importance in relation to light than it is in relation to sound. One of the earliest applications of the principle in the realm of light was made, as we have seen, by Sir William Huggins, who was enabled by its means to solve a problem which Comte, for instance, had declared to be necessarily impossible of solution throughout all time—*viz.*, the problem of ascertaining the motion of the fixed stars to or from the earth, or our motion relatively to them—in the line of sight. This problem might indeed appear insoluble, but Sir William Huggins has been able to ascertain, by the application of Döppler's Principle, the movements of stars which may be moving directly towards us or from us, and the light of which is constantly affected in wave length and frequency accordingly. Finally, we may quote the latest application of Döppler's Principle to the facts of light as made by Professor Poynting. Perhaps the best account of the principle, though not of its latest application, is to be found from the pen of Professor Poynting himself on page 51, vol. xxv., of the "Encyclopædia Britannica," ninth edition.

Reflection and Recoil of Light. Let us now return to radiation pressure and consider a few of its consequences and one or two of the facts which it may more or less certainly explain. From this point of view we have to consider light as a momentum carrier. Now, there are certain fundamental dynamical laws which have their application in this sphere also. We believe, for instance, that action and reaction are equal and opposite. If, then, when you fire a rifle, it kicks, there ought to be a similar back push or recoil when a radiant body fires off, so to speak, a train of light waves. The physicist knows, indeed, that this must be so. It is therefore extremely interesting to observe that, when Professors Nichols and Hull made their now celebrated experiments, they obtained just double the result in respect of pressure when the waves of light with which they experimented were reflected. In other words, these waves of light first of all exercised a pressure when they struck the surface and then gave it a kick as they were reflected from it.

75,000 Tons of Light. Professor Poynting has also studied the influence which light pressure due to radiation from the sun—or, to be more accurate, the whole radiation pressure from the sun—must ever be exercising upon the earth, with the consequence of tending to arrest its onward motion. This amounts to what at first sight would appear to be a formidable figure, the equivalent of the weight of 75,000 tons. But that this resistance to the earth's movement is trivial, and can have marked consequences only in the remotest future, will be evident if we consider that this push of the sun must be pitted against his gravitational pull, which is millions of times greater.

Various conclusions of importance follow from the fact that, whereas the force of gravitation varies as the mass of a body, the force of radiation pressure varies as its surface.

One extremely interesting speculation may just be alluded to. Professor Poynting has sought to apply the now demonstrated fact of radiation pressure to the problem which has been afforded astronomers by the rings of Saturn ever since Galileo discovered them 300 years ago—ever since, indeed, they caused him the utmost consternation by what looked like their disappearance, which threatened to throw discredit upon all his work. Professor Poynting has shown how it may be conceived that the rings of Saturn are formed of small particles derived from without and perhaps from the débris of comets. The attraction of such particles, but their arrest before reaching Saturn—which at that time, if not now, was doubtless a luminous body, the light from which exercised a very considerable radiation pressure—and their collection into rings which rotate around him, and into which the particles are sorted according to their size—all of these are capable, it would appear, of an adequate interpretation if the facts of radiation pressure are brought to bear upon them.

CARRIAGE TRIMMING

Trimming Materials: Their Uses and Methods of Attachment. Vehicle Linings and Hoods

Group 29
TRANSIT
11
VEHICLE CONSTRUCTION

continued from page 3481

By H. J. BUTLER

TRIMMING is confined to the passenger-carrying vehicles. We have, indeed, the padding of horse boxes, the various types of cushions, and back rests used by van and cart builders, and even tarpaulins and other waterproof covers, but, taking it as a whole, we do not find a trimmer's shop in a factory set apart entirely for vehicles designed to convey goods and merchandise. Many, especially those in the motor trade, talk of a body being "upholstered," but this is a term which is properly applied only to the furniture trade.

The Object of Trimming. Trimming has for its object the comfort of the occupants, by isolating them from the framework of the vehicle. It also decorates, a well designed lining and leatherwork skilfully carried out adding to the beauty of the carriage. Most of us have experienced journeys in railway carriages, and on the roof seats of trams and omnibuses, where the hardness of the seat causes considerable discomfort. Trimming remedies this.

Trimming is also frequently introduced where the passenger is seated on a set of springs apart from those applied to the body and undercarriage, thereby destroying vibration almost entirely.

In railway work we are familiar with the grades of comfort provided in different classes of carriages. First we have cushions with or without comfort for the back, and, as we pay more, we have pillar holders, elbow rests, floor coverings, and other details. In public service vehicles we have cushions inside, the modern electric tramcars being the most advanced in ministering to the comfort of passengers; while, no satisfactory means having been found to protect the cushions on roof seats during inclement weather, we find only aprons.

Road carriages of all descriptions constitute the chief outlet for the skill of the trimmer, not only in the cushions and linings, but in the covering of the wings and dashers, and in the construction of the folding head.

The highest degree of comfort is in the furnishing of American railroad cars. In these one may be seated in an armchair with reclining back and adjustable footrests. The Pullman cars running on the London, Brighton, and South Coast Railway are examples of the comfort provided on the other side of the Atlantic.

Trimming Materials. The trimmer has a large and varied stock of materials to handle. Woollen cloths of the best "West of England" quality are generally used in the darker colours, silk being employed for lining only in special cases, but finding favour as blinds in the form of lutestring. Satins and velvets we see only for carriages used on grand occasions, while plushes in various qualities find their way into the trimming of public service vehicles. Although the pile of plush is a receptacle for dust, yet the nature of the surface gives a firm seating. The coach trimmer is not fond of much pattern in his lining materials, generally preferring it quite plain, although in railway work we see more latitude in this direction. Underfoot we have Brussels, Wilton, and other carpets.

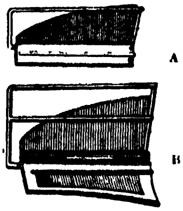
Leather and Leather Working. A fully qualified trimmer is not only a worker in cloth, but also an expert in leather working. The folding heads of landaus, victorias, and similar vehicles, the dashers, wings, and shaft leathers are places where leather is used. In some shops the qualification of the workman includes harness-making.

Bull hides are thicker and coarser than those of the cow, bullock hides being intermediate. Bull hides are used in harness making and as border leathers for edging seat boards, while they are also divided into two layers, the hair or grain side being known as *bag hide*, and the flesh side being called *split*.

These split and bag leathers are japanned, a process whereby we obtain glasslike surfaces. This variety is used for covering the iron frames of wings and dashers, the japanned split being the cheapest. Similar to the japanned leathers but more elastic, are the enamelled hides. Here we find a material well suited for folding head leathers and aprons. Pigskin is used in the trimming of sporting and other carriages. It is to be recommended for its durability.

Apart from carpets there are other types of floor coverings. Kamptulicon and linoleum combine in some measure the qualities of carpet and oilcloth. They wear well, and are impervious to damp. The cheaper covering floorcloth or oilcloth—is prepared on a groundwork of flax or tow, over which layers of paint are spread. Good linoleum may cost more than double the price of oilcloth, but it will wear at a moderate estimate more than four times as long.

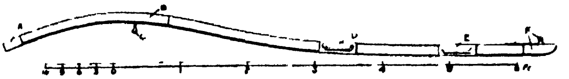
Coach Laces. The ancient and universal art of weaving has produced in modern carriage laces beautiful trimmings with excellent wearing qualities. When we speak of lace in connection with coach work, the ordinary network of threads in various designs is not implied, but in this instance the term is applied to what might be called a wide decorated braid. In broad lace used for fronts of seat rails, glass strings, and pillar holders, we have a woven material with the two selvedges averaging about 2½ in. wide. Wide lace with a single selvedge is used for binding the edges of seat falls and pockets. Pasting lace has a single tape edge, and is used for hiding nail heads, the edge being nailed, while the remainder is folded over and pasted. It is used in varying widths for pockets, seat falls, and similar purposes. Seaming lace has two tape edges. It is used for concealing seams and for fixing linings which are sewn to it. Seaming cord is placed inside this lace when it is desired to give it a rounded form, the two tape edges being sewn together, and in this shape it is used for cushion edges, giving them a better and more lasting shape—a purpose it also fulfils in other departments of carriage trimming. Both seaming and pasting lace are comparatively narrow, the former running about 1¼ in. wide, and the latter about ⅞ in. to 1 in. We can quite understand that the introduction of railways greatly increased the demand for trimmings generally, and for a time it was difficult for the manufacturers to turn out supplies of pasting and seaming lace sufficient to meet the demand. The introduction of the power loom solved the difficulty. Cloth and leather pipings are sometimes used instead of seaming lace.



56. DRIVING SEAT OF (A) A BROUGHAM AND (B) A BAROUCHE

Details and Stuffing Materials. There are also many small items that go to make up a luxurious interior. Laces with rose patterns are used to fix the top of the pillar holder to the pillar. A check-string of silk or a speaking-tube with a whistle and mouthpiece is provided to call the attention of the coachman. Then there are tabs and tassels for blinds, the guide line of silk on which the blinds ascend and descend, and the buttons and tufts whereby the stuffing material is kept in its place.

Stuffing materials, although not seen, must be of good quality, otherwise a lifeless cushion or flabby squabbing results.



57. CARRIAGE SHAFT

A, Tip; B, Point; C, Tug stop, D, Breeching staple; E Kicking staple; F, Stop

Curled horsehair, taken from the living animal, is in its best qualities unsurpassed for the retention of its elasticity. Flock. coconut fibre, shavings of bass and maple, moss, and even hay are used in cheap work. Lately the use of steel springs in cushion and lining work has been common, patent varieties being manufactured where each separate cushion or part of the trimming is made up on a wire frame to the size required, the special springs being firmly clipped into position and to each other.

Leather Stitching. The young trimmer has first to learn how to make his thread and then to acquire the skill to use it. The coach-trimmer does not use the bristle, but punches his hole in the leather with an awl having a diamond-shaped point, and then inserts his thread attached to a blunt harness needle. In a dash, he must have sufficient japanned hide to form a layer on each side, about ¾ in. being allowed for stitching and dressing off. During the operation of sewing the two layers of leather together with the iron frame between, the work is damped and tightly stretched with special pincers. Here there is disagreement between the older and the younger members of the trade regarding the respective merits of hand and machine work. Where there is a highly finished surface, as in a japanned leather, it must be admitted that a careful workman will often produce a better finish than a machine. After sewing, the work is pared off within 3/16 in. of the stitches and the edges dyed, oiled, and polished.

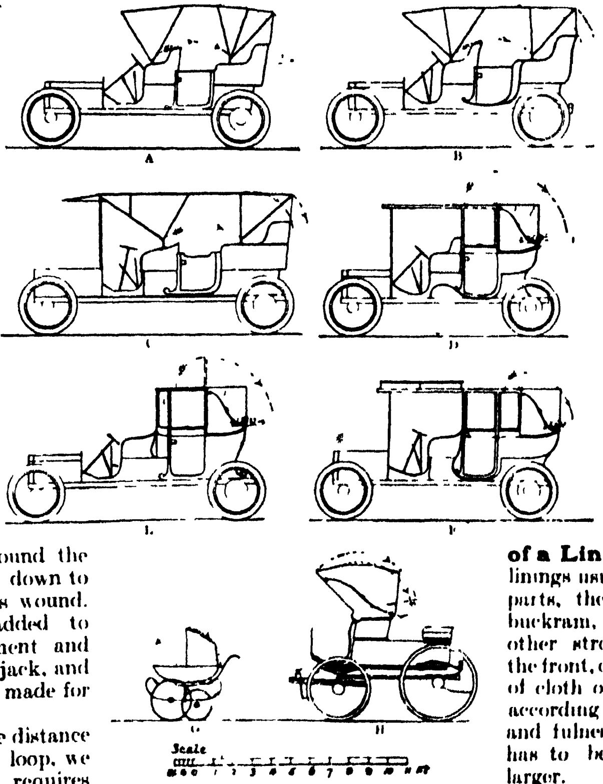
The work on curved wings and front splashers requires more skill, and may be attempted after the straight work has been mastered. In best work we have the seat rail irons covered with leather, the join being made on the inside where it is least visible.

Seat Valances. The edges of driving and other carriage seats are, when exposed, finished with a border or valance [56]. In cheap work this may be simply of wood; the leather may be mounted on a wooden foundation, or stout border hide japanned on one side and blacked on the other may be used alone. The edges of the leather are welted or bound with enamelled leather, while the fixing of the border itself is hid by the beading placed over, and is retained by its shanks in the same way that a head leather is fastened to the pillar tops and elbow. A seat border not only decorates but it serves to retain the cushion in its proper position.

Head Valances. Similar to seat borders are head valances, used on the folding heads of victorias, barouches, sociables, and similar carriages. Their duty is to hide the joins of the head lining and leather, to finish off the head itself, and they should be fixed so as to prevent water from entering the vehicle when the head is up. A head valance is sometimes cut out in one piece, but may be joined at the corners or in the centre of the back. A bead finishes it, as in the case of the seat valance.

Shaft, Pole and Bar Leathers. The shafts of carriages and carts have leather fixed at the point or front ends and at the kicking and breeching staples [57]. The sewing is done underneath, the herringbone stitch being much employed. Japanned split is used for this purpose. Oil leather known as *pole piece backs* is used for pole work. The stuffed pad is generally situated about 25 in. from the pole crab. Leather work is also in evidence on the splinter bar of a carriage. Here it is used at the bases of the roller bolt ferrules and washers on the bar to prevent the traces from chafing the iron and woodwork. Similar material to that used in pole work is required, while the caps of the bolts may be ornamented with japanned split.

Aprons. Aprons are fitted to keep the lower limbs dry in wet weather, to add to the passengers' comfort in cold weather, and, in the case of the front inside seat of a sociable or barouche, to protect the front seat cushion and lining when not in use. It will be readily understood that however supple the enamelled leather may be, the appearance of the covering will be better preserved if, when the vehicle is not performing a journey, the aprons are opened out.



58. TYPES OF VEHICLE HOODS

The dotted lines and arrows indicate the position of the heads when folded, and the direction of the folding. A Cape cart hood for side entry motor-car, two sticks in front, three behind. B Ditto, but three sticks in front and two behind. C. Ditto, but provision made for proper protection of the front glass screen. D Motor single landaulette. E Motor double landaulette. F. Motor limousine landaulette. G Bassinette. H. Mail phaeton

This remark, of course, applies also to the heads of landaus and victorias, and explains why we see them closed in the show-room and coach-house.

C-Spring Braces. C-spring braces are of vital importance in a carriage mounted on this type of suspension, and are made of oil leather similar to pole piece backs. A loop runs from the body connections to the top of the C-spring. Then the body of the brace continues round the back of the spring down to the jack where it is wound. Five inches is added to allow for attachment and adjustment at the jack, and allowance must be made for splicing.

Together with the distance twice over at the loop, we find a brace often requires 75 in. to be cut out of a width about ½ in. wider than the spring. The brace is made of two thicknesses of leather and may be sewn with four rows of stitches, the inside rows being made to form a simple pattern.

Folding Heads. Of the leather work we have noted so far, none requires so much skill in fitting as the enamelled head leather, unless, perhaps, the moroccos and other leathers used in making linings. There may be three to five sticks in a head. The underside of the centre stick requires to be 3 ft. 8 in. from the seat board, and even 4 ft. in such vehicles as Stanhope and mail phaetons where the driving seat is protected. The top of the back or corner stick is usually thrown back 1 in. to 1½ in. from the square line of the corner pillar, and 3ft. 6in. to 4ft. is allowed, horizontally, from it to the front stick. The trimmer having placed his sticks in the proper position, they are temporarily held in position by webbing. Both lining and leather are made in four pieces, the former stitched to list, nailed to the front of the sticks, in the same way as inside roof coverings are attached. Many varieties of folding heads are shown in 58.

How the Trimming is Fixed. The squabbing is not all fastened directly to the proper framework of the body, but special pieces of wood, generally pine, are glued, canvased, and fitted to the quarters and other parts.

Sometimes it is necessary, owing to the shape of the vehicle, to fill up the hollow parts, and, apart from this, the trimmer should always work his materials so that no undue prominence is given to the work in the centre, otherwise the occupants will be rolled into the corner while travelling.

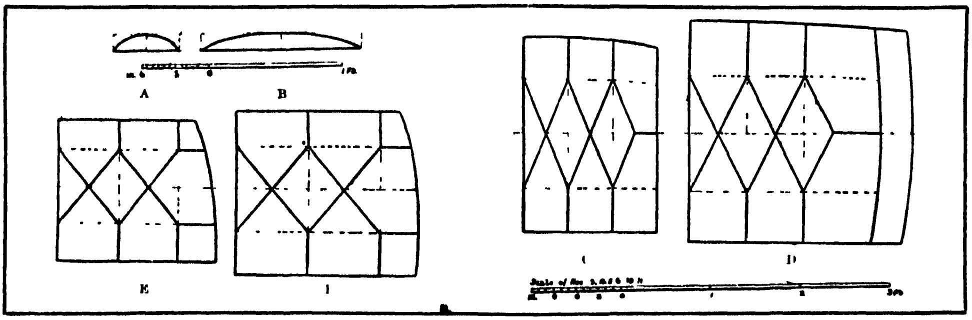
Construction of a Lining. Cushions and linings usually consist of two parts, the back of Forfar buckram, black linen, or other strong material, and the front, or trimming proper, of cloth or morocco, which, according to the squabbing and fulness of the stuffing, has to be made so much larger.

Having taken the interior measurements of the body, the canvas, roughed out to shape, is tacked in the body and pencilled round, then laid out flat on the board or bench and kept in position by pieces of iron covered with leather or other fixing.

Allowance for Fulness of Squabbing. The design of quilting, whether in squares or diamonds, is marked out, care being taken to do it accurately, otherwise a distorted trimming will result. The arrangement must exactly balance each side of a centre line in such cases as back squabs and cushions.

A diamond, when stuffed with hair, will stand up 1½ in. or so from the canvas. Knowing the length of the diagonal marked on the canvas, we may estimate the size of the diamond on the cloth by drawing on a piece of paper and measuring with a piece of string [59 A and B] a section of the stuffed diamond on each diagonal. This arrived at, the larger diamonds are marked on the back of the cloth. The stiffer the canvas, the less need be allowed for stuffing. The holes for the fixing of the button or tufts may be lined with calico to prevent tearing, and the folds of the pattern are ironed in the case of cloth and scraped when a morocco lining is used.

Door Trimming. In trimming a door, the work is kept as flat as possible. A quarter of an inch being allowed at the bottom above the rocker to allow for carpet, the border is made of 2½ in. broad lace finished off at the outer edge with seaming lace. Three-quarters of an inch would be allowed in this case for the fulness of the cloth.



59. MARKING OUT OF VEHICLE TRIMMINGS

A. Transverse section of a squab, the curved line representing the cloth, the base line the canvas B. Longitudinal section of A. C. The marking out on the folded canvas for a bottom back squab D. The above marking on the cloth. E. The folded canvas for a brougham inside cushion F. The folded cloth for a brougham inside cushion

Bottom Back Trimming. In a bottom back, a convex curve is cut on the two sides to counteract the drawing-in of the cloth when stuffing. The design [59 C and D] is worked folded in the centre, so as to obtain an equally balanced setting-out, and in an average brougham the canvas is about 36 in. wide by 26 in deep, 1½ in. being left on the bottom, 1 in. at the top, and a full half-inch at the sides. The fewer the number of buttons used, the greater the freedom given the hair to use its elasticity. Also, an excess of buttons conduces neither to the comfort of the occupant nor to the beauty of the trimming.

The diamonds never finish right at the edge of the pattern. A distance of 6 in. is left on the edge of the cloth besides about 4½ in. for attachment.

Wadding is placed on the top of the hair to keep the latter from showing through the cloth. In making up, we must not forget that the pleats brush from right to left. The bottom back is bound with pasting lace sewn all round the edge. Seaming lace is fastened to the trimming rail bottom, to this is "frenched" or blind sewn the pasting lace on the top of the bottom back. The bottom row of buttons is usually dealt with first, and the back row in cushions. In folding the diamonds, see that it is done downwards, so that in brushing the dust is not liable to work in. The marking out of a cushion is illustrated in 59 [E and F]. A morocco lining for a double brougham requires some 11 or 12 skins, a single brougham demands 10, and a victoria four or five, the provision of a cricket seat in the last mentioned bringing the total to six. There is about three square feet in a morocco.

Trimming a Double Brougham in Cloth. For a double brougham we require for a cloth trimming—roof 1¾ yd. (60 in. wide), the top and bottom of the back with fulness is allowed 1½ yd., the quarters (top and bottom) 1½ yd. for both sides, the hind body cushion 1¼ yd., the front ditto ¾ yd., the front squab ¼ yd., the front back ½ yd., the front quarters ¼ yd., and for the fronts of the seats inside the waste of the above will suffice. Driving cushions, seat box, and fall are given 1½ yd., and the doors ½ yd. The roof brushes to the front (or an omnibus towards the door), the top, bottom back, quarters, and other parts brush downwards, while cushions brush forwards from back to front, front borders of cushions downwards, and sides as convenient. The box brushes as one piece of cloth.

The broad lace from the seat, up the pillar, along the roof across the back takes 4½ yd., the two doors 5¼ yd., the front of seats 2½ yd., the holder lace 2½ yd., hanging down 27 in. One pair of glass strings are 36 in. long, and one pair 24 in. Of seaming lace 40 yd. is required, of pasting lace 36 yd. Other necessities are: one pair of glass string guards, two gross of buttons to match the cloth, check string, 7½ yd. of buckram, ½ yd. of black American cloth (duck back), 3 curtains, 2¼ yd. silk (lutestring), 18 yd. silk curtain line, three triggers (acorns), one dozen ivory headed nails, four ivory buttons, four glass string slides, one pair metal door-pulls covered with morocco, 30 lb. horsehair (second quality grey hair, as the best quality is too hard), and 2½ yd. of carpet.

PSYCHICAL RESEARCH
continued from page [illegible]

By HAROLD BEGBIE

THE process of modern science, which consists in "an interrogation of Nature, entirely dispassionate, patient, systematic; such careful experiment and cumulative record as can often elicit from her slightest indications her deepest truths," has never, in the contention of Frederic Myers, been applied to "the all-important problem of the existence, the powers, the destiny of the human soul."

What do the Legends Mean? It is because of her very *thoroughness*, because of her faith that the slightest indications of Nature speak often of her deepest truths, that psychical science has concerned itself with ghosts and ghost stories. The fact of ghosts may not be established; but the fact that there are legends of ghosts is a fact beyond dispute, and those legends, be it noted, are to be found in every race under the sun, and persist even in the most enlightened countries in our own day. What are their significance? What is the external fact of the stream of things hidden in their superstition?

Psychical science gropes among the obscure facts of human consciousness because she hopes to obtain from them that light upon the mystery of existence which neither mathematics nor geology, neither chemistry nor astronomy seems able to afford. She is persuaded that these legends signify something. She is assured that they have an origin and a meaning. She has never once professed her conviction that the fact of the legends existing is proof that the ghosts themselves existed; that would be unscientific, and would lead nowhere; she merely insists that as the legends exist, and exist so universally, they must have had some relation to fact, and what that relation to fact is she has set herself to discover. "Whether through reason, instinct, or superstition," says Myers, "it has ever been commonly held that ghostly phenomena of one kind or another exist to testify to a life beyond the life we know."

The Place of the Witch in Science. Already psychical science has laid many a ghost; but in this work she has not been only destructive—though destruction of superstition and error is admirable; she has been constructive as well. She has shown how it is people originally came to believe in these particular ghosts, and this revelation has meant a revelation of some of the workings of the human mind hitherto overlooked by the psychologists. Let us take the question of witches. Until recently we were justified in believing that legend exaggerated the powers, if not the very existence, of these people. To-day we understand how such people came to exercise so great a power over the minds of the populace. We can to-day produce in the minds of hysterical people precisely the same effect produced by witches. An hysterical woman, indeed, can create in herself, without any assistance from the hypnotist, ideas of the most extravagant and even terrible kind. The witch, then, is no longer for us a stupid myth or a devil-ridden sinner, but an hysterical woman of considerable interest to pathology, with some little power of hypnotism, which as much surprised herself as it terrified those who approached her.

The Two Kinds of Phantoms. In the same way, we hope by a patient investigation of ghost stories to discover the pregnant fact behind their terrors and alarms. Instead of neglecting them, as psychology neglects them, psychical research investigates them patiently in the conviction that they must shed light on the problem of consciousness, even if they do not guide us to the desire of all knowledge. Psychical research has already progressed sufficiently far in her investigations to make a very sensible division of these ghost stories, a division of the living and a division of the dead. Ghosts have been seen of living people, and ghosts have been seen of dead people. We speak, therefore, of *Phantasms of the Living* and of *Phantasms of the Dead*. The very division is significant enough, and the intelligent student will easily see, when he has examined the general items of the first division, that the explanation of the first may in some measure be a form of the ultimate explanation of the second, a consummation eagerly desired apparently by the majority of people, since it would seem to buttress the good old sturdy conviction that the dead never return.

Phantasms of the Living. Ever since the dawn of history there have been cases of men and women seen by their fellows at times when they themselves were beyond the range of vision. Let us consider one case which came under our notice only the other day, and which may be taken as typical of all the cases under this head.

A lady, going upstairs, saw the nurse come from the bath-room, rubbing her hands together as if she had just washed them; the nurse was dressed in black bonnet, grey jacket, and white skirt; she did not turn her head on hearing her mistress, but passed on into the night nursery. Almost at the same moment a child in the nursery called to her mother asking her to tie a pinafore, and the mother replied that the nurse was in the night nursery and would attend to it. "No, mother, nurse isn't there; she's downstairs," replied the child, and at that moment the lady saw the nurse coming up the stairs dressed in a manner entirely different from that which she had seen in her vision.

The lady is a woman of great practical commonsense, and she protests that she did not see a ghost, and does not think that she did, but she protests with equal earnestness her conviction that she saw the figure of the nurse at that moment as distinctly and as vividly as she ever saw it in real life

Seeing by Imagination. Now, the explanation of this apparition is comparatively simple, and will carry conviction to every mind except the mind of the lady. (It is a curious fact that it is far more easy to persuade people who have not seen a particular ghost that your explanation accounts for it, than it is to persuade those who have seen that ghost that the explanation of those people who have not seen it is the right one!) In this particular case it would seem as if the lady had on many occasions seen the nurse issuing from the bath-room after washing her hands; on this occasion her mind, working automatically, suggested to her a customary sight at the top of the stairs, and she, being more or less in a tired state of mind, received the suggestion and believed that she had actually seen the nurse. In that wonderful volume "Phantasms of the Living" the reader will be able to make himself acquainted with endless instances of this kind, and he will be able to form his own opinion on the working of the human mind. Nor need he be confused in cases where the apparition has been the forerunner of disaster, since the materialistic theory can explain this as the theory of telepathy. The anxiety of a mother in a moment of crisis is quite likely to affect the child so as to project the image of the mother upon the child's mind. There are many instances of this extreme form of sympathy operating in the case of twins over considerable distances.

But it will be seen that this theory, even though it lays ghosts in as wholesale a fashion as an expert skittle-player floors ninepins, reveals to us an operation of the mind as important to psychology as the attraction of the earth is important to physics. The trouble is that people, accepting the disproof of the ghosts, do not accept the proof of telepathy. They do not perceive that we have evidence here which endows the mind with powers of an extraordinary order, powers which lift it out of the category of material things, and bestows upon it at least a spiritual significance. In the article following this we deal with the question of Telepathy, but it is important to explain here the obvious and most suggestive conclusion that the only theory which accounts for phantasms of the living is one which concedes to the human mind faculties of an almost spiritual nature.

Phantasms of the Dead. We are now brought face to face with the supreme question of our subject. Is the evidence sufficient to convince the ordinary man that spirits have returned from Hades to visit these pale glimpses of the moon? Has the ghost of a dead person been seen by more than one credible witness long after the time of his decease?

Frederic Myers, who believed himself that this evidence is sufficient, concludes the seventh chapter in "Human Personality" with these words: "I do not venture to suppose that the evidence set forth in these volumes, even when considered in connection with other evidence now accessible in our 'Proceedings,' will at once convince the bulk of my readers that the momentous epoch-making discovery has been already made. Nay, I cannot even desire that my own belief should at once impose itself upon the world. Let men's minds move in their wonted manner; great convictions are sounder and firmer when they are of gradual growth. But I do think that to the candid student it should by this time become manifest that the world-old problem can now in reality be hopefully attacked; that there is hopeful and imminent possibility that the all-important truth should at last become indisputably known; and, therefore, that it befits 'all men of goodwill' to help towards this knowing with what zeal they may."

The Face at the Window. We will quote two stories of apparitions which seem to us inexplicable on the grounds of telepathy, and also so simple in their details as to convince the inquirer of their genuineness. The first story reached the Society for Psychical Research through the Bishop of Carlisle, and is related by the Rev. G. M. Tandy, Vicar of West Ward, near Wigton, Cumberland:

"When at Loweswater I one day called upon a friend, who said: 'You do not see many newspapers; take one of those lying there.' I accordingly took up a newspaper bound with a wrapper, put it into my pocket, and walked home. In the evening I was writing, and, wanting to refer to a book, went into another room where my books were. I placed the candle on a ledge of the bookcase, took down a book and found the passage I wanted, when, happening to look towards the window which was opposite to the bookcase, I saw the face of an old friend whom I had known well in Cambridge, but had not seen for ten years or more—Canon Robinson (of the Charity and School Commission). I was so sure I saw him that I went out to look for him, but could find no trace of him. I went back into the house, and thought I would take a look at my newspaper. I tore off the wrapper, unfolded the paper, and the first piece of news that I saw was the death of Canon Robinson."

In this story, it will be noticed, Mr. Tandy had not seen Canon Robinson for a number of years; there was no apparent reason why he should be thinking of him; no apparent reason why Canon Robinson should desire to appear to an old college friend; and no question at all of telepathic communication. The newspaper was in its wrapper, and the news of Canon Robinson's death had not reached his friend. No explanation in the world is possible for the apparition except the simplest of all—namely, that Mr. Tandy saw a ghost.

The Commercial Traveller's Story. The second story is pronounced by Frederic Myers to be "one of the best-attested, and in itself one of the most remarkable that we possess." We quote from a letter written by the subject of the experience:

"In 1867 my only sister, a young lady of eighteen years, died suddenly of cholera in St. Louis, Mo. My attachment for her was very strong, and the blow a severe one to me. A year or so after her death the writer became a commercial traveller, and it was in 1876, while on one of my Western trips, that the event occurred. I had 'drummed' the city of St. Joseph, Mo., and had gone to my room at the Pacific House to send in my orders, which were unusually large ones, so that I was in a very happy frame of mind indeed. My thoughts, of course, were of the orders, knowing how pleased my house would be at my success. I had not been thinking of my late sister, or in any manner reflecting on the past. The hour was high noon, and the sun was shining cheerfully into my room. While busily smoking a cigar and writing out my orders I suddenly became conscious that someone was sitting on my left, with one arm resting on the table. Quick as a flash I turned and distinctly saw the form of my dead sister, and for a brief second or so looked her squarely in the face, and so sure was I that it was she that I sprang forward in delight, calling her by name, and as I did so the apparition instantly vanished. Naturally, I was startled and dumfounded, almost doubting my senses, but the cigar in my mouth and pen in hand, with the ink still moist on my letter, I satisfied myself that I had not been dreaming and was wide awake. I was near enough to touch her, had it been a physical possibility, and noted her features, expression, details of dress, etc. She appeared as if alive. Her eyes looked kindly and perfectly naturally into mine. Her skin was so lifelike that I could see the gloss or moisture on its surface, and, on the whole, there was no change in her appearance otherwise than when alive.'

The Mystery of an Unknown Mark. "Now," proceeds the narrator, "comes the most remarkable *confirmation* of my statement, which cannot be doubted by those who know what I state actually occurred. This visitation, or whatever you may call it, so impressed me that I took the next train home, and in the presence of my parents and others I related what had occurred. My father, a man of rare good sense and very practical, was inclined to ridicule me . . . but he, too, was amazed when later on I told them of a bright red line or *scratch* on the right-hand side of my sister's face, which I had distinctly seen. When I mentioned this my mother rose, trembling, to her feet and nearly fainted away, and as soon as she had sufficiently recovered . . . she exclaimed that I had indeed seen my sister, as no living mortal but herself was aware of that scratch, which she had accidentally made while doing some little act of kindness after my sister's death. She said she well remembered how pained she was to think she should have, unintentionally, marred the features of her dead daughter, and that, unknown to all, how she had carefully obliterated all traces of the slight scratch with the aid of powder, etc., and that she had never mentioned it to a human being from that day to this. In proof, neither my father nor any of our family had detected it, and positively were unaware of the incident, yet *I saw the scratch as bright as if just made.* So strangely impressed was my mother that even after she had retired to rest she got up and dressed, came to me and told me *she knew*, at least, that I had seen my sister. A few weeks later mother died happy in her belief she would rejoin her favourite daughter in a better world."

The Remarkable Features of the Story. In this story we have some remarkable features. *In the first place*, the subject of the experience is not a woman, not hysterical, not emotional; a commercial traveller attending to his business and smoking a cigar is not of the order of persons who usually see ghosts. The vision appeared nine years after the sister's death, and it wore the unknown feature of a disfigurement which had been made after death. Now, he would be a bold man who asserted that the mother unconsciously projected the vision of the daughter upon the *son's mind*. *In the second place*, we know of no case in which a person has projected the picture of another person on a distant mind. If it had been the mother who appeared to the son telepathy might be the explanation, but even here we should be puzzled to explain the apprehension of the vision on the son's part in the midst of his considerable occupation.

We have no room to quote further cases. We must ask the serious inquirer to consult the volumes of the Society of Psychical Research. Our contention is that while telepathy may explain many phenomena of this kind and even then, be it most carefully noted, does but present the mind with a problem almost as wonderful as that of apparitions it yet does not explain *many cases in which perfectly trustworthy people have solemnly declared before men that* they have seen phantasms of the dead a considerable period after the time of decease.

Messages from the Dead. We must point out, in conclusion, that the dead do not always *appear*, but very frequently so far as the records tell—communicate by other means —*viz.*, automatic writing and through the mouths of mediums. *The reader is not asked* to believe all or any *of these stories, but he is* advised, before passing his judgment on the question, to consider whether all these obscure and somewhat *alarming phenomena*, if sufficiently investigated, are not likely to contribute some elucidation to the problem of consciousness, and, possibly, to throw light across the threshold of the Life beyond this phase of life

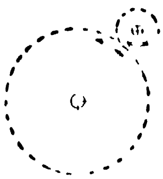
Continued

THE TURNERY & MACHINE SHOP

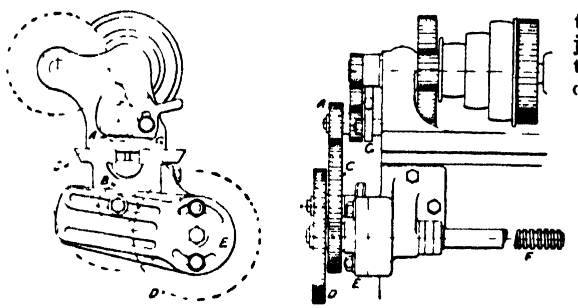
Screw Cutting. Gear Cutting. Turret Work. High-speed Tools. Templeting. Subdivision in the Shops

By JOSEPH G. HORNER

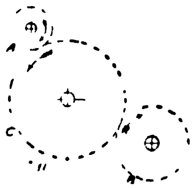
SCREWS are cut with dies comprising several cutters, or with single pointed tools. The latter are used in Fox, or chasing lathes, sometimes in the capstan lathe, and in the ordinary screw-cutting lathe. Either dies or comb tools are employed for bolt cutting, and for the formation of threads in capstan lathes. The screwing dies generally contain three cutters, in a cam plate operated by a scroll and lever. The plate is indexed for setting the positions of the dies, and fitted with an adjustable stop. Those dies are arranged with their cutting edges radially, so that they point to the centre of the work, no matter what its diameter. They cut a full thread at one operation. Bolts are largely done in the open-spindle chasing lathes. These are constructed, except for the open spindle, much like the ordinary hollow-spindle lathes. But the employment of an open spindle permits of the turning and chasing of bolts and screws with heads from the solid bar, and also permits of the ready chucking of single bolts and screws for chasing; while in stud turning the workman can pass his hand into the open spindle for the ready adjustment of the bar without going to the back of the headstock for the purpose. The centres of these lathes range from 6 in. to 10 in., those of from 8 in. to 10 in. being double geared.



289. SIMPLE TRAIN



290. METHOD OF GEARING UP CHANGE WHEELS



291. SIMPLE TRAIN CONNECTED BY IDLER

Long Screws. All bolts and short screws and studs made in quantities are produced by the foregoing methods, by dies, or chasers of some form or another, the guidance being embodied in self-leading dies, or in a hob which imparts longitudinal movement to the chaser bar. But what we have to consider here chiefly is the cutting of long screws by means of a single-edged tool, which is traversed in the slide rest by the lead or guide screw, at a rate which is predetermined by certain arrangements of change gears. The pitch of the guide screw is unalterable; the variable element is provided by the twenty-two change gears, which are capable of an immense number of combinations. They number 20, 25, 30, 35, 40, 45, 50, 55, 60, 65, 70, 75, 80, 85, 90, 95, 100, 105, 110, 115, 120 teeth, with one or more duplicates, as 20, 40, 60, 80, 100. These derive their motion from the headstock mandrel or spindle which rotates the work to be threaded, and communicate it at equal or different rates to the guide screw. The only method which comes into rivalry with this, and that only in recent years, and to a limited extent as yet, is the formation of threads by milling cutters in what are termed *screw milling machines*. The difference is that the cutter in these rotates, and more rapid results are attained.

Methods of Calculation. In the common screw-cutting lathe the elementary basis of calculation between the guide screw, of fixed pitch, and the screws to be cut, of many pitches, finer, and coarser than that of the guide screw, is simply that of the *ratio*, or proportion which subsists between the two. As this takes the form of a fraction, the calculations are put in the same form.

The simplest way to consider this subject is to remember that three principal cases occur: (1) screws cut with pitches equal to that of the leading screw; (2) screws with pitches finer; and (3) screws of coarser pitches than that of the lead screw. The first class would be cut with wheels of equal numbers of teeth on mandrel and guide screw; the second with a smaller wheel on the mandrel driving a larger one on the lead screw, so *retarding* the movements of the tool; and the third with a larger wheel on the mandrel driving a smaller one on the guide screw, so *accelerating* the movements of the tool. Or, put in another way—which is of universal application—*the pitch of the guide screw is to the pitch of the screw to be cut as the number of teeth on the mandrel change wheel is to the number of teeth on the guide screw wheel.*

There are two practical methods of obtaining the change wheels necessary to cut a given thread: (1) by obtaining ratios direct, the other (2) by cyphers.

(1) To cut a thread of 2 per inch with a guide screw of 4 per inch

$$\frac{4}{2} = 2.$$

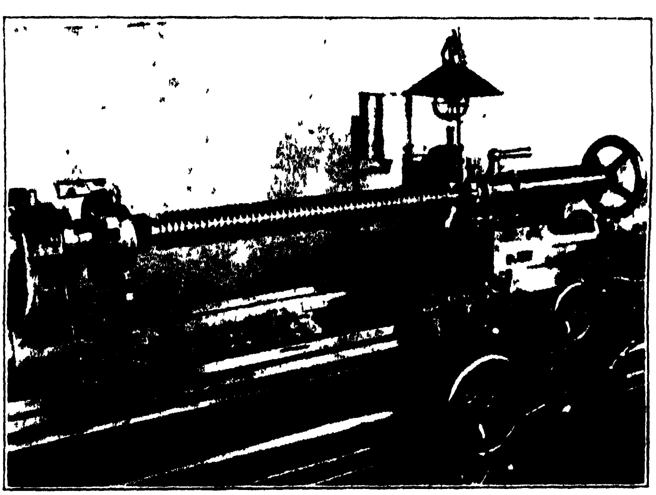
The change wheels must therefore have a ratio of 2 to 1.

(2) Place the number of threads in the guide screw for a numerator, and the number in the screw to be cut for a denominator, and add a cypher to each to obtain the numbers of teeth in the change wheels:

$$\frac{\text{Guide screw}}{\text{Screw to be cut,}} \quad \frac{4}{2} = \frac{40}{20},$$

and wheels of 40, and 20 teeth will cut the screw required, and 40 will go on the mandrel and 20 on the guide screw.

Simple and Compound Trains. When two wheels only are used the train is a simple one [289]. But when ratios exceed 6 to 1 simple trains do not suffice, because one of the wheels would exceed the limits of the centres of mandrel and guide screw, or the size of the largest wheel in a set. Compound trains [290] consisting of four or more wheels are then used, but the ratios of drivers and driven remain unaffected.



292. LATHE CUTTING A LEFT-HAND SCREW

If a screw of 20 threads per inch be wanted, the guide screw having two threads per inch, then:

$$\frac{2}{20} = 0{\cdot}10,$$

a ratio of 0·10 to 1, or $\frac{1}{10}$th; or, putting it in the form of a fraction:

$$\frac{1}{10} = \frac{10}{100}.$$

But as the lowest wheel in a set has 20 teeth, this fraction must be multiplied by 2:

$$\frac{10}{100} \times 2 = \frac{20}{200}.$$

But, now, 200 exceeds the highest numbered wheel in a set, and so other wheels must be found. There are several ways by which a compound train may be deduced, by breaking up into factors as follows:

$$\frac{20}{200} = \frac{10 \times 2}{20 \times 10} = \frac{100 \times 20}{200 \times 100} = \frac{50 \times 20}{100 \times 100} = \frac{25 \times 20}{50 \times 100}.$$

These last factors give wheels in a set without requiring duplicates, and they have the same ratio as $\frac{10}{100}$ or $\frac{20}{200}$; and 25 and 20 are the driving wheels, and 50 and 100 are the driven wheels.

In the case of very fine or very coarse pitches, the compounding has to be increased to six or eight wheels; but the ratios must always be observed exactly. The final arrangements obtained can always be tested by multiplying together the drivers and the driven separately, and dividing one quotient by the other, as in the example just given.

It will be evident that, the object being to select workable wheels—that is, wheels in the standard sets—the breaking up into factors in the example given may be done by halving, or doubling, or adding, or lessening by any suitable increments, as fourths, fifths, or thirds. But the essential point is that the factors which stand for numerators and denominators respectively must be increased or diminished in the *same proportions* in order to retain the same *ratio*.

Gearing Up. Fig. 290 illustrates the method of gearing up change wheels. The driving wheels here are A, B, and the driven C, D. E is the quadrant, or swing plate pivoting around the axis of the guide screw F, the object of which is to afford a large range of adjustment for the centres of the change wheels. The first wheel, A, derives its motion from the mandrel through the fixed gears shown, the function of which is the reversal of the direction of rotation of the lead screw by the reversing plate G. Fig. 291 shows a simple train, A, B, connected by an idler, C, to cause the lead screw to rotate in the same sense as the mandrel, to cut towards the headstock. The photo 292 illustrates the cutting of a left handed screw in the shops of Ludwig Loewe & Co.

Fractional Pitches. Pitches often have to be cut which are not integral parts of the guide screw, but comprise integers and fractions. Then the denominator of the fraction is used as a multiplier, thus: 9½ threads per inch to be cut with a lead screw of 4 per inch:

$$\frac{9\frac{1}{2}}{4} \times 2 = \frac{19}{8} \text{ ratio.}$$

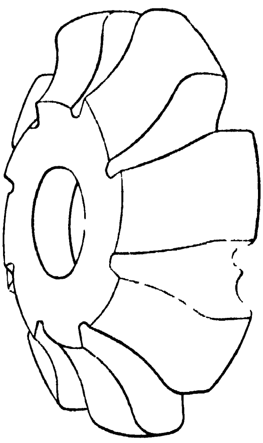
We may multiply this by, say, 5:

$$\frac{19}{8} \times 5 = \frac{95}{40} \text{ wheels;}$$

and 40 will be the driver, and 95 the driven.

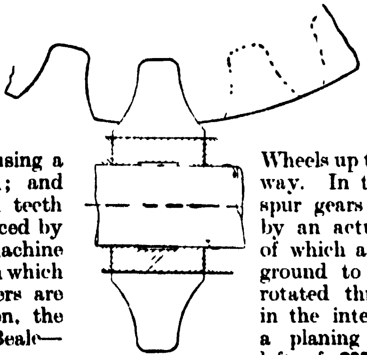
The foregoing simply give the principles on which screw-cutting calculations are worked out. Calculations may also be worked decimally. Millimetre pitches may be cut with an English lead screw by using a wheel of 127 teeth. The question of cutting screws having prime numbers to the inch often has to be considered. So, too, the problem often arises of cutting, not so many threads per inch, but of a certain number of threads in a given length of so many inches, and fractions of an inch, all of which admit of more extended treatment than can be given here. But no real difficulty need arise if the essential *ratio* between lead screw and screw to be cut, as previously stated, be borne in mind.

The cutting of multiple threads is done by chalking the teeth of the mandrel wheel and of the driven wheel which engages with it in two equal parts for double threads, in three for treble threads, etc., and using these marks as points at which to start each thread. There are also other devices. The question of catching threads at proper places has to be considered when the pitch of the screw to be cut is not divisible by that of the lead screw without a remainder. The cutting of square threaded screws gives rise to difficulties in grinding the angle of the tool, for which a diagram must be made of the developed thread. These and other details render screw cutting a highly specialised department of the turnery.



293. MILLING CUTTER

Gear Cutting. Recent years have witnessed an extensive substitution of cut for cast gears. There are many reasons for this into which we cannot enter. But with regard to the machine shop, the result is that the numbers of machines have increased, and that several new types have been designed. The most remarkable growth has been that of the *planer* type, using a *form*, or enlarged pattern tooth; and the *generating* type, in which teeth mathematically true are produced by mechanism embodied in the machine itself. These include machines in which rotary and reciprocating cutters are used—the Bilgram, the Warren, the Fellows, the Robey-Smith, the Beale—machines which have little in common except the resulting teeth produced by generation without either formers, or tooth shapes embodied in the cutters themselves.



294. MILLING CUTTER

Cutters. In the ordinary or older practice of gear cutting, all teeth are formed by milling cutters [**293** to **295**]. These answer very well for spur gears, though the accuracy of the teeth depends entirely on that of the cutters. But these are approximate only, since eight cutters have to produce all teeth from those of a rack to the smallest pinion in a set, and 24 cutters have to suffice in cycloidal teeth, as in the tables above:

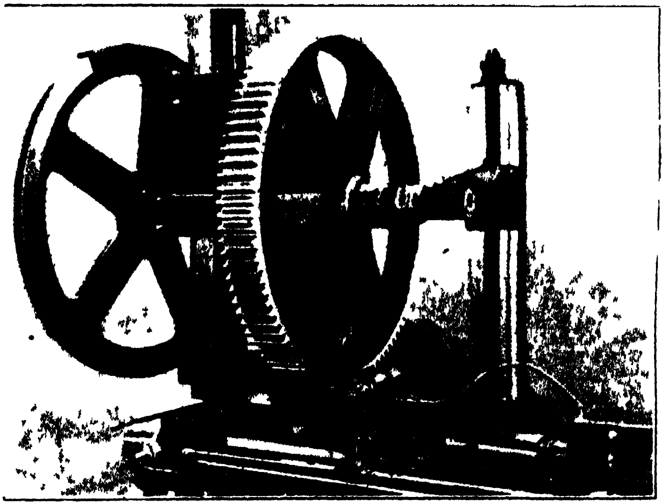
For the differences in teeth, see the course on Drawing for Engineers.

In some of the Gleason machines a form is used as a guide for the roughing-out planing tool, A in **296**. As this leaves fine ridges on the teeth, finish is imparted by the tool B, the shape of which is the counterpart of the tooth spaces. Wheels up to 20 ft. diameter are cut in this way. In the Fellows' machine, used for spur gears only, the teeth are generated by an actual wheel [**297**, A] the teeth of which are hardened, backed off, and ground to form cutters; the wheel is rotated through a small arc, and cuts in the intervals of each movement by a planing action, as indicated to the left of **297**. This process is identical with that which would happen if a wheel of a hard substance were rotated in relation to a wheel blank of a plastic material. One wheel thus generates the teeth of any wheel of any size of the same pitch with perfect accuracy. In **297** the right-hand illustration shows a pile of wheels, B B B, arranged to be cut simultaneously. At C, below, an internal gear is being cut. The gears B are being tooled with a draw cut, hence the reason for the resistance afforded by the adjustable stop D above.

Cutters for Bevel Wheels. But the difficulties in cutting bevel wheel teeth with rotary cutters are far more serious than those which occur with spurs, because of the tapering forms of the teeth, due to the attempt to cut teeth, the sectional shapes of which change constantly, with rotary cutters of unalterable section [298]. The result is a compromise. Absolutely true teeth are impossible in this system, hence the reason for the employment of planing and generating machines.

In planing machines for bevel wheels, a *form*, or enlarged tooth about three times larger than the wheel tooth on the major diameter, is used as a guide to the arm which carries the reciprocating cutting tool, which travels in a path always towards the apex of the pitch cone [299]. The result is teeth the accuracy of which depends on that of the form used. The process is a slow one, hence many of these machines have two arms and tools cutting on opposite flanks. The Sellers, the Oerlikon, the Gleason, and the Greenwood and Batley belong to this group.

The first generating machine made—the Bilgram—embodies roll cones by which the reciprocating arm is coerced, and accurate teeth are thus generated, and this machine still holds a leading place. The Robey Smith embodies a rather complicated link mechanism by which the movements of the two cutting arms are controlled. In the Warren, the tools are controlled by slides, the angles of which change constantly.



295 MILLING CUTTER CUTTING SPUR GEAR

The duties of the machinist operating gear cutting machines obviously vary very much with the class of machine used. In the ordinary types the pitching has to be done by hand through a division plate and change wheels, in the fully automatic types one man or youth can attend to several machines. The turning of the blanks is done elsewhere at the lathes, or in some cases they are milled. The wheel blanks, turned to the correct outlines, terminating at the points or ends of the teeth, are also bored. The bore affords the means by which they are held on an arbor during cutting, though they are fixed [295] firmly by bolts in addition.

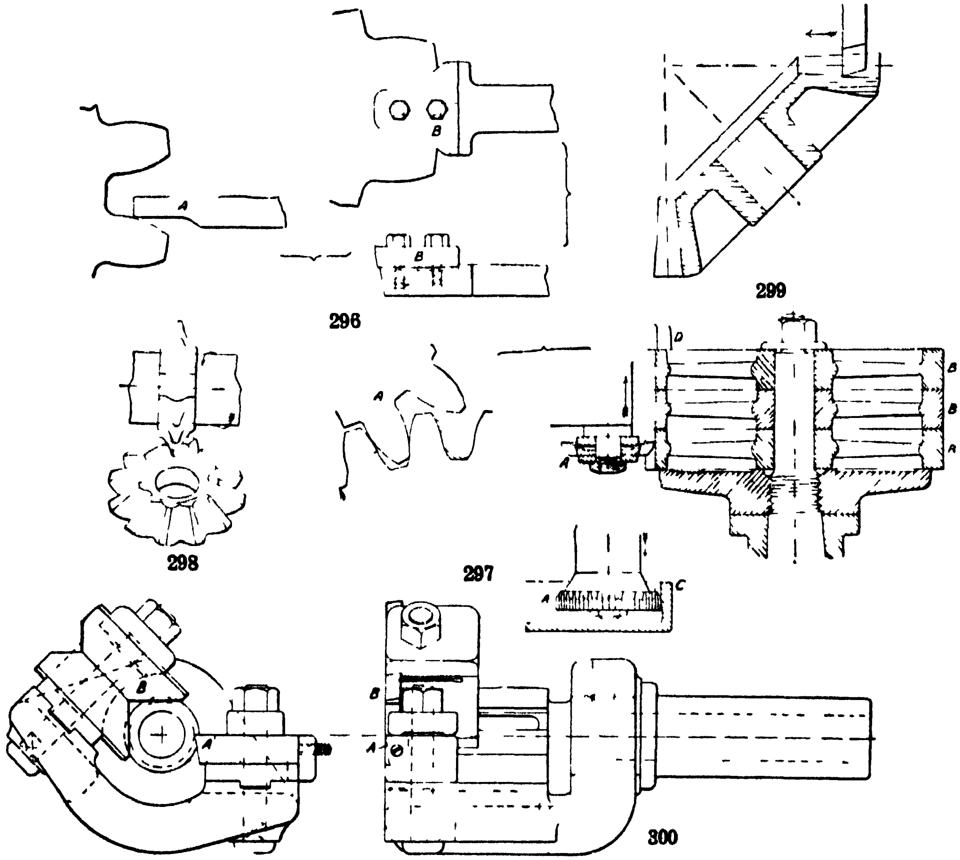
Turret Work. The large group of machines which are included under the terms *turret lathes* and *automatic screw machines* constantly grow in importance. They are rivals to the common lathes and to screwing machines. The essential feature by which they are distinguished is that, instead of setting a tool or tools in succession in a slide rest, a number of tools are fixed up and set permanently in turret and cross slide [301] to operate in succession on a piece of work, and that the operations on any number of similar pieces are repeated without any refixing or readjustment of the tools. This means that all the dimensions of a piece of work are fixed by the tools with the result that tentative measurements during the progress of the cutting are avoided. This is true in turret and automatic lathes alike. But the latter embodies, in addition, all provisions necessary for the automatic movement and gripping of the work, of the rotation and locking of the turret and its tools, and of the tools in the cross slides, and all are timed to take place at the precise instant required.

Turret Tools. Tools used in turret practice comprise roughing and finishing tools for turning, boring, and forming tools for cutting off, drills, reamers, and screwing tools. They are gripped in the turret directly, or in intermediate boxes, or in the cross slide. No measurement is ever taken with rule or calipers after the tools are once fixed up until after the work is removed from the lathe. The range of movement of each tool is predetermined by the use of stops and throw out mechanism, so that subsequent gauging detects but a small proportion of inaccurate pieces. The action of the tools is much assisted by the free use of lubricant pumped under pressure on the tool points and the portions of the work which are undergoing cutting. Their cutting edges are thus preserved good for very considerable periods, generally for some days, and the accuracy of the work produced is not impaired by any important rise in temperature.

Points in Turret Practice. In the employment of these tools there are several other matters which have to be borne in mind as affecting the accuracy of results—the embodiment and the maintenance of alignment, the prevention of vibration or distortion, the flexure of tools and their holders, and the synchronising of the movements of the tools with those of the work are essentials. It must be remembered that, in the interchangeable classes of products which are done on the turret lathes, uniformity in dimensions is necessary within a finer limit than a thousandth of an inch, and therefore flexure, distortion, or vibration to that amount would be fatal to the degree of accuracy demanded in such work.

The multiplication of tools is the most distinguishing feature of the turret lathes. Instead of putting in and clamping tools in a rest one after another for performing successive operations, all the tools required are held in a revolving turret and on a cross-slide [**301**], so that they may be brought into position in succession as rapidly as possible, and by means of stops may be checked at predetermined positions, enabling work to be repeated indefinitely to uniform dimensions. The tools are constructed so that they cannot cut smaller or larger through any mistake on the part of the attendant, who simply has to move the handles to feed up and withdraw the tools. In automatics even this is dispensed with, and the movements are actuated by cams without human intervention.

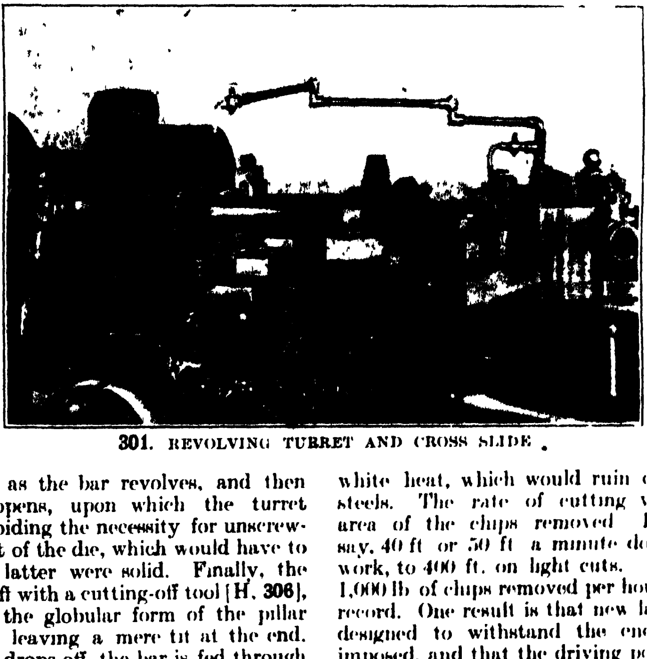
A great improvement introduced by the turret lathes is that of making pieces from solid plain bar, instead of using forgings of the approximate shape required, and finishing them. By using a bar, a considerable length can be gripped in the chuck and fed through at intervals as pieces are turned off, and there is no bother with scale as on forgings, or difficulty in holding up to dimensions. Bars up to 6 in. diameter are thus worked from on semi-automatics and full automatics.



296. Gear cutting with form as guide **297.** Details of Fellows' gear-cutting machine **298.** Rotary cutter at work **299.** Bevel gear cutting by planing **300.** Box tool for turret lathe

Example of Turret Work. The example of turret practice shown in **300** to **306** will serve to illustrate the principal operations done with turrets, the case being taken from the practice of Alfred Herbert, Ltd. on one of their automatics. The piece being produced is a locomotive handrail pillar, which is finished from a bar, A, the size of the largest diameter, held in the headstock chuck and rotated by it. The turret, shown with its complete set of tools in **302**, first brings up a starting tool, B, with three flat cutters held in such a way that the end of A is bevelled or pointed, as seen in **302**, to enable the box tool C [**303**] to begin easily. Before, however, C can begin, B has to retreat, and the turret be given a partial turn, bringing C into line with the bar, when it commences to travel up the latter. The box tool, seen in detail in **300**, comprises a cutter, A, held in a cast-iron frame or box, and clamped and adjusted therein by a bolt and grub screw, and a pair of adjustable V-guides [B] located opposite the cutting edge. The bar cannot, therefore, spring away from the tool, as it may in ordinary turning, but is kept up to it by the guides, enabling heavy cuts to be taken and ensuring uniform diameters on numerous pieces. Two diameters may be turned on a bar by fitting a couple of the tools and guides A and B in a box, one behind the other, a longer box being used if required.

Returning again to the sequence of operations, in **304** the box C has retreated, and another, D, is brought up for finishing to exact size—because C had to rough off a large amount—and also to cut down the end of the bar smoothly to length, with a facing tool held in the shank of D. Forming is the next operation, done with a broad, deep tool [E, **305**], held on the cross-slide and fed into the bar until it assumes the shape seen in **305**. A steady bush, F, in the turret supports the end of the bar during forming, to prevent it from springing back under the heavy stress. Screwing is done next with the die [G, **306**], which cuts the thread as the bar revolves, and then automatically opens, upon which the turret moves back, avoiding the necessity for unscrewing the work out of the die, which would have to be done if the latter were solid. Finally, the piece is parted off with a cutting-off tool [H, **306**], formed so that the globular form of the pillar end is retained, leaving a mere tit at the end. When the pillar drops off, the bar is fed through the spindle again, and the cycle of operations is repeated.



301. REVOLVING TURRET AND CROSS SLIDE

In addition to these common operations, others which can be done on turret lathes are boring, recessing, and threading holes, broad facing, with tools travelling on the cross-slides, taper turning and boring, reamering, knurling, etc., some of which entail the use of special rigs.

Influence of Turret Work. The modern practice of turret lathes and automatics has effected profound changes in the forms of and methods of operation of many cutting tools. From the comparatively simple forms used on the semi-automatic lathes, in which all the various movements of the tools and of the work are effected by the volition of a workman who dares not move away from his post, they have grown into very complicated mechanisms. The reason of this complication is twofold: first, the desire to be able to perform two or more cutting operations simultaneously; and, secondly, the economical necessity of making the machines and their movements wholly automatic. The result is the evolution of the boxes that contain several tools. The movements of each tool are predetermined, and in the more elaborated types there is mechanism introduced for producing movements of the tools in the boxes, independently of the primary motion of the box derived from the movement of the turret.

High-speed Tools. The advent of the high-speed tool steels in 1900 has changed the practice of the machine shop in a more radical fashion than any other innovation since the inventions of the slide rest lathe and the planing machine. These steels do not owe their value to carbon, as do the ordinary tool steels, but chiefly to chromium, tungsten, and molybdenum They are not tempered, but hardened right out in cold air. They operate best at high speeds and at high temperatures. They show to better advantage in turning mild steel than cast iron. They are forged at a white heat, which would ruin ordinary carbon steels. The rate of cutting varies with the area of the chips removed It ranges from, say, 40 ft or 50 ft a minute doing very heavy work, to 400 ft. on light cuts. From 800 lb. to 1,000 lb of chips removed per hour is no unusual record. One result is that new lathes have been designed to withstand the enormous stresses imposed, and that the driving power in machine shops using these steels has had to be trebled and quadrupled. The same steel is used largely for drills and milling cutters, and some remarkable performances are on record.

Templeting. A section of modern practice which is of vast and growing importance is that denominated *templeting*, *fixture*, and *jig work* The terms are used rather loosely, but may be defined as follows. A *templet* or *template* is used to avoid the lining out illustrated in a previous article. Its function is either to embody centres and edges for lining off work by, or to be employed as a guide for machining by. The first-named is the templet proper, the second is often termed a *fixture*, something which is attached to the piece of work, or vice versâ, thus obviating any lining out whatever. The advantage is that not only is much time saved, but any number of pieces machined thus will be all alike, which cannot be guaranteed when lines have to be worked by.

The simplest example of the templet, or jig, is that used for drilling and allied operations [307]. The holes provided in it control the drill or reamer so that there can be no departure from exact centres. As the holes would wear in time with the friction of the drill, they are generally bushed with hardened steel [307], or cast-iron bosses are screwed or riveted to the sheet metal templet [308]. Provision is also made for setting or adjusting the templet to the work, and this is often not an easy thing to design when fitting has to be made to rough castings and forgings.

In strictness, the term templet, though applied loosely to fixtures and jigs, signifies something by which work is lined out, though drilling templets, as just shown, are constantly spoken of. A *fixture* denotes something which is specially designed and attached to a machine for holding special pieces in repetitive work without involving tentative settings. It may or may not include provision for controlling the movements of tools. But if it does embody such provisions, the term *jig* is usually applied. Some of these fixtures and jigs are of a simple character, others are extremely complicated and costly. Many embody provision for controlling the whole of the tooling on an elaborate casting or forging, as planing, milling, drilling, reaming, etc., at one or more settings. They may cost many pounds, but in an interchangeable system of manufacture the cost per piece becomes almost inappreciable, and often comparatively unskilled labour may be employed, since neither lining out nor measurement has to be done. In modern practice these devices are largely adopted.

Subdivision in the Machine Shop. This is carried out to a greater extent than it was a few years ago. It is done in two ways—either by grouping machines under a single roof, or by arranging them in separate shops. In a works of medium size, the first is the better plan, but as firms increase in dimensions the latter possesses advantages. In the first case, the entire shop can be under the control of one foreman; in the second, since more than one foreman is necessary, it is better to keep the departments in separate buildings. It is more convenient for power transmission and for handling materials and work to have machines grouped, when in large numbers, in separate buildings. The modern method, therefore, is not to mix up all sorts and sizes of machines, as lathes, planers, shapers, drills, indiscriminately, but to have a heavy planing department, and a light one also, light milling machines distinct from the heavy, light drills also—a system which lends itself to the better control of tools and jigs, to the training of hands, and to economies in production.

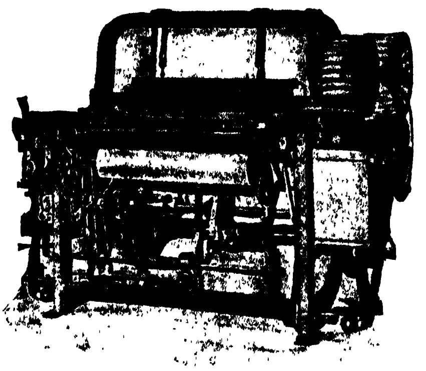
AUTOMATIC LOOMS

The Advantage of Continuous Supply of Weft. Efforts to Attain this. Automatic Weft Feed on the Northrop Loom

Continued from page 3403

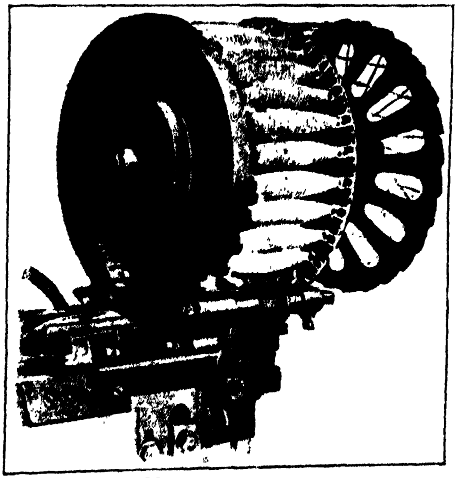
By W. S. MURPHY

WHEN Edmund Cartwright invented the power-loom he imagined that he had discovered the principle of automatic weaving; but practical experience soon showed him his mistake. The loom itself would go on working so long as the driving power was applied; but the weaving ceased so soon as the weft spool in the shuttle was exhausted. Here the inventor met with an obstacle he could not surmount. The shuttle is not attached to the mechanism of the loom; it runs to and fro, an independent unit. To be refilled, the shuttle must be taken out; this involves a complete stop. We have also been compelled to devise means by which the loom is thrown out of gear when the weft breaks. Here is the problem: How is the loom to be kept going while the shuttles are being changed, or while the weft supply is being maintained?



163. THE NORTHROP LOOM

The Northrop Loom. After the lapse of 100 years, and after many a man had worn himself out with attempts to get over the difficulty, news came from across the Atlantic that the problem had been solved by a citizen of the United States. The solution took the form of what is now known as the *Northrop loom* [**163**]. Strictly speaking, the loom was a novelty only in the sense that it made commercially practicable what had before been regarded as experimental.



164. WEFT CARRIER

Continuous Supply of Weft. The main feature of the Northrop loom is the apparatus for the continuous supply of spools to the shuttle. It was originally intended to be made applicable to all forms of existing looms; but, as we shall see from our examination of the appliance, some modification of structure was necessary.

The bobbin or spool carrier [**164**] is placed on the breast of the loom. Two discs, the length of the spool apart, are sleeved on the supporting bracket, and on the inner sides of the discs are set small springs which hold the spools. A guard is formed on the supporting bracket to keep the bobbins in position, while the one nearest the loom, and in position for delivery, is constantly pushed by a spring pawl. On the boss of the disc is a ratchet which engages the spring pawl and regulates its action. Further out on the spindle bearing the spool carrier, we find another disc over which the thread from the spool is led, and held tense.

Spool. The spool of the Northrop loom is special [**165**]. In the tip is a little hole to fit on the spring of the holder; on the butt end grooves or rings are made to catch into the spring of the shuttle; and the spool must be fairly strong.

Shuttle. A common shuttle is solid, with an eye at one end for the threading of the weft; but the Northrop shuttle [**166**] requires to be of such a structure that it will allow a spool to be thrust into it by mere force, and yet hold it tightly. Inside, the shuttle is grooved, and a spring tongue grips on to the spool; at the end where the eye is required, a slit opens to admit the tensely drawn thread of the spool, and then closes with the motion of the loom.

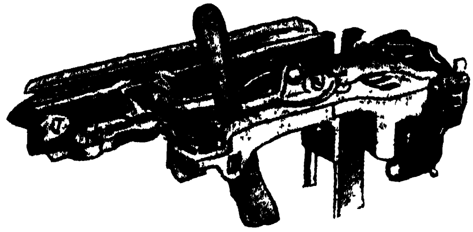
Mechanism of the Feed. We have seen the tools, but the most important parts are yet to be examined. In the ordinary loom, the weft fork stops the loom as soon as the thread breaks; this is the mechanism which the inventor of the Northrop has utilised for his purpose. Instead of the hammer and presser acting on the spring lever which throws the belt off the driving pulley, they have a different function to perform. Connected with the slide at the end of the weft fork, we find a pair of rocking levers, one of which has on its end what is called a *feeler* [167], while the other acts on the spool carrier. By the combined action of these levers, the weft spool is taken from the carrier and driven into the shuttle.

Control of Weft and Warp. When the weft is spent it leaves a trail of thread; to do away with this the Northrop loom is fitted with a cutting device which severs the thread at the edge of the cloth. Warp-breaking is also detected by another ingenious improvement on the usual warp-stop motions. It consists of a series of slotted steel slides in the healds, through which the warp is passed. If a thread breaks or slackens, the steel slide drops and stops the loom.

165. SPOOL OF NORTHROP LOOM

Working the Northrop Loom. Assuming that the loom is going and the weft laid properly in the shed, we find all the special mechanism of the Northrop out of action—the pusher is raised, the feeler is laid back, there is no contact between presser and shuttle box, for the weft fork tilts at every beat of the slay. But now the weft breaks, and the fork stands still; the hammer, hitherto beating the air, is met by the slide on the end of the fork, which it drives back, setting the other levers in motion. The lever controlling the shuttle feed is brought up, and is met by a small iron projection on the body of the slay. By this finger the lever is brought down, and the spool pushed out of the holder into the shuttle. At the same moment the spool drives out the spent or faulty spool, and threads its yarn into the shuttle. This action is clearly illustrated by **168.** As will be noted, it was the forward movement of the slay which called those motions into play; when the slay has swung back and reached its limit, the action is completed; before it comes forward to make another beat, the weft is in the loom, and weaving has been resumed. With the same act, the ratchet on the carrier gets a turn, and another spool is put into position. If, from any cause, the feeding apparatus fails to act, the loom stops. Every detail of this loom has been carefully devised, and covered by patents.

166. SHUTTLE OF NORTHROP LOOM



167. NORTHROP LOOM FEELER

The "Burnley" Loom. Though the best known of the automatic looms, the Northrop does not occupy the field alone. We do not refer to the Hattersley, and other looms of that class, which also have undoubted claims; but there is one rival, at least, based on the same principle as the Northrop, and this must be given some attention.

A cast-iron hopper, containing specially made weft-cases, is fixed on the breast of the loom. The bottom of the shuttle box is cut away, and beneath it a curved slot extending to the front of the slay has been framed. Two spring fingers are fixed in front of the mouth of the slot, and project towards the breast beam. At each side of the hopper a vertical slide is mounted, and these slides between them hold a cradle, which keeeps the weft cases in position. Upon these slides the weft fork acts when the weft fails, causing a weft-case to drop down and into the mouth of the slot. At the same time, the position of the dropped case is occupied. When the slay comes back, the weft-case cannot obtain re-admittance to the hopper; it meets a solid resistance; therefore, it is driven through the slot and up into the shuttle from which it expels the spent weft-case. A weight brings back the cradle into its normal position.

The "Seaton" Loom. It has often been said that the shuttle is the thing which prevents the loom from being completely automatic. The inventors of the Northrop, the Burnley, and other looms less famous, have devised means of making the feed of the shuttle automatic; but others have tried to do away with the shuttle altogether. Reluctant as we may be to part with such a faithful servant of the textile industry, we confess to the belief that in this direction lies the complete solution of the problem. Of several devices already being tried, the loom known as the Seaton, seems most typical and promising. In this loom the shuttle is abandoned, and another contrivance adopted, which we must examine in detail.

Weft Carrier. In the place of the shuttle, we find in the Seaton loom a double steel carrier, with grippers on each end. This carrier has two motions; the first drives it across the shed; the second pushes it further inward. During the first motion the grippers of the carrier are closed; during the second they are open. When home, the grippers are again closed, and they hold a thread

Weft Feed. Weft bobbins stand at the sides of the loom, and from the bobbins the weft is led up through a guide eye into a tube with clearing and regulating appliances. Thence the thread passes into a measuring and tension apparatus, which pays out to the carrier exactly the length of thread required, and then the shears come up and nip off the thread. The carrier bears the weft through the shed, and the slay comes up and drives it home. At the other side of the loom, the other end of the carrier performs in the same style. So thread by thread the loom works without stop. In other respects the Seaton loom is controlled by the same mechanism as the common power-loom. Should the weft fail from any cause, the weft fork will act and stop the loom.

Automatic Weaving. The three looms so briefly sketched are taken as representative of the types of machine at present practical and in actual work. There are many others, for the difficulty of the problems involved attracts ingenious minds, and the profit offered for success is very great. Though thousands of Northrop looms are working on both sides of the Atlantic, and producing cloth constantly, it can hardly be accepted as the complete solution of the problems involved in automatic weaving. Production of plain cloth is only the first step in weaving. We do not belittle the Northrop in saying that it is a complex machine; it is the common power-loom, with the automatic appliances added on. Add further the complexity of the dobby, the jacquard, the swivel, or the lappet, and we have complication of a bewildering kind. Looms of the Northrop and "Burnley" have undoubtedly a useful future before them, but the great difficulty in the way of complete automatism in the loom has not been overcome.

Some hint of the possible solution of the problem may be got from the "Seaton" loom, which discards the shuttle; but it seems that the whole method of forming fabrics should be thoroughly reconsidered. The lace loom, the various knitting machines, the gauze looms, the looms with changing warps and circular shuttle boxes, all suggest that some machine lies hidden which, if discovered, would unify the whole of fabric manufacture. Unknown to all save their own workers, and, perhaps, a privileged observer, some manufacturers have already made considerable strides towards the realisation of this ideal. At the present moment there are horizontal looms upon which lace curtains are woven; cloth is being made on what has hitherto been deemed only a knitting machine; the traditional alternation of warp and weft has been obviated in the secret production of several kinds of fancy fabric. These mysteries lie far beyond the limits of our present study; but we point to the facts as showing how progress is being made, though no trumpeting proclaims it, and as a stimulus to further effort. Weaving is a practical business, and the wise manufacturer is more concerned about making a profit than achieving fame as an inventor. He devises methods of making a fabric for which he hopes to have sale; the market supplied, he discards the mechanism for something else. The field of manufacture is strewn with discarded contrivances, many of them valuable if we could recover them. The art of weaving has progressed, but much remains to be done.

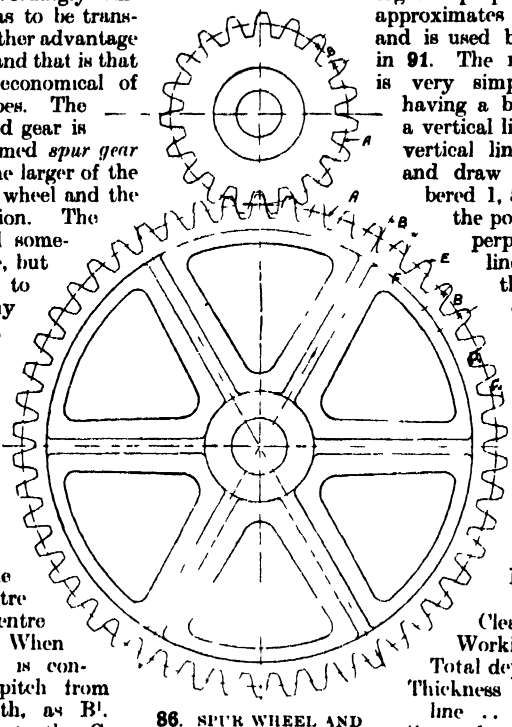
SPUR WHEEL TEETH

Toothed Gears. Pitch Circles. Proportions of Teeth. Scale for Teeth. Forms of Teeth—Cycloidal and Involute. How to Make and Use an Odontograph

By JOSEPH W. HORNER

Toothed Gears. We have seen that a belt or a rope does not transmit power accurately, but that a certain loss of speed occurs, due to "slip." Toothed gears are not open to this objection, and are accordingly employed where motion has to be transmitted accurately. Another advantage accrues from their use, and that is that they are much more economical of space than belts or ropes. The simplest form of toothed gear is shown in **86**, and is termed *spur gear* or *spur and pinion*. The larger of the two wheels is the spur wheel and the smaller one is the pinion. The term *pinion* is applied somewhat loosely in practice, but is generally understood to mean the smaller of any two wheels in contact, or any wheel having less than 20 teeth.

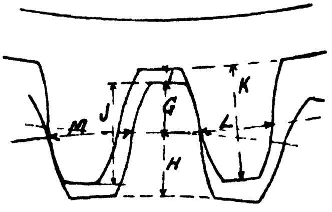


86. SPUR WHEEL AND PINION

The dotted circles marked A are the *pitch lines* or *pitch circles;* these are the theoretical lines of contact and from them measurements are taken. The pitch of the teeth, B, is the distance from the centre of one tooth to the centre of the next one. When measuring a wheel it is convenient to take the pitch from the edges of the teeth, as B¹. That portion of the tooth, C, which extends above the pitch line is termed the *face* or *addendum;* while that portion, D, which lies below the pitch line is called the *flank* or *dedendum*. The extreme outer end, E, of the tooth is the *point*, and the lower end, F, is the *root*.

Proportions of Teeth. The average English proportions of gear teeth are indicated in **87**, and are as follows:

Height of tooth above pitch line (G) .. .. = ·33 pitch
Depth of tooth below pitch line (H).. .. = ·40
Clearance at root (I) .. = ·07
Working depth of tooth (J) .. .. .. — ·66
Total depth of tooth (K) .. .. = ·73 pitch
Thickness of tooth at pitch line (L) = ·47 „
Space between teeth at pitch line (M) = ·53 „



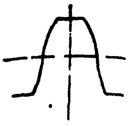
87. PROPORTIONS OF TEETH

It is very essential that a manufacturing house should have all its gear patterns made to some uniform system of proportion, so that any two wheels the same pitch shall work together properly. A useful *scale* which approximates the above proportions and is used by some firms is shown in **91**. The method of construction is very simple. Draw a triangle having a base line 12 in. long and a vertical line 4 in. long, divide the vertical line into 15 equal parts, and draw lines from parts numbered 1, 5, 6, 7, 8, 10, and 11 to the point of the angle. Erect perpendiculars on the base line in such positions that their respective lengths correspond with definite pitches, as ¼ in., ½ in., ¾ in., etc.; then on any vertical line the tooth dimensions for the corresponding pitch may be taken off with compasses, the proportions being:

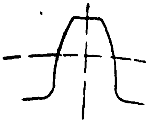
	pitch
Height of tooth above pitch line	$\frac{5}{15}$
Depth of tooth below pitch line ..	$\frac{6}{15}$
Clearance at root ..	$\frac{1}{15}$
Working depth of tooth ..	$\frac{10}{15}$
Total depth of tooth ..	$\frac{11}{15}$
Thickness of tooth at pitch line	$\frac{7}{15}$
Space between the teeth at pitch line	$\frac{8}{15}$

This scale is perhaps more useful in the pattern shop than in the office, as all the teeth are there marked out full size, and the dimensions can be taken off the scale direct and transferred to the pattern or tooth-block.

Forms of Teeth. The forms of the teeth of gear-wheels have occupied the attention of engineers to a very considerable extent; an ideal gear would have a constant motion identical with that of two smooth-faced pulleys whose diameter would represent the pitch circles in contact. If the tooth form does not permit this constant velocity at the pitch line, then a more or less noisy and inefficient gear results. A badly-formed tooth



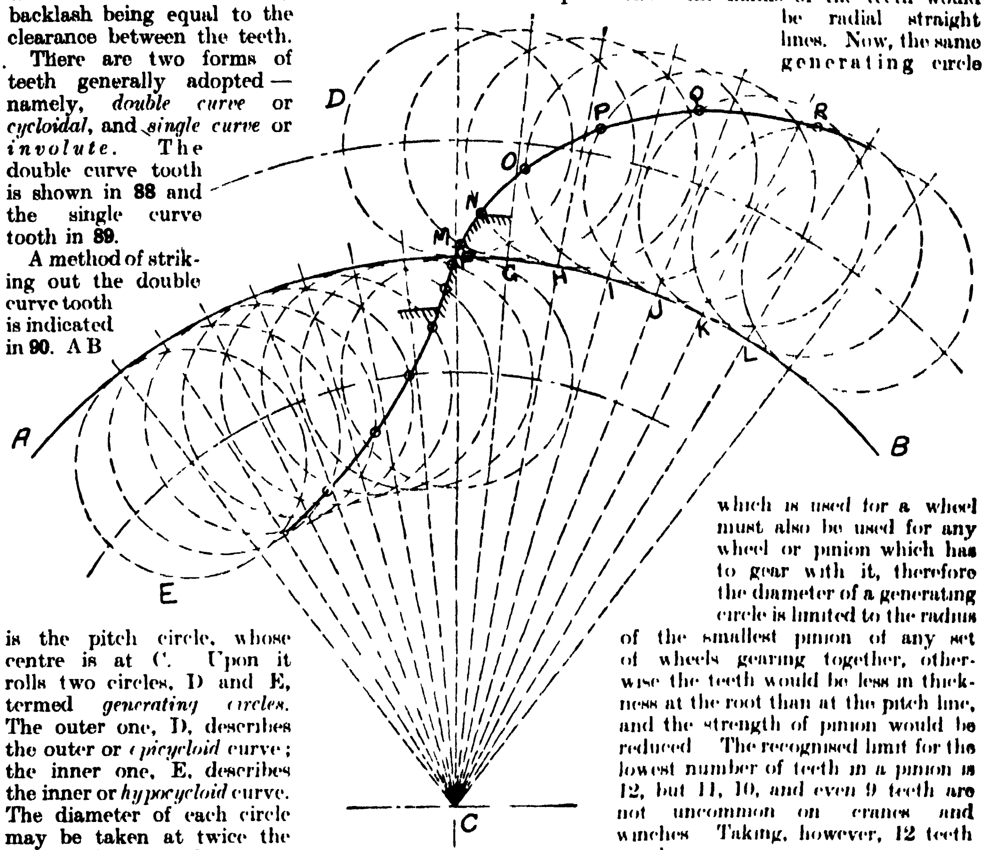
88. DOUBLE CURVE TOOTH



89. SINGLE CURVE TOOTH

is contributory to what is called *backlash*. A variation in velocity causes relative movement between the teeth in gear, and they leave their driving faces and come into collision with the teeth in front of them, the amount of the backlash being equal to the clearance between the teeth.

There are two forms of teeth generally adopted—namely, *double curve* or *cycloidal*, and *single curve* or *involute*. The double curve tooth is shown in **88** and the single curve tooth in **89**.



90. CYCLOIDAL CURVE

A method of striking out the double curve tooth is indicated in **90**. A B is the pitch circle, whose centre is at C. Upon it rolls two circles, D and E, termed *generating circles*. The outer one, D, describes the outer or *epicycloid* curve; the inner one, E, describes the inner or *hypocycloid* curve. The diameter of each circle may be taken at twice the pitch. Taking the outer circle first, mark it out in a number of equidistant positions as shown, and draw the centre lines through to C; then take the arcs F G, F H, F I, F J, F K, and F L, and step round similar arcs on the generating circle in its various positions so that G M is equal to G F, H N is equal to H F, I O is equal to I F, J P is equal to J F, K Q is equal to K F, and L R is equal to L F, remembering always that the curved line or arc must be measured, and not a straight line or chord. Through the points M, N, O, P, Q, and R lies the true path of the *epicycloid* curve. The *hypocycloid* is obtained in a similar manner, with the inner generating circle rolling in the reverse direction. Only a portion of the curve is required for a tooth, as shown in hatched lines. The diameter of the generating circle has a great influence on the thickness of the tooth at the root and at the point; if it were made of equal diameter to the radius of the pitch circle the flanks of the teeth would be radial straight lines. Now, the same generating circle which is used for a wheel must also be used for any wheel or pinion which has to gear with it, therefore the diameter of a generating circle is limited to the radius of the smallest pinion of any set of wheels gearing together, otherwise the teeth would be less in thickness at the root than at the pitch line, and the strength of pinion would be reduced. The recognised limit for the lowest number of teeth in a pinion is 12, but 11, 10, and even 9 teeth are not uncommon on cranes and winches. Taking, however, 12 teeth as the minimum in average practice, the diameter of the generating circle works out to practically twice the pitch.

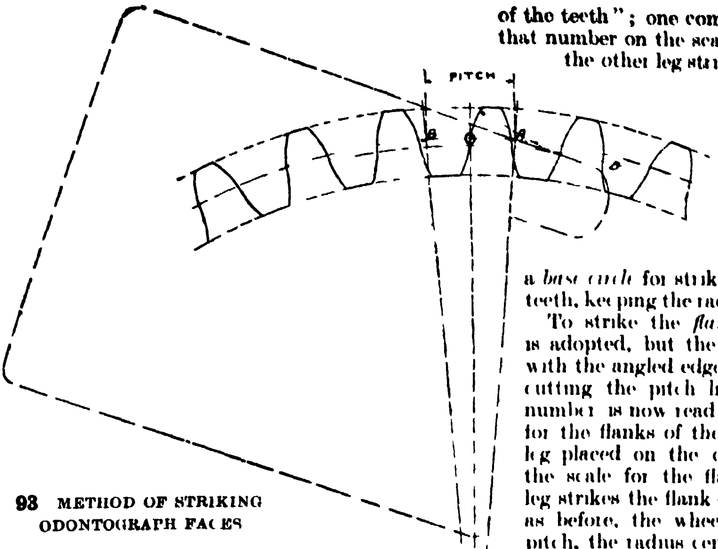
92. THE ODONTOGRAPH

The Odontograph. The odontograph is an instrument invented to avoid the labour of marking out the cycloidal curves for each and every size of wheel and pinion that may be required. Suitable radii are given upon the instrument for the faces and flanks of teeth for all ordinary numbers. One of its edges is cut to an angle of 75°, which can be laid in certain definite positions relatively to the pitch and pitch line, and so used in order to obtain the centres of the radii.

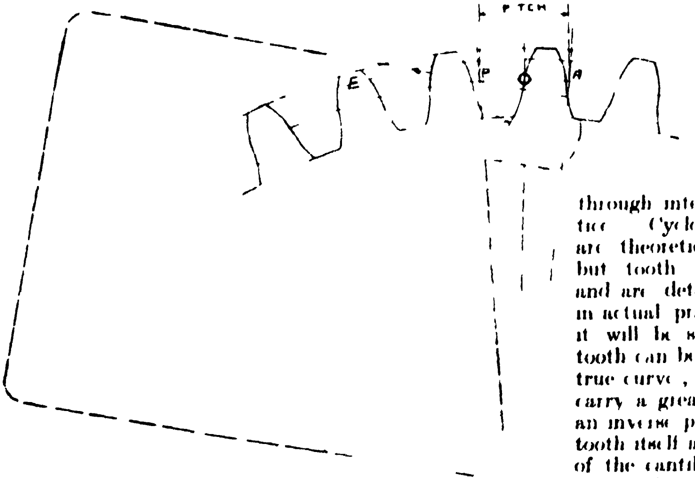
The odontograph is shown in 92. It can be made by the student of stiff drawing paper or Bristol board. The width may be 10½ in. and the length 13¾ in. measured over the point. The angle of the sloping edge is 75°, and this angle is carried through as a line to the edge of the scale. Marking this line at zero, the scale is laid down parallel to it right and left in ½ in. divisions, each division being subdivided into 10 parts. The scale on the point comprises



93 METHOD OF STRIKING ODONTOGRAPH FACES

40 divisions, whilst the scale on the other side has 200 divisions; the former gives radii for *faces* of teeth and the latter gives radii for the *flanks* It is very convenient to have the tables of centres on the instrument as shown [92]

How to Use the Odontograph. First of all draw the pitch circle of the wheel required, also lines representing the tops and roots of the teeth, then lay down the pitch and bisect it on the pitch line, obtaining points A and B [93 and 94], the centre of the bisection, O, becomes the edge of the tooth To strike the *faces*, lay the odontograph on the drawing, with the angled edge on line A [93] in such a position that the scale edge just cuts the pitch line The radius of the face is found by reading the radius number off the table of "Centres for the faces of the teeth"; one compass leg is placed against that number on the scale of centres for the faces, the other leg strikes the face curve from O Suppose the wheel to have 40 teeth 2½ in pitch, then according to the table the radius centre is at 19 on the scale Having once found this centre, a dotted circle D may be drawn through it and used as a *base circle* for striking the faces of the other teeth, keeping the radius constant for each face



94 METHOD OF STRIKING ODONTOGRAPH FLANKS

To strike the *flanks* [94] a similar method is adopted, but the odontograph is now laid with the angled edge on B, the scale edge again cutting the pitch line The required radius number is now read off the table of "Centres for the flanks of the teeth, and the compass leg placed on the corresponding number on the scale for the flanks, the other compass leg strikes the flank curve from O Assuming, as before, the wheel to have 40 teeth 2½ in pitch, the radius centre is at 35, and a dotted circle E may be drawn through it as a *base circle* for striking the flanks of the other teeth

The odontograph does not provide for pinions having less than 12 teeth, and such pinions must therefore be set out by means of generating circles, as previously described, the diameters of the circles being taken at half the diameter of the pinion

The depth of wheel teeth is quite independent of the tooth curves, and it may be noted here that there is at present a distinct tendency to use shorter teeth than formerly, this tendency takes effect in machine cut gear (described in the next lesson), and would undoubtedly obtain in ordinary cast gear but for the confusion that would arise in many engineers shops through interference with existing practice Cycloidal and involute curves are theoretical lines, and do not vary, but tooth proportion are arbitrary, and are determined by trial and error in actual practice For instance in 90 it will be seen that the length of the tooth can be varied without affecting its true curve, naturally a short tooth will carry a greater load than a long one in an inverse proportion to its length, the tooth itself is no stronger, but the length of the cantilever is less *Working* conditions demand teeth of sufficient length to ensure good contact even when wheels are not set accurately and the pitch circles do not coincide In dealing with gears to transmit great power, it is usual to design the teeth specially, and then the length of the *tooth may be reduced* to 5 of the pitch, or even less.

THE PRONOUN

Personal Pronouns

The personal pronouns are substantives of three persons.

The first person indicates the person who is speaking: *io cammino*, I walk

The second person indicates the person to whom we speak: *tu leggi*, thou readest.

The third person indicates the person of whom we speak: *egli canta*, he sings.

First person singular *io* (subj.), I; *me* (complement), me (pronounced *ee-o*, *meh*).

First person plural *noi* (subj. and compl.), we, us.

Second person singular *tu* (subj.), thou; *te* (compl.), thee (pronounced *too*, *teh*).

Second person plural *voi* (subj. and compl.), you.

Third person singular, masculine, *egli*, *esso* (subj.), he, it; *lui*, *esso* (compl.), him, it.

Third person singular, feminine, *ella*, *essa* (subj.), she, it; *lei*, *essa* (compl.), her, it.

Third person plural, masculine, *essi* (subj.), they; *loro*, *essi* (compl.), them.

Third person plural, feminine, *esse* (subj.), they; *loro*, *esse* (compl.), them.

For both genders and numbers: *sè* (compl.), *oneself*, *himself*, *herself*, *etc.*

1. The forms *lui*, *lei*, *loro*, are commonly used as subjects instead of *egli*, *essa*, etc. This is the case (1) when attention is particularly called to the subject; (2) after *anche* (also), *più* (more), *nemmeno* (not even), and similar words. Examples: *Lo dice lui* (*ma non io*), He says so (but not I); *Anche lei era là*, She also was there.

2. The forms *me*, *te*, *lui*, etc., must always be used instead of the subjective forms when they stand as the second term of a comparison. Examples: *Egli studia più di te*, He studies more than thou; *Io sono meno ricco di lui*, I am less rich than he.

3. The pronoun of the third person *sè* is always referred to the subject of the sentence, as: *Pietro pensa per il suo amico Carlo, ma Carlo pensa solo per sè*, Peter thinks for his friend Charles, but Charles thinks only for himself. (Note that *per lui* in this sentence would mean *for Peter*.)

4. *Noi* and *voi* may be strengthened by the addition of *altri* (for the masculine), *altre* (for the feminine), as: *Noi altri andiamo a casa*, We are going home; and all the pronouns may be strengthened by placing after them *stesso*, *-a*, *-i*, *-e*, which correspond to the English *self*, *selves*. Example: *L'ho visto io stesso*, I have seen it myself; *Essa stessa venne da me*, She herself came to me; *Egli pensa solo a sè stesso*, He only thinks of himself.

5. Prepositions (*di*, *a*, *da*, *in*, *con*, *su*, *per*, *etc.*) are followed by the objective forms, as: *Io non ho paura di lui*, I have no fear of him; *Ho una lettera scritta da lei*, I have a letter written by her; *Venite con me*, Come with me; *Pietro è andato con lui*, Peter has gone with him.

6. Instead of *con me* (with me), *con te* (with thee), the contracted Latin forms *meco*, *teco*, may be used. Note that *seco* means *con lui* (with him), *con lei* (with her).

Exercise XXIII.

cascare (*cah-scàh-reh*), to fall
capire (*cah-peè-reh*) to understand
accompagnare (*ahccompah-neeàhreh*), to accompany
tenère (*tehnèh-reh*), to keep (to have)
pacco (*pàhcco*), parcel
proposta (*propòstah*), proposal
bisogno (*beesò-neeo*), need
invece (*eenvèh-cheh*), instead

Note the following expressions, in which the verb "to be" in Italian must agree with its subject: It is I, *sono io*; it is thou, *sei tu*; it is he, *è lui*; it is they, *sono essi*; it is not they, *non sono essi*; it was not we, *non eravamo noi*, etc.

1. Noi abbiamo lavorato più di voi. 2. La lèttera è stata scritta da me e non da lui. 3. Se voi accompagnate me, io accompagnerò voi. 4. Esse pènsano sempre tutto il contràrio di quello che dìcono 5. Loro crèdono di far bene, e invece fanno molto male. 6. Noi non abbiamo mai niente; essi tèngono tutto per loro. 7. Lei é gentilissima, ma lui no. 8. Quando siamo stati in bisogno, esse hanno sempre fatto molto per noi. 9 Tu pensi sempre a te, e non pensi mai agli altri. 10. Un signore ha domandato di voi.

Exercise XXIV.

1. Where are you going? If you will wait a little longer I will come with you. 2. You have come in time; we were just speaking of you. 3. We thought it was he, not she. 4. One should learn to do everything by oneself. 5. We have written to him as well as to her several times, but they never answered our letters. 6. Who has broken that vase? 7. Not I, it has fallen by itself. 8. To whom have you consigned the parcel—to him or to her? 9. To neither of the two, because they were not at home. 10. I cannot understand (*non posso* or *non so capire*) why he has made such a proposal to me.

Idioms

The four irregular verbs of the first conjugation (*stare*, *andare*, *dare*, *fare*) are used in many idiomatic expressions.

The most common of these expressions are :

star bene, *star male*, to be well, to be ill
star mèglio, *star pèggio*, to be better, to be worse
come state ? how are you ? how do you do ?
state a sentire, listen
stare a disàgio, to be uneasy
stare in forse, to be in doubt
stare in pensiero, to be anxious
stare allegro, to be gay
star quieto, to keep quiet
andar via, to go away
andare a monte, to prove vain
andar tentoni, to grope about
andar d'accordo, to agree
va bene, good, all right
dare a intèndere, to make one believe
dare in prèstito, to lend
dar disturbo, to trouble
non fa niente, no matter
far tardi, to be late
che tempo fa ? what kind of weather is it ?
far mostra, to make a show
far calazione, to breakfast
far conto, to reckon
fatemi sapère, let me know
far attenzione, to pay attention
fare a meno, to do without
far fronte, to face
far orècchio del mercante, to pretend not to hear

Conversazione

Che tempo fa ?

Cattivo tempo.

Sarà mèglio aspettare ancòra un poco.

Aspettate voi ; io vado a cercare una carrozza e ritorno sùbito.

Va bene ; ma fate presto, se no faremo troppo tardi.

Avete fatto colazione ?

Si ; ho incontrato un mio amico, e ho fatto colazione con lui.

Come sta vostro padre ?

Sta molto mèglio, grazie. E come stanno i bambini ?

La bambina è sempre un po'pallidùccia ; sto molto in pensiero per lei.

Che cosa farete domani ? Andrete di nuovo da vostra cugina ?

Si ; andrò da lei. Poverina, non sta bene

Quando fate conto di restare un po' con noi ?

Spero di esser lìbero per la pròssima settimana, e allora profitterò della vostra gentilezza.

Con chi avete parlato, con lui o con lei ?

Ho parlato con lei, ma questa sera o domani al più tardi andrò a parlare anche con lui.

Fate attenzione alle loro parole.

Key to Exercise XXI.

Andremo ? Andiamo. Non andiamo. Non andremo. Andàrono. Andammo. Io diedi. Non darò. Lo (*it*) farete ? Lo fo *or* fàccio *or* sto facendo. Lo fanno ? Non daranno ? Sta ? Non starà. Andaste ? *Sono* andato. Se dessi. Non darebbe ? Essi non lo farèbbero. Non andrò ? Non andaste. Sarèbbero andati. Se io non fossi andato

Note. The compound tenses of the verb *andare* are formed with the auxiliary *èssere* The past participle after *èssere* must always agree with the subject of the sentence.

Key to Exercise XXII.

1. Noi andiamo a teatro stasera. 2. Voi dove andate ? 3. Che cosa faremo domani ? 4. Io vado *or* andrò in campagna. 5. Noi andremo a vedere la chiesa nuova. 6. Che cosa fate ? 7. Sto copiando un interessantìssimo passàggio da questo libro. 8. Date qualche cosa da mangiare a questo ragazzo ; ha fame. 9. È necessàrio che io vada in città. 10. Facciamo presto, è molto tardi 11. Io vado un pochino fuori e ritornerò a ora di pranzo.

VERBS—continued

Peculiarities of the First Conjugation. 1. Verbs ending in CER, such as *avancer*, to advance ; *prononcer*, to pronounce, take a cedilla under the c before *a* and *o*, as an indication that the soft sound of the *c* is to be retained : *nous prononçâmes*, *nous avançons*.

2. Verbs ending in GER, such as *manger*, to eat ; *partager*, to share, retain *e* after *g* before *a* and *o*, so that the *g* may have the same soft sound as in the infinitive : *nous mangeons*, *partageant*.

The tenses and persons affected by these two rules are shown in the following table :

Indicative

Present

nous avançons
nous mangeons

Imperfect

j'avançais, tu avançais, il avançait, ils avançaient.

je mangeais, tu mangeais, il mangeait, ils mangeaient.

Past Definite

j'avançai, tu avanças, il avança, nous avançâmes, vous avançâtes

je mangeai, tu mangeas, il mangea, nous mangeâmes, vous mangeâtes

Imperative

avançons
mangeons

Subjunctive

Imperfect

que j'avançasse, que tu avançasses, qu'il avançât, que nous avançassions, que vous avançassiez, qu'ils avançassent.

que je mangeasse, que tu mangeasses, qu'il mangeât, que nous mangeassions, que vous mangeassiez, qu'ils mangeassent.

PARTICIPLE PRESENT

avançant
mangeant

3. Verbs ending in ELER and ETER double the *l* and the *t* before a mute *e*, so that two mute syllables may not follow each other: *appeler*, to call; *j'appelle*, I call; *jeter*, to throw; *ils jettent*, they throw. The tenses and persons affected by this rule are shown in the following table:

INDICATIVE

Present

j'appelle, tu appelles, il appelle, ils appellent;
je jette, tu jettes, il jette, ils jettent

Future

j'appellerai, tu appelleras, il appellera, nous appellerons, vous appellerez, ils appelleront.

je jetterai, tu jetteras, il jettera, nous jetterons, vous jetterez, ils jetteront

CONDITIONAL

Present

j'appellerais, tu appellerais, il appellerait, nous appellerions, vous appelleriez, ils appelleraient

je jetterais, tu jetterais, il jetterait, nous jetterions, vous jetteriez, ils jetteraient.

IMPERATIVE

appelle, qu'il appelle, qu'ils appellent;
jette, qu'il jette, qu'ils jettent.

SUBJUNCTIVE

Present

que j'appelle, que tu appelles, qu'il appelle, qu'ils appellent;

que je jette, que tu jettes, qu'il jette, qu'ils jettent.

It is to be noted that, although the infinitive has but one *l* or *t*, the future and the present conditional, which are formed from it, double the consonant throughout. The reason for this is that whilst in the infinitive the *r* goes with the *e* to form a sounded syllable: *ap-pe-ler, je-ter*, after the addition of *ai* or *ais*, etc., it is joined to these endings, and leaves the preceding *e* mute: *j'ap-pe-le-rai, je je-te-rais*. But this new division of the syllables gives two consecutive mute syllables. It is to avoid this that the consonant is doubled: *j'ap-pel-le-rai, je jet-te-rais*, etc.

4. A few verbs in ELER and ETER, instead of doubling the *l* and the *t* before mute *e*, take a grave accent on the *e* that precedes those consonants: *acheter*, to buy; *j'achète*, I buy; *geler*, to freeze; *il gèle*, it is freezing. Such are the following:

bourreler, to torment
celer, to conceal
ciseler, to carve
geler, to freeze
démanteler, to dismantle
denteler, to indent
écarteler, to quarter
harceler, to harass
peler, to peel

acheter, to buy
becqueter, to peck
breveter, to patent
crocheter, to pick (a lock)
décolleter, to uncover the neck
déchiqueter, to cut up
épousseter, to dust
étiqueter, to label
haleter, to pant

5. Verbs that have a mute *e* in the last syllable but one of the infinitive, take a grave accent on that *e* when it is followed by another mute syllable, as *mener*, to lead; *je mène*, I lead; *soulever*, to raise; *je soulèverai*, I shall raise.

The tenses and persons affected by this rule are the same as those that double the *l* and the *t* in verbs in *eler* and *eter*.

6. Verbs that have *é* in the last syllable but one of the infinitive, like *espérer*, to hope, *céder*, to yield, change the acute accent into a grave accent before a mute syllable.

This rule does not, however, affect the future or the conditional:

céder, je cède, ils cèdent, qu'il cède, but *je céderai, je céderais.*

7. Verbs ending in *yer* change *y* into *i* before a mute syllable: *ployer*, to bend, *je ploie*, I bend; *essuyer*, to wipe, *j'essuierai.*

The tenses and persons affected by this rule are the same as those that double the *l* and the *t* in verbs in *eler* and *eter*.

If the ending *yer* is preceded by *a*, as in *payer*, to pay, the *y* may be, and usually is, retained before a mute syllable: *payer, je paye, je payerai.*

8. It is to be noted that in the ordinary course of regular conjugation verbs in *ier*, like *prier*, to pray, take *ii* in the first and second persons of the imperfect indicative and of the present subjunctive: *nous priions, vous priiez, que nous priions, que vous priiez.*

9. It is also to be noted that verbs in *éer*, regularly take *ée* where other verbs have only one *e*, as *agréer*, to accept, *j'agrée*, I accept, *il agréera*, he will accept. In the masculine past participle they have *éé*, and in the feminine *éée*. Example: *créé, créée*: *L'âme a été créée immortelle,* The soul has been created immortal.

EXERCISE XXV.

1. The more he advanced in age, the more he advanced in wisdom (*la sagesse*).
2. The manner (*la manière*) in which (*dont*) the Romans pronounced Latin was very different from that in which we pronounce it nowadays (to-day).
3. He divided his fortune between (*entre*) his three children.
4. According to (*selon*) a French proverb (*le proverbe*), appetite comes from (*en*) eating.
5. He invokes (calls) upon his benefactor (*bienfaiteur*) the blessings (*bénédictions*) of heaven
6. It is said of a man who squanders (*dissiper*) his fortune, that he throws his money out of (*par*) the window.
7. That letter brings us (*annoncer*) good news.
8. The lesson begins at page seventy.
9. Send that timepiece to the watchmaker's (*horloger*) in order that he may put it right (*arranger*).
10. I would willingly (*volontiers*) wager (*gager*) a hundred francs that it is not he who will carry off the prize.
11. In 1660, Charles II. was recalled (*rappeler*) to the throne (*le trône*).
12. That fish is too small; throw it back (*rejeter*) into the water.

13. When the fishermen are out at sea (*en pleine mer*) they will cast their net (*le filet*).

14. Those who employ (*employer*) their time badly are the first to complain (*se plaindre*) of its shortness (*brièveté*).

15. Light takes (employs) from seven to eight minutes to come to us from the sun.

16. We often pardon (*pardonner à*) those who bore (*ennuyer*) us; but we rarely pardon those whom we bore.

17. We have bought the victory at the price of our best soldiers.

18. What is bought retail (*en détail*) is dearer (*cher*) than what is bought wholesale (*en gros*).

19. It has frozen all night; if it still freezes to-morrow we shall perhaps be able (*pourrons*) to skate (*patiner*) Saturday.

20. God drew (*tirer*) heaven and earth from nothingness (*le néant*): He created them by His word (*la parole*).

21. Accept (*agréer*), sir, my respectful salutations (a) formula (*la formule*) which is often used in ending a letter.

22. We are sometimes obliged to yield (*céder*) to circumstances (*circonstance*)

23. It is not he who possesses his fortune, it is his fortune that possesses him

24. Every road leads to Rome, says the proverb.

Continued

GERMAN

Continued from page 3504

By P. G. Konody and Dr. Osten

LXXI. Verbs with Two Objects. With transitive and reflective verbs [see XLI., page 2489] the object (answering the question wen? whom? or was? what?) stands in the accusative (nearer object). If a second object, that of the person (answering to the question wem? whom? or was?) is in the sentence, it stands in the dative (more distant object). In sentences with two objects the dative object precedes the accusative, unless the latter is a personal pronoun: Er gab dem Bettler (dative object) ein Almoſen (accusative object), he gave the beggar [an] alms; but: er gab es (accusative object, personal pronoun) dem Bettler (dative object), or: er gab es ihm.

It should be remembered that the reflective pronoun ſich is the same in the dative and accusative. In sentences with two objects the distinction between the cases sounded alike can therefore only be made by putting the question Wem? to whom? - corresponding with the dative of the person: Der Radfahrer hat ſich verletzt, the cyclist has hurt himself (whom? accusative object); and: Der Radfahrer hat ſich (dative object) das Bein (accusative object) verletzt, the cyclist has hurt his leg (literally: The cyclist has hurt himself the leg). In the latter sentence the dative ſich answers to the question (literally translated): To whom has the cyclist hurt the leg?

The verb werfen, to throw, is used irregularly with dative and accusative objects: Er warf ihn (accusative) in den Sand, He threw him into the sand; and: Er warf ihm (dative) Sand (accusative) ins Geſicht, literally: He threw him sand in the face (He threw sand in his face); and: Er warf ihn (accusative) mit Sand ins Geſicht, He pelted him (accusative) with sand in the face. In similar manner are used: Einem (dative) or Einen (accusative) auf die Finger klopfen, to knock (tap) someone on the fingers, in accordance with the question wem (dative)? or wen (accusative)? whom? Einem (dative) or Einen (accusative) in die Wangen kneipen (or kneiffen), to pinch someone's cheeks [in the cheeks]; and the verbs ſchneiden, to cut; ſtechen, to sting; beißen, to bite (to itch); treten, to step (to tread on).

LXXII. Intransitive Verbs Governing the Dative. Many intransitive and compound verbs require the complement of a noun standing in the dative, or govern the dative, such as Ich antworte Ihnen (dative), I answer you; Er ähnelt ſeinem Vater (dative), He resembles his father; Man muß der Not gehorchen, One must obey necessity; Er folgte der Fährte, He followed the track; etc. Where these nouns are of the personal kind (personal substantives or personal pronouns), this dative is a "dative of the person," in all other cases a "dative of the thing." Similarly the dative is required by several reflective verbs (reflecting an action on the acting person): er hilft ſich (reflective pronoun dative), he helps himself. The following list of verbs requiring a complement in the dative should be carefully committed to memory:

Many compounds with the prepositions ab-, an-, auf-, aus-, bei-, ein-, ent-, er-, miß-, nach-, ver-, zu-; for instance: ab'helfen, to remedy; ab'raten, to dissuade from; an'gehören, to belong to; an'ſtehen, to beseem, to suit; auf'fallen, to be striking, to attract attention; auf'paſſen, to wait for, to watch, to spy; aus'helfen, to render temporary assistance; aus'weichen, to evade; bei'ſtehen, to help, relieve; bei'ſtimmen, to agree with, to assent to; ein'fallen, to fall in, to come into the mind; ein'ſtehen, to answer for; entflie'hen, to escape, to run away; entſprin'gen, to escape, to spring, to arise; erſchei'nen, to appear, to be evident; erlie'gen, to succumb, to yield; mißfal'len, to displease; mißglü'cken, to fail; nach'forſchen, to search, to inquire after; nach'ſtellen, to place behind, to pursue; vor'beugen, to bend forward, to prevent; vor'kommen, to overtake, to occur; zu'fallen, to shut (of itself); zu'ſehen, to look at, to connive at; and many other verbs, such as ähneln, to resemble; ant'worten, to answer; bleiben, to remain; danken, to thank; dienen, to serve; drohen, to threaten; glücken (Einem), to succeed; ſchaden (Einem), to hurt, to damage, to spoil; zürnen, to be angry; lauſchen, to listen, etc.

LXXIII. Impersonal Verbs. There are two kinds of impersonal verbs, the real and the seeming - the former connected with the neuter personal pronoun es, it, as their real and sole subject, whilst with the latter es precedes only the real subject. For instance in Es ſchwindelt mir, I am dizzy [in the sense it (an unknown power) is dizzy within me], the verb ſchwindeln is a real impersonal verb; but in the sentence Es ſchwindelt mir der Kopf, My head is dizzy, the pronoun es precedes the subject „der Kopf“, and the verb is only seemingly impersonal. Many real and seemingly impersonal verbs govern the dative of the person. With some „es“ can be omitted: Wie iſt (es) Ihnen? How are you? [how is it with you?], but Wie geht es Ihnen? How are you? [how is it going with you?], where the es cannot be dropped.

1. In their impersonal form the verbs ſchwindeln, to be dizzy, giddy; ahnen, to forebode; ſcheinen, to shine, to appear, to seem, govern the dative of the person. Dünken, to seem, to appear, governs the dative or the accusative: Es dünkt (däucht) mir or mich, Methinks, it seems to me. The transitives freuen, to rejoice; ergötzen, to delight in; betrüben, bekümmern, to trouble, to grieve; verletzen, to hurt, to wound; ſchmerzen, to ache, to suffer pain, etc. govern the accusative with es, if there is no other subject: Es freut mich, I am glad [it gladdens me]; Es ſchmerzt mich, It hurts me, it grieves me, etc.

Some of these verbs have no passive form; it is impossible to use freuen, to rejoice, in the passive voice and to say: Ich bin gefreut, etc. The passive voice is in these cases formed by the help of compounds with the inseparable prefixes er-, be-, etc.: Ich bin erfreut, ich war erfreut, etc.; ich bin bekümmert, I am grieved, etc. The following verbs are used with the dative of the person: fehlen, to miss; mangeln, to want, to lack; genügen, to suffice; gefallen, to please; behagen, to suit, to please; träumen, to dream, to imagine; mißraten, to fail, to miscarry; fehlſchlagen, to fail; klarwerden, to become clear about something, to dawn upon one; ein'leuchten, to be evident, obvious; frei'ſtehen, to be at the disposal, to be at liberty to; geziemen, to become, to beseem; vor'kommen, to happen, to occur.

2. With transitive impersonal verbs the genitive is sometimes used in the place of the subject in the nominative: Mich jammert dieſer Menſch, I feel pity for this man (literally: this man grieves me), or: Mich jammert dieſes Menſchen (genitive); Es lohnt der Mühe (genitive), it is worth while [of the while].

LXXIV. Verbs Governing the Genitive Case. The genitive is also used in certain cases with the auxiliary verbs ſein and werden: Er iſt des Todes (genitive), He is as good as dead [he is of death]; Es iſt nicht meines Amtes, It is not my business (my duty, my office). These and similar genitives are the result of omission: Er iſt (ein Kind) des Todes; es iſt nicht (die Sache) meines Amtes. Similarly genitives, that are not really dependent, but more of a predicative character, are employed in: Jemand iſt ſchlechter Art, freundlichen Weſens, anderer and gleicher Meinung, entge'gengeſetzter Anſchauung, ſchlechter Laune, etc.; literally: Someone is of bad kind (has a bad disposition), of friendly temper, of another *or* of the same opinion, of opposite view, of bad humour, etc. Genuine dependent genitives are used with the intransitive verbs bedürfen, brauchen, to want; denken, to think; gedenken, to remember; gewahren, to be aware; harren, to wait; ſpotten, to chaff, etc.

LXXV. The Expectation in Questions. It has been shown that the question, in German as in English, is formed by the simple displacement of subject and predicative verb. But in German the question may convey the expectation of the enquiring person as regards the affirmative or negative nature of the answer. Where the affirmation is expected or desired, the opposite negative nicht, not, is added: Kommt er nicht? Doesn't he come? This affirmative expectation can also be expressed by the addition of the conjunction doch, yet, however, and the adverb wohl, well, probably: er kommt doch? er kommt wohl? and er kommt doch wohl? If the affirmative is not desired, the adverb etwa, possibly, is added: kommt er etwa? Similarly Kommt er ſchon? Does he come already? conveys the hope that the person referred to is not coming yet.

LXXVI. Position of Words in a Simple Sentence. For normal positions see LXX., page 3503. If the predicate is a verb with a separable prefix, the latter stands at the end of the sentence in the simple tenses: an'hören, to listen to; Der Schüler hört den Lehrer an, The pupil listens to the teacher; and in the perfect: Der Schüler hat den Lehrer angehört, The pupil has listened to the teacher; aus'gehen, to go out; Ich ging nach dem Eſſen aus, I went out after the meal (after dinner); and: ich bin nach dem Eſſen ausgegangen.

1. Agreement of Subject and Predicate. The verb (predicate) agrees with the subject in person and number: der Vater ſchläft (singular), The father sleeps; and: die Kinder ſchlafen (plural), The children sleep, etc. With collective substantives the verb stands in the singular, but if the collective noun is directly connected with a substantive in the plural, the verb is employed in the plural: Das Gebirge erhob ſich vor meinen Augen, The mountain rose before my eyes; but: Ein Dutzend Fäſſer wurden (plural) gebracht, A dozen barrels were brought; Eine Menge Soldaten erſchienen (plural), A crowd of soldiers appeared.

2. A sentence with several subjects and one predicate, or with several predicates, attributes, objects, or adverbial nouns, and one subject, can be contracted to give the speech more conciseness and better rhythm. The part of the sentence to which the other words refer is not repeated: Das Sonnenlicht ſtimmt die Seele heiter, der Regen (ſtimmt die Seele) mißmutig, [The] sunlight makes the soul serene, [the] rain dreary.

(*a*) If a contracted sentence contains as subjects a personal pronoun in the first, and another in the second or third person, the predicate stands in the first person plural: Ich und du (or dein Bruder) zanken immer, I and you (*or* your brother) are always quarrelling; Ich und er ſind die beſten Freunde, I and he are the best of friends. With personal pronouns in the second and third person, the verb stands in the second person plural: Du und er (or deine Freunde) ſeid ſtets willkommen, You and he (*or* your friends) are always welcome.

(*b*) If the predicate refers to several subjects, it stands in the plural: Geld und gute Worte wirken Wunder, Money and good words work miracles.

(*c*) If several subjects are regarded as part of the same idea, the verb stands in the singular: Auf blutige Schlachten folgt (singular) Geſang und Tanz, Song and dance follow (plural) bloody battles.

3. If the common member of the sentence does not agree in gender, number, case, or tense with the other parts to which it belongs, no contraction can be effected. Thus: Ich begegnete und grüßte den Lehrer, I met and greeted the teacher, is wrong, because begegnen governs the dative, and grüßen the accusative. The correct form would be: Ich begegnete dem Lehrer (dative) und grüßte ihn (accusative), I met the teacher and greeted him, which is also a contraction, as the subject ich is mutual to both predicates, with which it agrees in person and number.

4. In sentences with several objects (*a*) the personal object precedes the other, the dative stands before the accusative, and the accusative before the genitive: Er ſagte mir (3) die Wahrheit (4), He told me the truth; Die Gnade des Königs rettete ihm (3) das Leben (4), The king's mercy saved his life [saved him the life]; Man darf ein Tier (4) nicht mutwillig des Lebens (2) berauben, One must not take wantonly an animal's life; Der Richter beſchuldigte den Gefangenen (4) des Verbrechens (2), The judge accused the prisoner of the crime.

(*b*) The prepositional object is placed after the simple object in the accusative: Der Sohn frug ſeinen Vater (4) um (preposition governing the accusative) Erlaubnis, The son asked his father for permission.

5. The adverb precedes the word which it qualifies: Ich beabſichtigte heute (adverb of time) abzureiſen, I intended to depart to-day. Where there is an object of the person and another object, the adverbs are generally placed between them: Sie werden mir (personal object) morgen (adverb of time) alles (object) erzahlen, You will tell me all to-morrow. Where there are several adverbs it should be remembered that the adverb of time usually precedes those of place, manner and cause: Er mußte geſtern (time) plötzlich (manner) abreiſen, He had to depart yesterday suddenly; Ich war heute (time) daheim (place) unausgeſetzt (manner) tätig, I was to-day at home continually busy.

6. The negation nicht is placed after the verb (but before the past participle or infinitive in compound tenses), if it refers to the whole sentence. In all other cases it precedes that part of the sentence which has to be denied: Der Kaufmann hat nicht einen Brief geſchrieben, ſondern eine Rechnung, The merchant has not written a letter, but an invoice; Nicht der Kaufmann hat den Brief geſchrieben, ſondern der Geſchäftsleiter, It is not the merchant who has written the letter, but the manager; Der Kaufmann hat den Brief nicht geſchrieben (negation of the whole fact), ſondern diktiert, The merchant has not written but dictated the letter.

7. The reflective pronoun precedes all other objects and adverbs and immediately follows the finite verb: Er ärgerte ſich heute wieder über ſein Mißgeſchick, He was vexed again to-day about his misfortune.

8. Displacements of nouns (inversions) are far more frequent in German than in other languages, for reasons of euphony as well as for reasons of expressiveness and strength. In poetry, in particular, the word on which stress is to be laid is often placed at the beginning or the end of the sentence: Ernſt iſt das Leben, heiter iſt die Kunſt, Life is serious, art is gay; Sein iſt alle Schuld! [his is all guilt], He alone is to blame!

EXAMINATION PAPER XIX

1. What is the relative position in the sentence, of the object of the person (dative), and the object in the accusative?
2. Which compound verbs and which simple verbs govern the dative?
3. How many kinds of impersonal verbs are there?
4. What rules determine the use of es with seemingly impersonal verbs?
5. How is the passive voice formed with such impersonal verbs as freuen, kümmern, etc.?
6. Which verbs are used with the dative of the person, and with which verbs can the subject in the nominative be replaced by a genitive?
7. With which auxiliary verbs is the genitive employed, and how can this genitive often be accounted for?
8. How can the question indicate the expectation of an affirmative or of a negative answer?
9. What is the normal position of the predicate in the simple sentence, and the relative position of the finite verb and the other part of the predicate in a compound tense?
10. If the subject of the sentence is a collective substantive, when is the predicate used in the singular, and when in the plural?
11. In which person is the finite verb employed in a contracted sentence containing personal pronouns in the first and second (or third) person as subjects? In the second and third person? When is it used in the singular? When is a contraction inadmissible?
12. What position is taken by the *personal* object in sentences with several objects, and what is the order of the objects, as determined by their cases (dative, accusative, genitive)? What is the position of the prepositional object, if the sentence also includes a simple accusative object?
13. What is the relative position of the adverb and the word qualified by it, and which adverbs precede, if the sentence contains more than one?
14. What considerations determine the position of the negative nicht in the sentence?
15. What is the position of the reflective pronoun?
16. What are the reasons for, and what is the effect of, the displacement of nouns?

CONVERSATIONAL EXERCISES

II. At the Hotel

Will you kindly pay the cabman?	Wollen Sie gefälligſt den Kutſcher bezahlen?
What is his fare?	Wie viel macht ſeine Taxe?
He drove me here from the station.	Er fuhr mich vom Bahnhofe hierher.
The fare, luggage included, is two marks 50 pfennigs.	Die Taxe einſchließlich des Gepäcks beträgt 2 Mark 50.
Can you tell me how much that is in English money?	Können-Sie mir ſagen, wie viel das in engliſchem Gelde iſt?
One mark is equal to one shilling, so the fare would be half a crown in English money.	Eine Mark iſt gleich einem Schilling; die Taxe wäre demnach eine halbe Krone in engliſchem Gelde.
I want a room.	Ich benötige ein Zimmer.
On which floor?	In welchem Stockwerke?
On the first or second floor.	Im erſten oder zweiten Stockwerke; (also: in der erſten oder zweiten Etage).
This room is much too small, and, besides, the windows open on the yard.	Dieſes Zimmer iſt viel zu klein, und überdies gehen die Fenſter auf den Hof hinaus.
Haven't you a bigger room with a view over the market place?	Haben Sie nicht ein größeres Zimmer mit der Ausſicht auf den Marktplatz?
On the third floor there is a front room vacant.	Im dritten Stocke iſt ein Frontzimmer frei.
Is it quiet?	Iſt es ruhig?
The rooms looking on the garden are quieter.	Die Zimmer nach dem Garten ſind ruhiger.
How much is this room?	Was koſtet dieſes Zimmer?
This room is five marks including attendance and electric light.	Dieſes Zimmer koſtet fünf Mark mit Bedienung und elektriſcher Beleuchtung,
Will you bring my luggage?	Wollen Sie gütigſt mein Gepäck bringen.
Please put the trunk by the door.	Den Koffer ſtellen Sie freundlichſt zur Türe.
How about the meals? Is one compelled to take meals at the hotel?	Wie ſteht es mit den Malzeiten? Muß man die Malzeiten im Hotel nehmen?
Not in our hotel, but in other houses the visitor who takes his meals outside has to pay more for his room.	In unſerem Hotel nicht, aber in anderen Häuſern hat der Gaſt, der die Malzeiten auswärts nimmt, für das Zimmer mehr zu zahlen.
Where is the dining-room?	Wo iſt der Speiſeſaal?
What can one have for breakfast?	Was kann man zum Frühſtück haben?
Coffee, tea, chocolate, milk, bread, butter, eggs, ham.	Kaffee, Thee, Chocolade, Milch, Brot, Butter, Eier, Schinken.
Bring me some coffee and milk, bread, butter, two boiled eggs and some ham.	Bringen Sie mir eine Portion Kaffee mit Milch, Brot, Butter, zwei gekochte Eier und etwas Schinken.
The eggs are boiled too much, and the ham is too fat.	Die Eier ſind zu hart gekocht und der Schinken iſt zu fett.
Can't I have some lean ham?	Kann ich nicht mageren Schinken haben?
The table d'hôte begins at one p.m.	Die Table d'Hôte beginnt um ein Uhr mittags.
I prefer to take my meals à la carte.	Ich ziehe es vor, meine Malzeiten à la carte zu nehmen.
What soup is there to-day?	Was für Suppe gibt es heute?
We have pea soup and tomato soup.	Wir haben Erbſenſuppe und Paradiesäpfel-Suppe.
Bring me some roast veal, potatoes, and French beans.	Bringen Sie mir einen Kalbsbraten mit Kartoffeln und grünen Bohnen.
What sweet will you take?	Welche ſüße Speiſe wünſchen Sie zu nehmen?
Apple-tart.	Apfelkuchen.
The bill, please!	Ich möchte zahlen.
How much is it?	Wie viel macht es aus?
Bring me some warm water in the morning.	Bringen Sie mir des Morgens etwas warmes Waſſer.
Give my washing to the laundress.	Geben Sie der Wäſcherin meine Wäſche.
But I must have it back to-morrow evening.	Aber ich muß ſie morgen Abend wiederbekommen.
I shall depart the day after to-morrow in the morning.	Ich reiſe übermorgen früh ab.
My luggage may be taken to the station.	Mein Gepäck kann zur Bahn gebracht werden.
If there are any letters for me, please forward them to Munich.	Wenn Briefe für mich kommen, ſo ſchicken Sie ſie mir nach München nach.

HISTORY

26

Continued from page [illegible]

By JUSTIN McCARTHY

HENRY VII., founder of the Tudor dynasty in England, married, soon after his accession, Elizabeth of York, the eldest daughter of Edward IV., as we have already seen. Henry had won his crown on the battlefield, but he was not a promoter of war, and had no inclination for the work of a soldier. He was a lover of peace, was much interested in the promotion of commerce and of international good understanding, and a patron of art and letters.

A Diplomatic Sovereign. He was one of the earliest of English kings who gave much time and attention to the development of diplomatic relations between England and other Continental states. Some of the marriages brought about during his reign bore striking testimony to his faculty for making international contracts, bearing promise of friendly relations with other states, which more enterprising and less scrupulous monarchs might have endeavoured to achieve by the sword.

Catherine of Aragon, daughter of Ferdinand and Isabella of Spain, was married to Henry's son, Arthur Prince of Wales, then only a boy, who died almost immediately after; and Henry, without delay, brought about the betrothal of Catherine to his next son, afterwards Henry VIII. with whom, on his succession to the throne, the marriage was solemnised. Henry also gave his eldest daughter, Margaret, in marriage to James IV. of Scotland; and thus the union of the two crowns, whose rivalry had been for so long a source of frequent war, was peacefully secured. Henry's preference for pacific arrangements was so marked that when, in 1492, in consequence of some serious quarrels, he invaded France, he made with Charles VIII. the Peace of Etaples, by means of which he obtained a large ransom and consented to withdraw his troops.

King or Scullion? Two notorious figures in Henry VII.'s reign were Lambert Simnel and Perkin Warbeck. Lambert Simnel accomplished a sort of far-distant anticipation of the Tichborne imposture of recent days. He was the son of a baker, and in 1487 represented himself as the Earl of Warwick, son of the Duke of Clarence who had been imprisoned in the Tower by Henry VII. on a political accusation for which he afterwards suffered death. Simnel passed himself off on many persons as the rightful heir to the Crown; and in Ireland his audacious venture met with so much success that he was crowned in Dublin as Edward VI., the rightful Sovereign of England. The feeling of the Dublin people probably was not friendly towards any existing English monarchy; and the fact of Lambert Simnel's not being recognised by the constitutional authorities in England was itself a strong recommendation. But Simnel carried his scheme too far when he crossed over to England and landed in Lancashire in June, 1487, with some 2,000 followers. He was defeated and taken prisoner at Stoke, but was treated by the King with singular clemency. He was not only allowed to live, but was even given an appointment as scullion and falconer to the Royal household. If Henry VII. possessed a sense of humour, it may well have seemed to him the most humiliating punishment he could inflict to convert this claimant to the Crown of England into a subservient and willing scullion.

Perkin Warbeck Imposture. Perkin Warbeck started a project much resembling that of Lambert Simnel. He was not an Englishman, and made his first appearance in public life in 1490 at the Court of the Duchess of Burgundy, sister of Edward IV. of England, and there claimed to be Richard Duke of York, the younger of the two sons of Edward IV., who were put to death in the Tower. He obtained a welcome reception at the Court of Charles VIII. of France; and in Scotland he was so well received that James IV. gave to him in marriage a kinswoman of his own, Lady Katherine Gordon. But when Perkin Warbeck tried more effective proceedings to obtain the Crown he was much less successful. He tried to organise an armed movement in England, but totally failed, surrendered on promise of pardon, and was put into prison. His uprising had not caused much disturbance, and it is possible that if he had remained in prison he might after a time have been released, as Henry VII. was not an unmerciful ruler. Warbeck, however, escaped from prison, was captured, and was then consigned to the Tower of London—a fact foreboding his impending doom. He was sentenced to death, and executed in November, 1499.

Henry died at Richmond on April 21st, 1509, and is said to have left behind him a vast treasure which he had gathered together by various devices, such as the imposition of large fines on offending barons or offending companies, and had hoarded with rigorous economy. It is stated that at the close of his reign it was found that he had bequeathed more than £2,000,000 to his successor.

The Early Days of Henry VIII. The successor to this treasure-holding ruler was his second son, Henry VIII., born 1491, who came to the throne under conditions at once auspicious and momentous. Few Sovereigns have ever been welcomed more cordially to the Royal position than was this boy king, who, during the first years of his reign, was regarded with hope, confidence, and affection by the great majority of his subjects. Throughout his youth he was believed to be one of the handsomest, most accomplished, and most intellectual men of his time.

The Renaissance. But the reign of Henry did not justify these anticipations; and it has probably been the subject of more bitter criticism and more extreme differences of judgment than that of almost any other English Sovereign. Whole schools of conflicting historical studies have been founded on the discussion as to whether Henry's reign was, on the whole, a blessing or a curse to the people over whom he ruled and to a large portion of the world outside his own dominions. He came into power at a time when Europe was beginning to pass through that new Renaissance of literature and art, that sudden development of practical science, those new ideas of politics and religion, those new inventions for carrying on war which changed the conditions of the civilised world. New fields of colonisation were opening to Europe in Africa and in India; new forms of enterprise were discovered day after day in commerce and money-making; the traditions of the Middle Ages were fading away, and there was an eager demand for novelty in every domain of life.

Most important of all these changes was the appearance of new forms of religious faith. This change was making itself especially manifest in England, although it did not, at the outset, take anything like the definite form which it assumed at a later period of the reign.

Henry VIII.'s marriage proved to have a great influence on the political affairs of England so far as England's dealings with foreign states were concerned. A greater, indeed, almost an unbounded, influence over Henry during the earlier part of his reign was that of the famous Cardinal Wolsey. Wolsey, who was born in 1471, was the son of a wealthy butcher in Ipswich. At Magdalen College he obtained his degree so young that he was called the Boy Bachelor, and became master of a small school attached to his college. Through the influence of powerful friends he was appointed Chaplain to the Archbishop of Canterbury, and later became Chaplain to the King. After that his progress was rapid, and for a long time he held the King's favour. In 1514 he was appointed Archbishop of York, and in 1515 he was made Cardinal by Pope Leo X.

Battle of Flodden Field. At that time the Pope was still an important figure in the temporal as well as in the spiritual affairs of Europe, and was then engaged in forming the Holy League with Spain for the purpose of counteracting the growing power of France under Louis XII. Henry VIII. joined the Holy League against France, and in 1513 he conducted an invasion into France in co-operation with the German King Maximilian, where he won the bloodless Battle of the Spurs and captured several important positions. During Henry's absence from England a great victory was won for his crown over the Scots under James IV. James, who had taken the side of the French Sovereign against England, crossed with his army into Northumberland, where he encountered the Earl of Surrey at the memorable Battle of Flodden Field on September 19th, 1513. The victory was complete for the English with comparatively small loss, while James was killed on the battlefield with a large number of his most distinguished nobles, and, it is said, some 10,000 of his soldiers.

King and Cardinal. Wolsey took a very important part in the guidance of Henry's movements in all this warlike policy. The Sovereign and the Cardinal had the same purpose at heart—that of holding the balance between France and Spain, preventing the one from obtaining a mastery over the other, and thus making England, in a certain sense, the ruling power over both. Such a policy required a constant and almost unmeasured expenditure of money; and Cardinal Wolsey was the chief instrument in obtaining, by bold systems of taxation, the supplies needed by his Royal master.

Wolsey took upon himself openly and ostentatiously the responsibility for all this exaction; and it is only just to say that his object was, while directing the king's policy, to save his master from public censure, and to direct all the popular indignation towards himself. Later on, when it seemed important that England should draw closer towards a good understanding with France, Wolsey worked towards that end with as much statesmanlike ingenuity as he had formerly employed to bring about a quarrel with that country, and he came to hold, if possible, a higher position than before. In 1515 Wolsey was made Lord Chancellor of England.

Meeting on the Field of the Cloth of Gold. The continent of Europe was during this time kept in incessant suspense by the rivalry between Francis I. of France, and Charles V., Emperor of Germany. Charles inherited from his father the sovereignty of the Low Countries and of Burgundy, and the succession to the Imperial throne; and from his mother, daughter of Ferdinand and Isabella, he was entitled to the rulership of Spain, of Naples, and of the Spanish possessions in South America, where Spain had already secured a large territory. Francis maintained that Burgundy belonged to his dominions and not to any stranger, and he further claimed the Duchy of Milan and the territory of Flanders. Both monarchs wished for the support of England. Charles V. visited Canterbury to confer with Henry VIII., and Francis I. arranged the famous meeting on the plain of Ardres, known as the Field of the Cloth of Gold.

The frequent wars of those times left the ownership of this or that European territory a source of constant dispute. There was no distinct and recognised France or Germany, Italy or Spain as these are marked out and acknowledged in modern Europe. The Emperor of Germany was sometimes also the ruler of Spain, while the King of England claimed to be the lord of a large part of France. At length, one chapter of the struggle between Charles V. and Francis I. ended, for the time, in the complete defeat and capture of Francis at the Battle of Pavia, in 1525. Then it became the policy of Henry VIII. and of Wolsey to take the opposite side. The power gained by the Emperor seemed to Henry to threaten the position of England as the power of France had appeared to threaten it before; and he and Wolsey believed it to be for the advantage of England to enter into an alliance with the King of France.

But, in the meantime, great movements were taking place throughout the Continent which had nothing to do directly with war or with political parties, but which brought about a revolution in human thought greater than any that had been wrought in the thoughts and the lives of men during all recent generations. It has been well said that every revolution, however great and powerful, is at first a thought in the mind of one man; and this may be said of the revolution then about to take place among the peoples of Europe.

Martin Luther. Luther, who was born at Eisleben, in Germany, on November 10th, 1483, belonged by birth to the working classes, and was the son of a German miner. Even in those days there was in Germany ample opportunity for youths of the poorer classes to obtain a good education; and Luther, after some study in the public schools, entered one of the universities and took his degree. He had from his earliest years a strong inclination for a spiritual life, had been a close student of the Scriptures, and spent three years in a monastic institution. He was ordained a priest in 1507, and won success as a preacher. Then he was sent to Rome, and with his stay there began that change in his religious views which led to such important events in the history of the world. His opposition to the doctrines of the Church of Rome began with his objection to the principle that the Pope and the Church had a spiritual right to grant what were called Indulgences to members of the Church. He returned to Germany, and there became, by his writing and preaching, an effective advocate of his own doctrines, and soon exercised a wide influence over the public opinion, not only of his own country, but of other European states as well. The longer the controversy went on the farther Luther found himself drawn away from his earlier faith; and before long he became an uncompromising opponent of the Church of Rome as the spiritual guide of Christianity.

"Defender of the Faith." There is no need to enter into the great religious controversy which divides the Christian world up to the present day. Its immediate effect upon the history of England is the most important subject of study in the story of Henry VIII.'s reign. Some of Luther's publications reached England, aroused much attention there, and had the immediate effect of provoking Henry VIII. into authorship and religious controversy. The King published a book as a reply to Luther's doctrine; and this reply found such a welcome in Rome that Pope Leo X. conferred upon the King the title of "Defender of the Faith," a title which was borne by Henry's successors long after the English crown had ceased to be worn by members of the Church of Rome. The King was understood to have been very proud of the success of his "Assertion of the Seven Sacraments."

Luther's publications met with much more success in Germany than in England, where, for the time, the leading force of influential public opinion seemed to go with the King. Luther's books were publicly burnt in St. Paul's by order of the Church authorities of England, and laws were put in force for the prosecution of any person who should take part in the promotion of the heretical doctrines. Luther's teaching was, however, spreading widely throughout Germany and over many parts of the Continent, and soon came to have a great effect on the minds of many of the thinkers and teachers of England. The whole religious controversy was much mixed up with the important political question as to the right of the Pope to any manner of control over the State affairs of countries outside his jurisdiction as a ruler. Henry VIII. came at last to identify himself thoroughly with the rejection of the Papal supremacy in religion, as well as in politics, and the bulk of English public opinion went with him. He suppressed most of the monasteries in England; and when uprisings took place in defence of them, he made that a reason for the suppression of all the other monasteries, and for the transference of their revenues to the Crown.

The Marriages of Henry VIII. The story of Henry's various marriages is not an edifying part of his reign. Henry insisted on obtaining a divorce from his wife, Catharine of Aragon, on the ground that the marriage was unnatural, as Catharine had actually been married to his elder brother just before his death. As the Pope was unwilling to assist the King to dissolve the marriage, Henry acted independently of the Papal authority, and married Anne Boleyn, a member of the ducal house of Norfolk. Henry appears to have fallen in love with Anne Boleyn, but his affection did not last long, for three years after the marriage he charged his wife with infidelity, and on that accusation she was put to death in 1536. The day before her execution, Henry married Jane Seymour, who died soon after, leaving a son, who became Henry's successor, Edward VI.

The King was quite ready for a new marriage, and chose Anne of Cleves as his fourth wife. This was not a marriage of affection, but one pressed upon Henry by some of those around him, on the ground that as she was a German and Lutheran princess his marriage with her might secure for England the support of the Protestant sovereigns and states of Germany. Henry accepted the union reluctantly, and within six months he obtained a legal decree declaring the marriage null and void. He then married Catharine Howard, another niece of the Duke of Norfolk; and before two years she underwent, too, the same accusation as that which had been brought against Anne Boleyn, and met with the like death penalty. The King then married his sixth wife, Catharine Parr, who outlived him.

SUGAR & THE SUGAR CANE

Properties and Uses of Saccharose, Lactose, Glucose, and Levulose. Propagation and Cultivation of the Sugar Cane. Its Yield and Composition

THE term *sugar* was formerly used to convey the idea of sweetness, and applied to products of both the vegetable and the mineral kingdoms. The term "*sugar of lead*" is a survival of this early usage. The word is now confined to those sweet substances which are found in the juices of plants. Chemically, sugar is classed with the carbohydrates, and the various kinds of sugar may thus be divided:

1. Saccharose, or cane sugar;
2. Lactose, or milk sugar;
3. Glucose, or grape sugar;
4. Levulose, or fruit sugar.

Saccharose. Saccharose, the most important sugar, is very widely distributed throughout the vegetable kingdom. The chief sources are the sugar cane, the sugar beet, palm, maple, sorghum, and maize. It is also found in noticeable quantities in carrots, madder-root, almonds, walnuts, barley, coffee beans, the sap of the lime, birch, and sycamore, mesquit pods, melons, and the nectar of flowers. It has been estimated that it would require the nectar of five and a half millions of red clover flowers to produce a kilogram of sugar; but, on the other hand, mesquit pods have been found to contain 29 per cent. of cane sugar.

Sources of Sugar. The coloured plate facing page 3649 represents the chief plants of the vegetable kingdom from which sugar is obtained on a commercial scale. Fig. A is a picture of the sugar cane, formerly the only source of sugar. It belongs to the grass order and is distinguished by its knotty stem. The whole plant is 8 ft. to 12 ft. in height. Figs. B, C, D, E show the chief varieties of the sugar cane and illustrate the characteristic features of the stems of (B) the Bourbon, (C) Black Tanna, (D) Striped Bamboo, and (E) Lahaina. The sugar beet shown in F, G, H, and J is the chief source of sugar in Europe. Fig. F shows the appearance of the beet when growing, G is an improved variety of beet, H is the white Silesian variety, while J shows the beetroot in section. Fig. K is sorghum, another source of sugar, L being the Early Amber cane, M a hybrid, and N the Liberian variety of sorghum. Fig. O is a scene in a forest of maple during the season of the collection of maple juice in Canada; this juice is afterwards boiled down to a thick syrup for household use, one of the methods being shown in P. Fig. Q is a familiar scene in India; it represents the manner in which the juice of the date palm is obtained. This juice when evaporated yields sugar of good flavour.

Properties of Saccharose. Cane sugar is a crystalline solid freely soluble in water, a cold, saturated solution containing over 65 per cent. of sugar, while as much as 82 per cent. of sugar can be taken up in a boiling solution. If a strong solution of sugar be slowly evaporated crystals are obtained which, if allowed to deposit on string, form *sugar candy*. Sugar is only slightly soluble in alcohol, and not at all in ether. When sugar is heated it melts, and if then allowed to stand till cold yields what is known as *barley sugar*. By combining butter and flavouring matter with melted sugar the familiar *butterscotch* is produced. If strongly heated, sugar darkens and gives a coloured product known as *burnt sugar*, or *caramel*. If the heat be continued and increased, acid vapours and combustible gases are given off and a black mass of charcoal remains behind. Sugar combines with lime to form a sucrate, the reaction forming the basis of an important method of purifying sugar juices. Strontia, baryta, and lead compounds can be formed in like manner.

The Difference between Cane and Beet Sugar. Cane sugar turns a ray of polarised light to the right, and has no reducing power on an alkaline sulphate of copper solution. These properties are made use of in sugar analysis, and are explained later. When sugar is warmed with sulphuric acid a black mass is obtained. Sugar mixed with chlorate of potash forms what is known as "white gunpowder," and takes fire if touched with sulphuric acid. When rubbed with lead oxide sugar takes fire. The question is often asked: What is the difference between beet and cane sugar? The answer is that sugars from any source are indistinguishable if equally purified. Impure beet sugar has a very disagreeable odour, but as such a product would not fetch a good price in the market it is obviously to the advantage of the manufacturer to thoroughly purify his beet sugar. An expert with a keen sense of smell could probably detect the difference between purified beet and cane sugar; but even experts make mistakes. The method is to put a few lumps of each in clean wide-mouthed stoppered bottles and let them remain for a day. On coming in from the fresh air and smelling each bottle it is sometimes possible to detect a difference. There is a slight difference in the amount of ash yielded by the two and also a chemical difference in the constituents. Beet sugar does not contain iron, as is sometimes erroneously stated.

Uses of Saccharose. Sugar is a cheap and economical food, although looked upon generally as merely a flavouring agent. It is an anti-putrescent, and on this account is used for preserving fruit. Sugar either *per se* or as jam is recognised as a soldier's ration, and the cruder forms are much used as a valuable fodder for

THE HISTORY OF SUGAR

cattle. Sugar is the source of alcohol in wines and beer, although cane sugar is not itself directly fermentable, but has to go through an intermediate stage before being acted upon by yeast.

Lactose, or Milk Sugar. This is the sugar found in the milk of mammals. Bouchardat states that it occurs also in the juice of the sapota tree, but this needs confirmation. Milk sugar is not so soluble in water as cane sugar, and its taste is much less sweet. When heated, milk sugar becomes yellow and then changes to brown; it reduces an alkaline sulphate of copper solution. When fermented with a yeast-like body milk sugar yields a drink called *koumiss*. Large quantities of lactose are used for infants' and invalids' food and also in the preparation of medicines.

Glucose. Glucose exists in grapes and honey. Small quantities exist in the animal body, the disease known as diabetes being characterised by an excessive secretion of glucose. On a manufacturing scale glucose is prepared by acting on starch with a dilute acid. Glucose dissolves in water, but is only about half as sweet as cane sugar. It is readily fermentable, and yields 48·67 per cent. of alcohol. Glucose is used in the brewing of beer, the manufacture of confectionery and jams, and in calico printing.

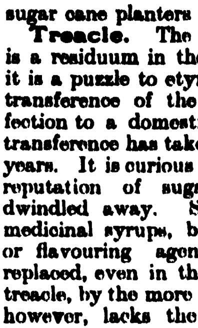
Levulose. Levulose exists in honey (with glucose) and ripe fruits. It is also contained to the extent of 50 per cent. in *invert* sugar—the product of the action of dilute acid on sugar. Levulose turns a ray of polarised light to the left. Invert sugar is of considerable importance in the brewing industry.

The Cane. The sugar cane is a huge grass with a knotty stem (1) It belongs to the natural order *Graminaceæ*, and is known botanically as *Saccharum officinarum*. The sugar cane is a native of India or of the most southern parts of Asia, whence it has spread to every tropical or semi-tropical country in the world. The Spaniards probably introduced the sugar cane into the West Indies and the American continent.

History of Sugar. Early writers, such as Herodotus, Theophrastus, and Seneca, were acquainted with sugar, but not till the Christian era do the references become clear. The cultivation of the sugar cane was well understood in Arabia and Spain from the earliest times, but the medicinal use of sugar was the object of the cultivation. During the Middle Ages England, in common with the rest of Northern Europe, was supplied with sugar from the Mediterranean, it being imported from Alexandria to Venice and thence to London. The average price of sugar in A.D. 1200 was 1s. per lb., and 100 years afterwards it was 1s. 7d. per lb. In 1353, John of France ordered that the apothecaries of Paris should not substitute honey for sugar in confections. As travelling became more general, the cultivation of the sugar cane spread, being introduced into Madeira in 1420, Domingo in 1494, the Canary Islands in 1503, Mexico in 1520, Martinique in 1650, Mauritius in 1750, and Australia in 1852. The cultivation of the sugar cane in Egypt almost became extinct, but of late years the Egyptian Government have made determined efforts to revive the manufacture of sugar. Factories on a scientific basis have been equipped, and the experiments have turned out successful. The discovery of beet sugar by Marggraf, of Berlin, in 1747, is referred to later on, the importance of the discovery being only apparent in recent years, when increasing cultivation of sugar beet has convulsed the cane sugar industry so much that international commercial agreements have had to be entered into to prevent the ruin of the sugar cane planters in the British possessions.

Treacle. The dark syrup known as treacle is a residuum in the manufacture of sugar, and it is a puzzle to etymologists to account for the transference of the name of a medicinal confection to a domestic article like treacle. The transference has taken place within the last 200 years. It is curious to note that the medicinal reputation of sugar and treacle has quite dwindled away. Sugar, it is true, is used in medicinal syrups, but only as a preservative or flavouring agent, while treacle has been replaced, even in the delectable brimstone and treacle, by the more refined golden syrup, which, however, lacks the slightest suspicion of the laxative action possessed by the old-fashioned treacle.

Varieties. There are many varieties of sugar cane known, the principal ones being the Mauritius, the Laina, the Otaheite, the Bourbon, the Ribbon, the Java, the China, the Singapore, the Indian, and Cristalline. Some of these are probably distinct species, such as the China sugar cane; the others differ from each other in the colour and hairiness of the stem. Some varieties are preferred in certain situations, the Cristalline cane, for example, having a reputation as a disease resister in the French West Indies. The Bourbon cane was originally introduced into the West Indies from the Isle of Bourbon. The varieties most in request are long-jointed canes, the leaves from which are readily detached from the stem as they die. As a rule, however, it may be taken for granted that each country has produced a special variety of cane suited to its climate and soil.



1. SUGAR CANES

The sugar cane grows in a wide range of climatic conditions, but flourishes best in high latitudes on account of the greater length of the days. Proximity to large bodies of water is favourable because the plants obtain the rays of light reflected from the surface of the water in addition to the direct rays of the sun. Light is essential to the storage of sugar by plants, the erect habit of the sugar cane having an important influence in obtaining the maximum of sunlight. Frost is harmful to the sugar cane.

What the Cane is Like. The sugar cane is perennial, and produces a stem 8 ft. to 12 ft. high and 1 in. to 2 in. thick, while there are from 40 to 60 joints. The leaves are produced at the joints, and are 4 ft. to 5 ft. long and 2 in. wide. As the canes grow the lower leaves dry up, fall off and are removed, the process being known as *trashing*. The sugar cane needs a fertile soil, clay and sandy soils being unsuitable. In French Guiana the only remunerative cultivation of the sugar cane is on low lands that are periodically manured by flooding with water from which black mud is deposited. In Queensland land of virgin soil is prepared by light ploughing to get rid of grass. The ground is then ploughed 9 in. to 10 in. deep, and worked with the harrow and roller to ensure sufficient soft mould for the plant.

Propagation. The sugar cane is propagated from cuttings or seed, but usually by the former method, seed being only used for obtaining new varieties. The cuttings may be either from the top or from the body of the cane, and recent experimental work in the Mauritius seems to indicate that the tops are preferable. If *tops* be used the leaves should be stripped from two or three buds so that they can come into immediate contact with the soil. If *plant canes* be used they should be cut into lengths of three buds each, care being taken not to injure the buds. The plants are then placed in drills at a distance of about 3 ft. from centre to centre. The canes are placed horizontally and with the buds pointing one way; 1 in. to 1½ in. of mould above the cutting is quite sufficient, since it will grow more rapidly than if planted deeper. After a few days, according to the weather, rootlets will spring from the joint surrounding the bud, and in from 10 to 21 days the buds will appear above the ground.

Cultivation. All the cultivation afterwards required will be to keep the ground open and clear of weeds as long as the horse-hoe can be used, after which the ground can be left until crushing season. Cutting of the cane is effected in several ways—some are cut with a knife, the cane being trimmed and topped while in the hand, while others are cut with a sharp hoe, the trimming and topping being done by another group of labourers. When the cane is light upon the ground or stands erect the former mode seems preferable, but where the crop is very heavy the latter method is used. In either case care should be taken to cut the cane close to the ground, as the *ratoon* (the cane which springs up from the stump) will rise from the highest bud on the cane root left, and if this be not below the surface support against the wind for the young cane will be lacking. The practice of different plantations varies in regard to replanting or growing from ratoons, for although cane will retain and yield crops for several years without replanting, ratoon crops are not so heavy as plant cane. The labour supply is a factor that has to be taken into account in this connection.

Manures. We now come to consider the various manures that are necessary. *Phosphatic manures* give considerable and very remunerative increase when used together with manures containing nitrogen and potash. Phosphate slag seems to be an excellent source of phosphorus for cane plantations, and ought to replace superphosphate. Nitrogen in the form of sulphate of ammonia, nitrate of soda, and dried blood shows a favourable influence on the yield. The best results obtained by the authorities of the Botanical Gardens of British Guiana were obtained with a mixture of one-third nitrate of soda and two-thirds sulphate of ammonia, although for large quantities sulphate of ammonia gives a better pecuniary result. Dried blood was notably inferior. Potash seems to be of only small efficacy. The employment of sulphate of potash on land not limed gave a slight benefit, but a loss on limed soils. The use of soda did not furnish satisfactory results. The employment of lime gave great increase of yield, the effect on the first crop being sufficient to pay the cost of its application, while the increase in the shoots constituted a net gain.

Diseases of the Cane. The cane is subject to a variety of animal and vegetable pests. In the first category are included rats. These are kept down by poison or the use of Danysz virus. The mongoose was introduced into Jamaica to kill the rats, but ultimately became as great a pest as the rats. Among insects the moth-borer is prevalent, and is only got rid of by systematically collecting the moth and destroying the diseased canes by fire. Several other borers are known, some of the pests making special attacks on the roots of the cane. Spraying with paraffin emulsion is recommended for destroying some of the small insects. Vegetable or fungoid pests, such as red smut, top rot, serch, ananas, and gumming disease, attack the leaf and stem. The remedies are to choose canes known to be disease resistant, to correct errors of cultivation, and to destroy all affected canes by burning. Rotation of crops and green manuring are also suggested as a means of combating fungoid diseases.

Yield and Composition. The weight of crop varies very much, from 70 to 80 tons having been taken from rich scrub lands in North Queensland. A fair average is 25 to 40 tons per acre, and with modern appliances and methods a ton of sugar is sometimes made from little more than 10 tons of cane.

There is 16 to 18 per cent. of sugar present in the sugar cane and about 70 per cent. of water. The sugar is distributed irregularly throughout the cane, the joints and the lower end being poorer in sugar than the higher parts of the stem. The softer parts of the cane contain the purest and richest juice, there being altogether about 88 per cent. of juice in the cane. The juice contains about 18 per cent. of sugar, the rest being water and a small proportion of mucilaginous, resinous, fatty and albuminous matters, and mineral salts.

Continued

A SHORT DICTIONARY OF TERMS USED IN SUGAR-MAKING

ANIMAL CHARCOAL, or CHAR—Charcoal made from bones and used for decolourising sugar.

BAGASSE—Refuse cane after the juice has been extracted.
Basket Sugar—A small-grained sugar sold in the Straits Settlement.
Battery—A row of evaporating pans as used in the Jamaica sugar-industry.
Black-strap—Refuse molasses.
Blow-up—The pan in which sugar is dissolved or melted in sugar refining.
Bull's-eye—The sight-hole of a vacuum pan.

CARAMEL—Burnt sugar used as a colouring agent.
Carbohydrates—Scientific term for the group of organic bodies to which sugar belongs.
Carbonatation, or Carbonation—The process of saturating limed beet-juice or cane-juice with carbonic acid gas.
Chancara—A small-grained sugar sold locally in Mexico.
Char Cistern—Large tank filled with animal charcoal.
Clairce—French term for a saturated solution of pure sugar
Clarification—The process of purifying raw juice by heat and lime.
Claying—The process of driving out the colour of a sugar-loaf by damp clay or rag.
Cleare—Bright, clear syrup used in liquoring sugar.
Coffee Sugar—An especially pure, refined sugar.
Concretor—An evaporating apparatus for cane juice.
Conveyor Cylinder—The large rotating cylinder of a Hersey granulator.
Copper Wall—Battery of open pans used for concentrating cane juice.
Corn Syrup—Glucose in a liquid state made from maize.
Cosettes—French term for beetroot slices.
Crystallisation—The property which many bodies have of assuming definite solid forms out of a saturated solution.
Crystallisation in Motion—The name applied to the method of crystallising the massecuite by keeping it moving during cooling.
Cube Sugar—Sugar moulded into the form of a cube
Curing—Cleansing sugar crystals by washing and draining.
Cush-cush—Name given in Guiana to the impurities in the juice from crushed sugar-cane.
Cut—The technical expression for half-emptying the vacuum pan when discharging massecuite.

DATE HONEY—A name sometimes applied to palm sugar.
Defecation—The process of removing, by heat and lime, the fecular matter from raw juice.
Defibrator—A mill that pulps the sugar-cane.
Demerara Sugar—Sugar of a yellow colour, produced in the West Indian Islands.
Dextrin-maltose—An unfermentable substance prepared by the action of acid on starch.
Diffusion Process—A method used in beet and cane sugar manufacture by which the beetroot in slices, or the cane in small pieces is macerated in hot water to soak out the sugar.
Do-kat—The second flow of sap after tapping the date-sugar palm.
Double—A term used in sugar boiling when half the charge in the pan has been emptied and fresh portions of syrup admitted.
Double Carbonating—When the process of carbonating is done twice on the same juice.
Double Effect, or Effet — An evaporating apparatus consisting of two vacuum pans working together but at different internal pressures.
Drained Sugar—Sugar from which the molasses has been drained in hogsheads.

FALSE GRAIN—An expression used in sugar boiling when small grains of sugar separate instead of growing on the larger crystals already formed.
Film Evaporators—An apparatus which depends on the principle of evaporating a thin film of liquid
First Molasses—That obtained from massecuite, which has had no molasses added to it.
First Sugar—Massecuite after treatment in the centrifugal machine.
First Throwing—Refined sugar purified in a centrifugal machine.
Fruit Sugar—Levulose.

GASSED — The process of passing sulphurous acid gas through raw juice.
Glucose—Dextrose, or grape sugar.
Golden Syrup—The finer kind of treacle.
Grain—The small crystals of sugar that form when syrup is being concentrated in a vacuum pan.
Green Syrup—The syrup that drains from sugar-loaves in the mould.
Grocery Sugar—Moist brown sugar.
Guarapo—Raw liquor treated with lime, but not yet concentrated.

HEATER—The vessel into which the massecuite is received when discharged from the vacuum pan.
Hydro Extractors—Another name for centrifugal machines.

INVERT, or INVERTED SUGAR—Sugar the behaviour of which in the polariscope has been changed from right to left.

JAGGERY—A raw sugar produced in India, obtained from the palm.
Jarra—The third flow of sap after tapping the date-sugar palm.
Jiran—The first flow of sap resulting from tapping the date-sugar palm.

LÆVO SACHARRUM—Invert sugar used as a malt adjunct in brewing.
Levulose—Fruit sugar.
Liming—The process of adding lime to raw juice.

MACERATION—The process of soaking beet slices or cane in hot water to extract the sugar.
Maize Sugar—Sugar obtained from the stalks of zea mays.
Maple Sugar—Sugar made from the sap of the maple tree
Massecuite—The finished mass of sugar crystals and syrup formed on concentrating syrup in a vacuum pan.
Megass—Cane after it has been pressed in the cane mill.
Melting—The term for dissolving sugar in water.
Molasses—A drained syrup from which sugar no longer crystallises on boiling.
Monte-jus—A pump for raising juice.
Multiple Effect, or Effet—An apparatus for evaporating syrup in which two or more vacuum pans, working at different pressures, are employed.
Muscovado—Raw sugar from which the molasses has been drained in tubs.

PANELA—A small-grained sugar sold locally in Central America.
Pilé—French term for white powdered sugar.
Premier Jet Sugar—Sugar purified in a centrifugal machine.
Proofstick—An instrument for withdrawing a sample of the contents of the vacuum pan.

RATOONS—The second crop of canes from one planting.
Raw Sugar—Unrefined massecuite after treatment in the centrifugal machine.
Refined Sugar—The finer qualities of sugar manufactured from raw sugar at central refineries.
Rendement—The net amount of crystal sugar obtainable from a given sample of raw sugar.
Revivification—Process of renewing animal charcoal that has become exhausted as a decolouriser of sugar.

SACCHARINE—Invert sugar, also applied to a sweetening agent obtained from coal-tar.
Saccharimeter—An optical instrument for measuring the amount of sugar in solution.
Shaker—Indian term for cane sugar clarified by alkalies.
Schnitzel—German name for beet slices.
Second Molasses—That which drains from massecuite that has had molasses boiled with it.
Seeding—Grain sugar added to the vacuum pan to start crystallisation.
Selecting—Process of improving the quality of beetroot, by always using only the best plants.
Semoule—French term for grain sugar.
Silo—Storing place for beetroots [see Agriculture, page 1970].
Sling—Name given to the concentrated syrup in the striking teach.
Starch Sugar—Glucose, or dextrose.
Steaming Out—Process of washing out hogsheads with steam, to remove adhering sugar.
Stirred Sugar—Prepared by evaporating syrup, and stirring until a dry, crumbly mass remains.
Striking Pan, or Teach—The end of a series of pans, in which the more concentrated liquor collects.
Sucrose—Cane or beet sugar.
Sugaring Off—The process and season for tapping maple trees.
Sweet Waters—Waters containing small quantities of sugar.

TATHES or TAYONES—The pans of the copper wall.
Taylor Filter A filter in which a large number of long filter bags are employed.
Teaches—The pans of the copper wall.
Tempering—The operation of adding lime to raw juice.
Third Molasses—The molasses drained from vacuum pan molasses sugar.
Trash—Dry cane leaves
Trashing—The operation of removing dry or faded leaves from the sugar-cane.
Treacle—The uncrystallisable part of sugar produced in the process of refining sugar.
Triple Effect—An evaporating apparatus, consisting of three vacuum pans worked together at different pressures.

ULTRAMARINE—A blue substance used for neutralising the yellow colour of refined sugar.

VIDE-JUS—An emptying pump.
Vinasse—The residuary liquors resulting from the extraction of sugar from molasses.

WHITE LIQUOR—Bright white syrup used for liquoring loaf sugar.
Windrowing—Protecting cut canes from frost by a furrow.

YELLOW CRYSTALS—Sugar dyed to imitate Demerara sugar.

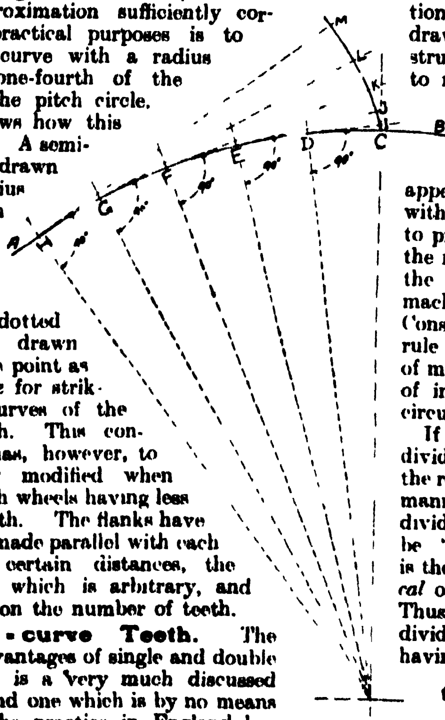
PROPORTIONS OF SPUR GEARS

Single-curve Teeth. Machine-cut Gears. Diametral Pitch. The Strength of Teeth. The Arms, Rims, and Bosses of Spur Wheels. Gear Wheel for Electric Tramcar

By JOSEPH W. HORNER

Single-curve Teeth. The method of constructing the involute curve of a *single curve tooth* is shown in 95, where A B is the pitch line. First mark off the equidistant points D E F G H, and from each point draw a tangent to the circle; then set off the distance D I equal to the arc D C, E J equal to E C, F K equal to F C, G L equal to G C, H M equal to H C, and a curve drawn through the points I J K L M will be the involute required. It is, in effect, a curve formed by the unwinding of a cord from the arc of the circle.

An approximation sufficiently correct for practical purposes is to strike the curve with a radius equal to one-fourth of the radius of the pitch circle. Fig. 96 shows how this is arranged. A semicircle, A, is drawn on the radius of the pitch circle, and the centre, B, is located upon it; a dotted circle is drawn through the point as a *base circle* for striking the curves of the other teeth. This construction has, however, to be slightly modified when dealing with wheels having less than 30 teeth. The flanks have then to be made parallel with each other for certain distances, the amount of which is arbitrary, and depends upon the number of teeth.



95. INVOLUTE CURVE

Double-curve Teeth. The relative advantages of single and double curve teeth is a very much discussed question, and one which is by no means settled. The practice in England has been for many years distinctly in favour of double-curve teeth, due, no doubt, to the wide adoption of the odontograph instrument, together with an exaggerated idea of the theory that single-curve teeth cause undue pressure upon the shaft bearings. The tendency at present is to adopt the single curve universally, and this has been brought about largely by the introduction of *machine-cut* gears.

When toothed gears of a very fine pitch are required, it has been the practice to cut the tooth spaces from a solid rim, in order to attain sufficient accuracy to ensure quiet running. It has been left to Messrs. Brown & Sharpe, of America, to develop this idea, and to standardise the forms and proportions of machine-cut gears of all sizes and pitches. The Brown & Sharpe involute gear cutters are now used regularly all over the world, and are as much recognised as a standard article as the Whitworth and the Sellars screw threads are in their sphere. Gears having cast teeth are, of course, still widely used, but for all accurate and high speed work cut gear has the monopoly.

Diametral Pitch. The basis of calculation for cut gears is the *diametral pitch.* When drawing wheel teeth on paper, or when constructing a pattern, it is convenient and natural to measure the pitch of the teeth on the circumference of the pitch circle, and such a measurement is termed *circular pitch.* Now, when dealing with cut gears, this method of measurement disappears. The pattern-maker is not concerned with the spacing of the teeth—he simply has to prepare a wheel blank of a certain *diameter*; the machinist has to turn the blank casting to the correct *diameter*, and the gear-cutting machine is set to cut a certain number of teeth. Consequently, circumferential measurements by rule or compass are not required in the process of manufacture. Therefore, the pitch is spoken of in terms of the diameter instead of the circumference of the wheel.

If the circumference of a pitch circle be divided by the number of teeth in the wheel, the result will be "circular pitch." In the same manner, if the diameter of the pitch circle be divided by the number of teeth, the result will be "diameter pitch." The *diametral pitch* is the reciprocal of diameter pitch. The *reciprocal* of a number is 1 divided by that number. Thus, the reciprocal of 4 is $\frac{1}{4}$, because $\frac{1}{4}$ will divide into 1 four times. Now if we take a wheel having 48 teeth and a pitch diameter of 12 in., the diameter pitch is $\frac{12}{48} = \frac{1}{4}$ in., and the diametral pitch is $1 \div \frac{1}{4}$ in. $= 4$. In other words, diametral pitch is the number of teeth per inch of diameter of pitch circle; this idea may be a little difficult to grasp at first, but the following calculations will show the simplicity of its application.

To find the pitch diameter of a wheel having, say, 94 teeth of 3 diametral pitch: Divide the number of teeth by the diametral pitch:

$$\frac{94}{3} = 31{\cdot}33 \text{ in.} = 31\tfrac{1}{3} \text{ in. pitch diameter.}$$

[See Table of Decimal Equivalents for Vulgar Fractions on page 3006.]

To find the diameter of a wheel blank to cut, say, 94 teeth of 3 diametral pitch: Add 2 to the number of teeth and divide by the diametral pitch: $\frac{94+2}{3} = 32$ in. diameter of blank, or *whole diameter of wheel*, as it is sometimes termed.

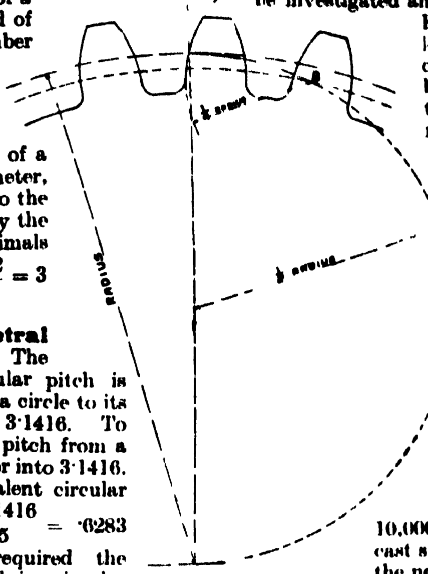
To find the diametral pitch of a wheel having, say, 60 teeth, and of 24 in. diameter: Divide the number of teeth by the diameter of the pitch circle: $\frac{60}{24} = 2\frac{1}{2}$ diametral pitch.

To find the diametral pitch of a wheel, say, 20 $\frac{21}{32}$ in. whole diameter, and having 60 teeth: Add 2 to the number of teeth, and divide by the wheel diameter (convert to decimals by table on page 3006): $\frac{60+2}{20 \cdot 66} = 3$ diametral pitch.

Relation of Diametral Pitch to Circular Pitch. The relation of diametral to circular pitch is the relation of the diameter of a circle to its circumference, which equals 3·1416. To obtain the equivalent circular pitch from a diametral pitch, divide the latter into 3·1416. Example: Required the equivalent circular pitch to 5 diametral pitch: $\frac{3 \cdot 1416}{5} = \cdot 6283$ circular pitch. Conversely, required the equivalent diametral pitch to 1½ in. circular pitch: $\frac{3 \cdot 1416}{1 \cdot 5} = 2 \cdot 0944$ diametral pitch.

A table is given on the next page showing the equivalent circular pitches for diametral pitches from 1 to 50. The Brown & Sharpe involute teeth may be set out generally as described for **96**, the proportions being as follows:

Height of tooth from pitch line, ·3183 circular pitch. Width of tooth on pitch line, ·5 circular pitch. Depth of tooth below pitch line, ·3683 circular pitch.



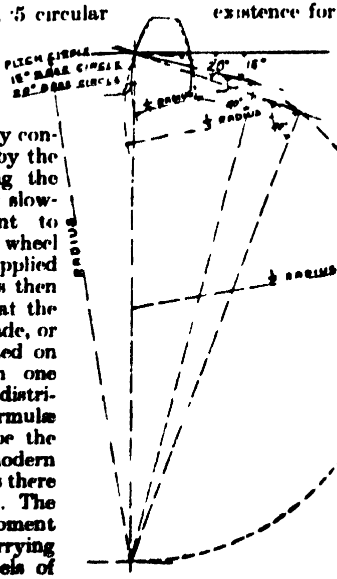
96. METHOD OF MARKING OUT AN INVOLUTE TOOTH

Strength of Spur Teeth. The strength of spur-wheel teeth may be calculated upon two bases; the one by considering a static load to be sustained by the tooth, and the other by considering the horse-power to be transmitted. For slow-moving machinery, it is convenient to estimate the load which comes on the wheel teeth, and to assume that this load is applied at the point of one tooth; the case is then treated as a simple cantilever loaded at the outer end. If the teeth are badly made, or if the wheels are not properly adjusted on the shafts, the load may come on one corner of the tooth instead of being distributed evenly across the face. Many formulæ in use deliberately assume such to be the case in ordinary work; but with modern machine-moulded or machine-cut gears there is no necessity to make such provision. The number of teeth in gear at the same moment will make a difference to the carrying capacity of a wheel; with large wheels of fine pitch gearing together, several teeth will divide the load between them; but if a small pinion be geared with a wheel, the full load may easily come on one tooth only.

Properly speaking, each individual case should be investigated and designed accordingly. Having determined the load which the tooth must carry, multiply that load by the full depth of the tooth for a bending moment; the modulus of a rectangle is $\frac{B H^2}{6}$ where B is the breadth or face of the tooth, and H is the thickness at the root; multiplying the modulus by the safe stress per square inch gives the moment of resistance of the tooth, which should be equal and opposite to the bending moment. A safe stress for cast iron is 3,000 lb. per square in., and 10,000 lb. per square in. for cast steel. [See the table on the next page.]

The thickness at the root of an odontograph tooth varies from ·4 to ·6 of the circular pitch when ranging from 15 to 60 teeth. The breadth or face of a toothed wheel may vary from one and a half to three times the circular pitch.

There are from 40 to 50 different rules in existence for the calculation of the horse-power which may be transmitted by toothed gearing, the majority of them depending upon an arbitrary factor which covers allowances for inaccurate workmanship and stresses due to centrifugal action. A safe rule is $H P = \frac{D P F N}{1000}$, where D = pitch diameter of wheel in inches, P = circular pitch, F = face of wheel in inches, N = speed of wheel in revolutions per minute.



97. THE ANGLE OF OBLIQUITY

The Wilfred Lewis Formula. This is used largely in connection with machine-cut gear. It was introduced by Mr. Wilfred Lewis

No. of Teeth.	Factor for Strength, Y.			No. of Teeth.	Factor for Strength, Y.		
	Involute 20 deg. Obliquity.	Involute 15 deg. and Cycloidal.	Radial Flanks.		Involute 20 deg. Obliquity.	Involute 15 deg. and Cycloidal.	Radial Flanks.

25	·108	·097	·063	rack	·154	·124	·075

at Philadelphia, U.S.A., in 1893. He assumes that the whole load is taken upon one tooth, and that the tooth is a cantilever loaded at one end. From a consideration of various sizes of involute and cycloidal gears he selects the weakest cross section of each, and determines its relation to the pitch; then from these data deduces the formula W = S P F Y, where W is the load transmitted in pounds, S is the safe working stress per square inch in pounds, P is the circular pitch, F is the face of the tooth in inches, and Y is a factor varying with the shape and number of teeth. The values of Y and S are given in the table on this page.

It will be noticed in the table that the involute is given as 20° and 15° obliquity; the angle of obliquity is measured between a horizontal line cutting the pitch circles at their point of contact and a line drawn perpendicular to the curve of the tooth, and being a tangent to the base circle. Fig. 97 shows the effect on the thickness of the tooth due to an alteration in the angle of obliquity; the greater the angle the stronger the tooth. A 20° obliquity gives a tooth radius of about one-third the pitch circle radius.

When drawing gears to be cut with Brown & Sharpe cutters the angle of 15° may be taken.

Arms of Spur Wheels. These are made oval section [98], cross section [99], or H section [100]. The first-mentioned is used for comparatively light machine-cut gears, the second is used chiefly for gear wheels moulded from patterns, the third is adopted for machine-moulded wheels and for large and heavy gears. Frequently machine-cut gears are made with solid web plates without arms. The strength of a wheel arm may be calculated in the same way that we dealt with pulley arms. For the cross arm section the following proportions give good results:

Thickness of rim (A) .. = ·46 circular pitch
Width of arm (B) .. = circular pitch × 2
Depth of rib (C) .. = circular pitch
Thickness of arm (D).. = ·43 circular pitch
Thickness of arm (E) = ·5 circular pitch
Thickness of boss (F).. = ⅓ of shaft diameter + ½ in.

The above dimensions apply at the centre of the arms, the taper being about ¾ in. per foot either way. The number of arms in a wheel may be taken as:

Up to 1 ft. 6 in. diameter .. .. 4 arms
Up to 8 ft. diameter .. .. .. 6 arms
Above 8 ft. diameter .. .. .. 8 arms

TABLE OF DIAMETRAL AND CIRCULAR PITCHES.

Diametral Pitch.	Circular Pitch.	Diametral Pitch.	Circular Pitch.
1	3·1416	15	·2094
1¼	2·5133	16	·1963
1½	2·0944	17	·1848
1¾	1·7952	18	·1745
2	1·5708	19	·1653
2¼	1·3963	20	·1571
2½	1·2566	22	·1428
2¾	1·1424	24	·1309
3	1·0472	26	·1208
3½	·8976	28	·1122
4	·7854	30	·1047
5	·6283	32	·0982
6	·5236	34	·0924
7	·4488	36	·0873
8	·3927	38	·0827
9	·3491	40	·0785
10	·3142	42	·0748
11	·2856	44	·0714
12	·2618	46	·0683
13	·2417	48	·0654
14	·2244	50	·0628

The proportion for H arms may be taken as follows:

Thickness of rim (A) = ·375 circular pitch
Depth of rib (B) .. A + ·01 pitch diameter
Width of arm (C) .. = circular pitch + ·035 pitch diameter
Thickness of web (D) ·375 circular pitch
Thickness of flange (E) ⅜ of breadth of tooth
Thickness of boss (F) = ⅓ of shaft diameter + ½ in.

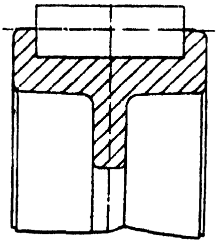
The remarks concerning the taper and the number of arms for cross section arms apply equally to H arms. It will be noticed that in the cross and H section arms that the face of the wheel is slightly wider than the width of the arms, this giving a better appearance to the wheel

SAFE WORKING STRESS FOR DIFFERENT SPEEDS.

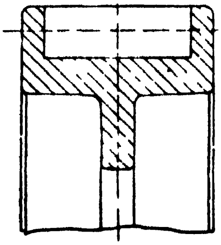
Speed of Teeth in Ft. per Minute.	100 or Less	200	300	600	900	1,200	1,800	2,400
Cast iron	8,000	6,000	4,800	4,000	3,000	2,400	2,000	1,700
Steel ..	20,000	15,000	12,000	10,000	7,500	6,000	5,000	4,300

than if both were flush, and in the case of machine-cut gear it facilitates the machining of the sides.

Cast gears are frequently shrouded up to the pitch circle as **101**, full shrouded as **102**, or shrouded partially, or wholly on one side only; this adds from 20 to 50 per cent. to the strength of the gear. A common device is to shroud a pinion, but not the wheel it gears with, this being done to compensate for the unequal strength of the teeth at their roots. The thickness of the shroud may be one-third of the circular pitch.



101. HALF SHROUDED TOOTH



102. FULL SHROUDED TOOTH

Split Gears. Sometimes gear wheels are made in halves for convenience of renewal. A typical example is given in **103**, which represents a working drawing of a *split spur wheel* for an electric tramcar axle. It is necessary both for railway and tramway rolling stock to force the running wheels upon the axles with sufficient pressure to ensure their rigidity when negotiating a curve at high speed, for if a wheel then slipped sideways upon its axle the vehicle would be instantly derailed. Now, when the wheels are so securely fastened to an axle, it is very important that anything between them shall be removable without disturbing them, and hence the dividing of the driving spur, which is keyed to the axle between the two running wheels.

Looking at the drawing **103**, it will be noticed that a groove is planed across the joint of one half to receive a register formed on the other half. This relieves the bolts from shearing forces while the teeth are being cut, and also from side pressures should they occur when running. Note the section cut on A B joined by a diagonal line for the convenience of showing two sections not strictly in the same plane. In wheels of this nature it is necessary to see that they contain an even number of teeth, so as to divide properly without parting a tooth at the joint. There is no necessity to show all the teeth on the drawing. In the data given on the drawing for cutting the teeth D P of course means diametral pitch, whilst the reference to No. 2 B and S cutter means a Brown & Sharpe cutter No. 2. These cutters are made in numbers as follows:

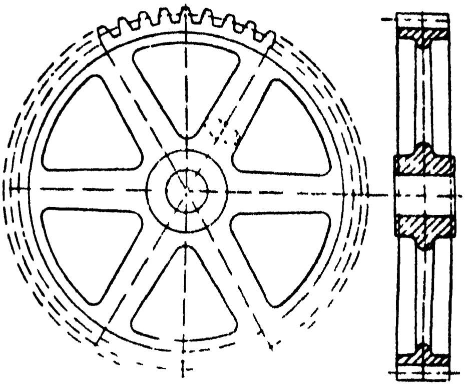
No. 1 will cut wheels from 135 teeth to a rack, inclusive.

No. 2 will cut wheels from 55 teeth to 134 teeth, inclusive.

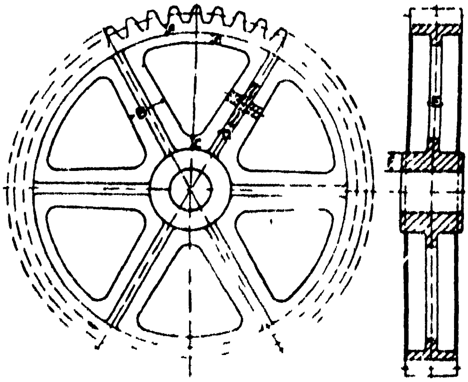
No. 3 will cut wheels from 35 teeth to 54 teeth, inclusive.

No. 4 will cut wheels from 26 teeth to 34 teeth, inclusive.

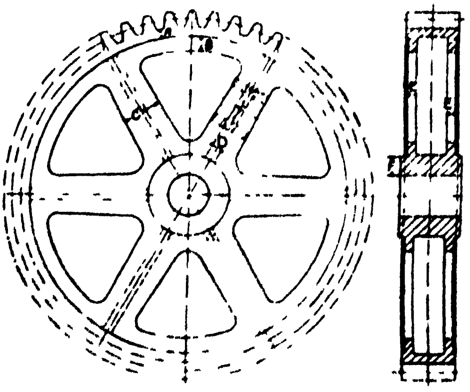
No. 5 will cut wheels from 21 teeth to 25 teeth, inclusive.



98. WHEEL WITH OVAL SECTION ARMS



99. WHEEL WITH CROSS SECTION ARMS



100. WHEEL WITH H SECTION ARMS

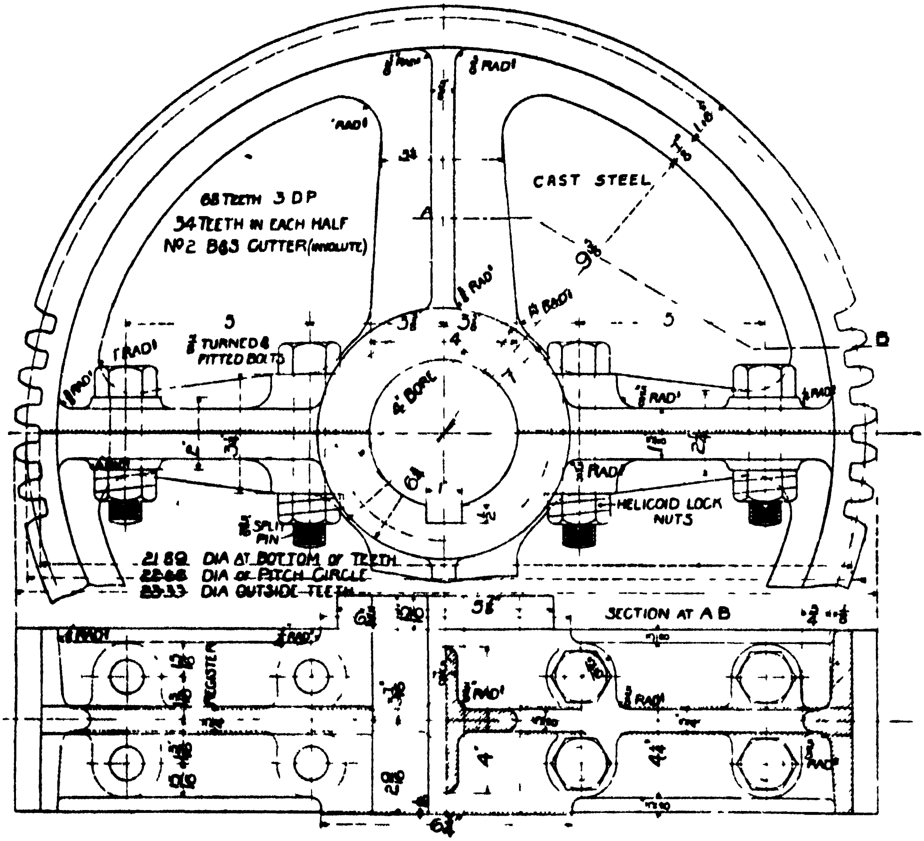
No. 6 will cut wheels from 17 teeth to 20 teeth, inclusive.

No. 7 will cut wheels from 14 teeth to 16 teeth, inclusive.

No. 8 will cut wheels from 12 teeth to 13 teeth, inclusive.

There are thus eight cutters required in order to cut a full range of teeth for any one pitch. It takes eight cutters to cut all involute 4-P gears having 12 teeth and over ; it takes eight other cutters to cut all gears of 5-P having 12 teeth and over, and so forth, each separate pitch requiring its own set of cutters.

Cutters are made for cycloidal gear teeth, but are not used to the same extent as the involute. They are made in sets of 24, and are lettered A to X, instead of being numbered. This is done in order to avoid confusion with the involute cutters. Each set is applicable to its particular pitch only.



108. SPLIT GEAR WHEEL FOR ELECTRIC TRAMCAR AXLE

Large spur wheels are built up in a similar manner to that described for large rope wheels, and chiefly for the same reasons. Gear teeth are also formed upon the rims of flywheels, etc., and are used as a means of starting an engine by levers or by a small geared engine.

Gears are made in cast iron, cast steel, mild steel, phosphor bronze, raw hide, etc. The construction of raw hide gears is dealt with in the next lesson together with helical teeth, mortise cogs, racks, bevils, screw gears, worms, etc.

Speeds of Wheels. The relative speeds of gear wheels may be calculated in the same way as we did with belt pulleys by using the pitch circle diameters, except that there is no loss due to slip. We may, however, simplify the calculations by using the number of teeth contained in a wheel instead of its pitch diameter. This is particularly useful when cut gears are involved, as their pitch diameters frequently run into vulgar fractions or decimals.

As in the case of rope wheels, there is a limiting speed beyond which gears should not be run. Cast-iron gears should not be run above 2,000 ft. per minute at the pitch line ; cast-steel gears, 2,500 ft. per minute ; small machine-cut gears, 3,000 ft. per minute ; above these speeds, gearing becomes noisy in running, and the wear is excessive.

THE THREE RIDDLES OF LIFE

How Psychical Research is Helping to Solve them. Thought Telegraphy. Hypnotism and its Value. Modern "Miracles." Is Materialism Honest?

continued from page 3527

By HAROLD BEGBIE

THERE are two ways in which humanity has become accustomed to transfer thought from mind to mind. One is by the spoken word, and the other is by the written word. In the first case, the organ of hearing conducts the thought to the brain; and in the second case, the organ of sight.

Mental Telegraphy. It is now certain that in a third way thought can be transferred from mind to mind, and this third way has been carefully investigated by men of science, and has been termed *telepathy* for the sake of brevity, though the word does not sufficiently express the mystery.

Frederic Myers, himself the inventor of the word, confesses in "Human Personality" the inadequacy of his nomenclature: "The communication between distant persons is not a transference of thought alone, but of emotion, of motor impulses, and of many impressions not easy to define. I ventured in 1882 to suggest the wider terms *telæsthesia*—sensation at a distance—and *telepathy*—fellow-feeling at a distance. . . . But I am far from assuming that these terms correspond with definite and clearly separate groups of phenomena, or comprise the whole field of super-normal faculty. On the contrary, I think it probable that the facts of the metethereal world are far more complex than the facts of the material world, and that the ways in which spirits perceive and communicate—apart from fleshly organisms—are subtler and more varied than any perception or communication which we know."

But the term will stand, in the present state of human knowledge, as denoting all those puzzling occurrences, familiar to everybody, in which ideas have communicated themselves from consciousness to consciousness, often over great distances, without mechanical means

An Absorbing Mystery. We would caution the reader against accepting any word, however successful its etymology, as the *explanation* of a mystery. The term *electricity* does not in the smallest way explain the mystery of electricity, and the term telepathy does not explain the mysteries it attempts to denote. There are many people who dismiss a ghost story with the verdict that it is merely a case of telepathy; they do not pause to acknowledge that the manifestation of a ghost is not one whit more inexplicable than the telepathic communication of mind with mind over a great distance.

Telepathy, one of the well-proven facts of psychical research, is an absorbing mystery. It opens up before humanity the vista of a new world, and gives promise of faculties and powers of which the most advanced of us have scarcely begun to dream. It is not a simple thing; not a mere physiological explanation of superstitious imaginings—it is a definite contribution to the study of the human mind, and one that seems to credit that mind with powers of an almost transcendental order.

Telepathy Annihilates Space. For it destroys, in the first place, as between mind and mind, all idea of space. It does not suggest, it actually proves that two minds may communicate instantaneously, though the one inhabit the western and the other the eastern hemisphere. A son dying in the Himalayas may convey his last anguish to his mother in London at the very moment of dissolution; and not only his anguish, but the very wishes in his mind concerning the distribution of his property—not merely frantic and unintelligible emotions, but definite and rational expressions of mind.

As soon as the investigator has appreciated this character of telepathy he is in a state of mind to follow the clue towards the goal of knowledge. So long as he uses the terms telepathy and coincidence merely as excuses for his own intellectual sloth, or as shields for his own ignorance—not troubling to discover what they really signify—he cannot hope to make progress in his ideas.

Now, the marvellous fact of telepathy is just this orderly transference of coherent thought. It would be wonderful if a child in its death agony should act upon the consciousness of its mother at a great distance so as to convince the mother of its distress; but it is something far more wonderful, and at the same time something inspiring us with the assured hope that we are exploring a definite faculty of human consciousness, when we find the child in its distress conveying calm and intelligible thought to its parent over thousands of miles.

Let the investigator emphasise in his mind that we are here dealing with a transference of *thought*. Thought, according to physicists, is a mental process, a cerebral action, a physical exertion; it is a movement of the brain; it is an exertion of physical energy; it is a definite and certain operation of the material brain.

The Dying Soldier's Message. Now, there are endless instances in the records of psychical research wherein coherent and unemotional messages have been received by people from those dear to them at moments of supreme crisis. A dying solider in South Africa narrated to his sister, by means of automatic writing, at the very moment of his decease, the manner of his dying, the names of comrades who held him when he fell, and expressed his wish that these two men—utterly unknown to the sister—should receive certain gifts out of his property as keepsakes. The story is explained easily enough by the intellectually slothful as a case of "telepathy." But how do these people answer us when we venture to point out that a gentleman in South Africa, with a bullet through his spine, with his nerves torn and lacerated, with his life's blood flowing from him in a ceaseless gush, is hardly in a position to give an unemotional picture of his plight to a lady in London, and to make a rational disposal of his property? Profound thought—or, shall we say, honest thought?—must convince the fair-minded that we are here fumbling at a new door in human experience, opening upon what wonderful fields of human enterprise we dare not venture to imagine.

Proof of the Soul. The great work of Frederic Myers in this particular department of psychical research proves, we think, beyond all question the existence of a spirit, or, in other words, proves the world-old faith that man is a *soul*. He points out that in cases of this kind we have two distinct factors—the *agent*, or the person who transmits the message, and the *percipient*, or the person who receives the message. Now, the agent must first manage his own brain, and at the same time manage the brain of the percipient. The materialists have not yet got so far in their positivism as to tell us how this is done. We are left by them to inquire how the agent works in his own organism, and how he works in the organism of others. The dying soldier in South Africa, according to this theory, arranges the mechanism of his own brain for the transmission of a message, arranges the mechanism of his sister's brain for the reception of his message, and then, somehow or another, transmits it. We need scarcely pause to point out the enormous demand which this hypothesis makes on our credulity. Finite matter, which somehow or another has become conscious of itself, is able so to direct and influence each molecule of the cells of which itself is composed—is able to exercise, in Myers's own phrase, "*selective guidance of each individual molecule*"; and by some movement within itself is able to influence another lump of self-conscious matter six or seven thousand miles away with intelligible impressions and rational desires. Let him who is able, believe.

The Working of the Brain. The inquirer will notice that in many cases where thought-reading or thought-transference, as practised by "professors," has been put to the test, it has failed to convince its examiners. Myers, Sir William Crookes, and Sir Oliver Lodge have all seen experiments which convince them of genuineness, but there are innumerable instances of half-and-half success, and innumerable instances of complete and utter failure.

We find in this a reason for hoping that telepathy is an operation of spirit. The number of people who can consciously direct their brains so as to effect a telepathic message is small; the number of people who have unconsciously received telepathic messages of the most important nature is very large. It seems to us that, at the moment of dissolution, or in any moment of grave distress, the automatic working of the brain ceases, and the perturbed mind clashes on discordantly, while the spirit frees itself to express itself spiritually. Myers speaks about "the achievements of will, as it shakes itself free from the limitations which are but shadows as contrasted with its own reality."

Claims for Telepathy. This is really the clue to the mystery of telepathy—the *will*. At present we are uninstructed in the exercise of the powers of the will. "The mind of the mind," as Richard Jefferies expressed it, remains untaught. But telepathy does suggest that we are on the verge of discovering some definite law of the will. Consciousness is not so much memory as it is will—that summing-up of personality, that fifth essence of character, which is the individual of every human form. Psychical research is here found pressing upon physical science the importance of examining human personality, and of exploring the secret places of consciousness. She claims for telepathy the place of a fact in the universe, and asks philosophers whether such a fact can profitably be ignored. It is not a question of this man or that man arguing from telepathy the proof of a soul; it is a question of fact, and the work of psychical research in this respect is an emphasis of the fact.

In conclusion, we recommend to the student a careful perusal of the Report on the Census of Hallucinations, made by a committee of the Society for Psychical Research, which included in its numbers Professor and Mrs. Sidgwick, Dr. A. Myers, Mr. F. Podmore, and F. W. H. Myers. It will be found from this report that there is at least ample evidence to support the general theory of telepathy, if there be not sufficient elucidation to give to the term telepathy a significance which it sadly lacks in the mouths of the unregenerate.

Hypnotism. As soon as people perceive that psychology is the science of the outside of the mind, they become favourably inclined towards *hypnotism*, which is the science of the inside of the mind. If an intelligent savage were to see a motor-car for the first time, he might come to some more or less useful conclusions concerning it by careful observation of its behaviour; but until he had explored the interior workings of the engine he could not possibly be said to *understand* a motor-car.

Psychology is the science of observation of the mind as it manifests itself in its operations. All its distinctions between the *subjective* and the *objective* carry us but a little way in our inquiry as to the absolute reality of mind. By studying the figures on a dial and the movement of the hands we learn from a clock nothing but the time. Psychology, as distinct from experimental psychology, is a purely empirical science. An exact science of the mind must have among its methods some process of dissecting and analysing a vital brain. Such a process, we contend, is to be found in the methods of the hypnotist.

In a Hypnotic Hospital. Hypnotism has become so confounded in the public mind with the grosser nonsense of mesmerism that it is necessary to point out that the hypnotism of which we are now speaking is the hypnotism of the medical man as it is practised in French hospitals and by some of the leading physicians in London. Let the reader take his stand, as Myers says, "at one of the modern centres of hypnotic practice—in Professor Bernheim's hospital-ward, or Dr. van Renterghem's *clinique;* let him see the hundreds of patients thrown daily into hypnotic trance, in a few moments and as a matter of course; and let him then remember that this process, which now seems as obvious and easy as giving a pill, was absolutely unknown, not only to Galen and to Celsus, but to Hunter and to Harvey; and when at last discovered was commonly denounced as a fraudulent fiction, almost up to the present day. . . . Mesmer's experiment was almost a 'fool's experiment,' and Mesmer himself was almost a charlatan. Yet Mesmer and his successors—working from many different points of view, and following many divergent theories—have opened an ever-widening way, and have brought us now to a position where we can fairly hope, by experiments made no longer at random, to reproduce and systematise most of those phenomena of spontaneous somnambulism which once seemed to lie so tantalisingly beyond our grasp."

We Hypnotise Ourselves. Hypnotism, as practised by recognised men of science, consists in, first, the removal, *as far as possible,* of normal consciousness, and then the suggestion of an idea to the secondary consciousness. We say the removal of normal consciousness *as far as possible* because in many cases such hypnotists as Dr. Milne Bramwell convey their suggestions while the patient remains convinced that he has not been hypnotised at all. In most cases, however, a deep trance is induced—so deep that the patient's mind is entirely emptied of its worries and perplexities, and is free to receive and to lay hold of any suggestion which is offered to it. And yet, be it noted, hypnotism is practised by everybody in the ordinary acts of auto-suggestion which make up so large a part of that conversation which consciousness holds with itself. You cannot offer your mind an idea without, in some measure, hypnotising yourself.

The Twofold Service of Hypnotism. The services of hypnotism are twofold—first, as a curative agent; and secondly, as a means of enlarging the borders of psychology. To take the first service, that of pathological hypnotism, we find endless cases of people freed from distressing mental disorders, otherwise incurable, by the healthful suggestions of the hypnotist. In old days, a person suffering from an obsession, or being driven towards insanity by a ghost of his own conjuring, was given a tonic by his physician, and bidden to go on a voyage and see what that would do for him. To-day he is sent to the hypnotist, who induces in him a state of hypnosis, or trance, and then tells him that his obsession is delusion, that nothing threatens him, that he is perfectly well, and that he must constantly inform himself of this fact when he issues from his trance. The patient is restored to consciousness, knows nothing of what has been said to him in trance, and goes away to find his obsession gradually fading from his mind. The hypnotist, be it particularly noted, has not imposed his will upon the patient; he has merely called into activity the patient's own healthy impulses. Hypnosis, as Dr. Bramwell has pointed out, is not due to any mysterious force or fluid emanating from the operator; the condition is a subjective one: the operator calls into action powers which are latent in the brain of his patient.

Two Definite States of Consciousness. The services of hypnotism as a means of enlarging the borders of psychology have next to be considered. As we said at the outset, hypnotism is the only means we possess of analysing a vital brain. When hypnosis has been induced, the patient is not properly unconscious; his normal consciousness has been removed, his secondary consciousness is in action. You may speak to a patient and he will answer you. You may discuss a problem with him, ask his opinion of a sonata, or discuss his opinion of his own normal consciousness. His answers will be perfectly rational and intelligible; he will speak of himself—that is to say, of both his normal and his secondary consciousness—in a manner which exhibits perfect knowledge of both. But when hypnosis has passed he is unaware of what he has said, and cannot remember that he has even spoken in his trance. That is to say, while his secondary consciousness has an intimate knowledge of his normal consciousness, his normal consciousness is completely ignorant of the secondary consciousness.

No words can exaggerate the importance of this discovery. No book of psychology can hope to throw light on the system of mind which does not take account of these two definite states of consciousness. Instead of a mind expressed in consciousness, we have a mind in which normal, or waking, consciousness plays but a meagre part, and in which a secondary and unapprehended form of consciousness plays a large part. Instead of regarding consciousness as the mind in action, we have to look upon it as a fragmentary and very imperfect form of the mind's general activity.

The Mystery of Suggestion. There are many familiar legends concerning the cure of diseases which at once suggest themselves, in the light of hypnotic knowledge, as cases illustrating the power of auto-suggestion. The miracles of Lourdes, the healings of Christian Science, and the legends of King's Touch—all have, in this light, a rational explanation. But they serve a more useful purpose than acting as mere illustrations of a theory. They force us, in an extremely suggestive manner, to apprehend the deeper mystery of what we call *auto-suggestion.* If I have a toothache I naturally wish that I should not feel the pain, but wish as I may, the pain rages. Why, then, am I to believe that the suggestion of the hypnotist will be sufficient to remove the pain which my own suggestion is incapable of affecting? Now, when we notice that in the case of the Lourdes miracles and in the case of Christian Science healings pain is undoubtedly removed, we perceive—without in any way committing ourselves to the hypothesis of the miracle—that an ecstatic perturbation, or a violent and intense emotion, has the power to effect on the physical organism results which ordinary suggestion fails to accomplish. This leads us to the conclusion which Dr. Bramwell himself holds—although combating its inference—that suggestion is not sufficient of itself to account for the effects produced by hypnotism. Suggestion does, indeed, persuade—powerfully persuade—the mind, but suggestion without hypnosis, or some other influence of a supernormal kind, is not sufficient to account for the revolution in tastes and morals, the entire change of habits and dispositions, so effectually induced by the hypnotist.

A Man Performs his own Miracles. But if we accept the definition of *suggestion* given by Myers as the *successful appeal to the subliminal self*, we are in a position to explain, at least tentatively, the cures of the hypnotist and the miracles of Lourdes. In the case of Lourdes the patient who is cured is generally of a hysterical or of a very simple nature; he believes implicitly what he is told; he is convinced that the water will miraculously cure him. His ecstasy sweeps away, more and more, the troublesome normal consciousness, until at last, when he reaches the holy waters, normal consciousness is in abeyance, and all the avenues to his soul are thrown wide open to the influences around him. So in Christian Science a formula is given which gets rid of the sceptical and discriminating normal consciousness, and slowly makes a way to the higher faculties of being, which exercise a far greater control over the mind. The higher and the more spiritual the faith, the more probable the miracle If a man can persuade himself that a chip of wood is a piece of the Holy Rood, and that it is efficacious in all sickness, he may cure himself of disease.

Myers was led to perceive by very careful observation of these "miraculous healings" that ecstasy in some form is a common feature of will cures. This led him to think that hypnotism, without knowing it, made possible by hypnosis that successful appeal to the subliminal self which is in truth the agent of cure in every case—religious or therapeutic.

The student will study for himself the evidence on this subject, and will decide how far Myers was justified in his theory. It remains only to say that, whether any theory can yet be substantiated by the evidence before us or not, the facts of hypnotism are in themselves a definite and revolutionising contribution to the study of the human mind. It is in this attitude that we would present hypnotism to the reader as a subject worthy of his most devoted attention.

The Higher Problems of Life. To a young community, such as a colony struggling to create itself anew after the ravages of war, life seems to present to it no other concern than the material objects of existence. Even in old and settled countries there are people who can conceive of life as nothing more valuable than the opportunity for improving sanitation, devising new forms of taxation, and amending the acts and by-laws created by their ancestors.

But as soon as a man's life becomes more or less ordered, and he has advanced some way from the forest necessity of a struggle for existence; as soon, we mean, as a man has no worry about his raiment, his nourishment, and his lodging, he begins to perceive that life presents to his intelligence certain important problems which it obviously behoves him to solve if he would live a rational life.

He must know, in the first place, what he is. He must know, in the second place, the object of his existence. And, in the third place, he must know what are the effects of death upon his consciousness. It will seem to him at the moment of this apprehension that life can scarcely have a more splendid occupation for his intelligence than a solution of these problems. Instead of appearing before him mistily and uncertainly, as the by-play and the hobbies of existence, they will appear to him the grand objects of life, beside which the struggle for existence is the mere passion of youthful barbarism.

The three great riddles, "What am I?" "Why am I here?" "What happens to me at death?"—have teased the intelligence of man from the earliest dawn of consciousness. The answers have been so various as to confuse the questions, and it is only now, with a definite procedure of science at our hands, that we are able, first, to see the questions in their true significance, and, secondly, to approach them with the definite hope of their solution. We have reason to believe that the questions are not vain, and that it is the end of human inquiry that we should reach their answers.

Are the Materialists Honest with Themselves? It must sometimes strike us when we are reading a book about the brain how oddly we are constituted, since the brain is here found reading about itself in the fond hope of discovering what it is! One knows not how the materialists feel when they are composing these books; but we must suppose them to sit back in their chairs now and then, and wonder how it comes about that the lump of matter which we call the brain is able to write so learnedly about itself without in the least understanding what it all means. It seems at first sight that these men cannot be honest with themselves, that they cannot definitely believe that the facts marshalled on their manuscript, the logic running through it all, and the conclusions gradually emerging with the utmost satisfaction to themselves, are all the products of a handful of matter struggling to see itself in the mirror of philosophy. The brain writes about the brain; the brain reads about the brain; and the more we absolutely regard the brain as this handful of matter the more are we amazed at the position.

Man is More than Matter. A very little inquiry into the labours of men who have seriously set themselves to answer the three great riddles of existence convinces us that we are dealing with subtler forces than any exercised by gross matter. We may not be able to subscribe to the conclusions they have reached, but we shall feel that these men are groping for light in the only region where light is to be found, and that already they have brought back sufficient illumination to convince us that man is something more than a material being, and that his imagination and his genius are something more than the by-products of accidental evolution.

There is one point in the methods of these men which differentiates them completely from the pronounced materialists; and it is a point of such importance that we would particularly beg the reader's attention for it. In reading the gospel of materialism the student will perceive that physical science postulates in its study of humanity, a type of being so rare that we might almost be excused for doubting that he exists at all. Man, we find, is habitually spoken of by materialists as a vigorous creature, judging from effect to cause, from cause to effect, free from all superstitions, his mind working with the handsome regularity of a steam-engine, his processes of thought running evenly, his emotions —if they ever venture to manifest themselves at all—revealing themselves only in the most orderly and pious fashion, one, in short, whose brain is absolute lord and master in the house, and whose digestion can account for any trivial aberrations in sleep which may from time to time disturb the unbroken sway of his intellect.

Hysteria and Insanity In reading the gospel of psychical research, on the other hand, the student finds a wiser science which sets up no perfect man as the norm of the race, but which seeks for humanity where it is to be found—even in the prisons, in the hospitals, and in the lunatic asylums. In search for the secret of consciousness, psychical science goes to every form of human consciousness, and examines it patiently with the most scrupulous devotion to the well-defined procedure of physical science. It examines all those phenomena which the materialists dismiss with the meaningless word *hysteria*, and it studies all those disintegrations of personality which the materialists also dismiss with another meaningless word—the word *insanity*. There is no alienist who can tell you what insanity means; there is no physician who can tell you what hysteria means. And yet these two words are the brooms which material science is in the habit of employing to sweep out of its survey of humanity some of the most important and suggestive aspects of human personality.

Great Men on Great Mysteries. In closing, we would draw the reader's attention to a few conclusions which have been arrived at on these great riddles by men of eminence.

In Reid's "Essay on the Intellectual Powers of Man" we read: "I am not thought, I am not action, I am not feeling; I am something that thinks, and acts, and suffers. My thoughts and actions and feelings change every moment; they have no continued, but a successive existence; but that *self* or *I* to which they belong, is permanent, and has the same relation to all succeeding thoughts, actions, and feelings which I call mine."

In Kant's "Werke," we read: "It is therefore as good as demonstrated, or it could easily be proved if we were to enter into it at some length, or, better still, it will be proved in the future—I do not know where and when—that also in this life the human soul stands in an indissoluble communion with all the immaterial beings of the spiritual world; that it produces effects in them, and in exchange receives impressions from them, without, however, becoming humanly conscious of them so long as all is well."

Dr. Alfred Russel Wallace says: "My position is that the phenomena of spiritualism in their entirety do *not* require further confirmation. They are proved quite as well as any facts are proved in other sciences . . . This being the state of the case as regards evidence and proof, we are *fully justified in taking the facts* of modern spiritualism (and with them the spiritual theory as the only tenable one) *as being fully established*."

An Intelligible Basis of Life. Sir Oliver Lodge says: "The mystery of incarnation and of gradual development, of the persistence of existence beyond bodily death and decay, and even some glimmerings of the possible meaning of the vague dream of so-called reincarnation, all become in some sort intelligible on a basis of this kind—the basis of a full and never wholly manifested persistent self, from which periodically sprouts a terrestrial manifestation, though never quite the same. Each terrestrial appearance flourishes and assimilates mental and moral nutriment for a time, and the result of each is incorporated in the constant and growing memory of the underlying, supporting, but inconspicuously manifesting, and at present barely recognised, fundamental self."

Frederic Myers writes: "*Spiritual Evolution*: That, then, is our destiny, in this and other worlds—an evolution gradual with many gradations, and rising to no assignable close. And the passion of life is no selfish weakness, it is a factor in the universal energy. It should keep its strength unbroken even when our weariness longs to fold the hands in endless slumber; it should outlast and annihilate the 'pangs that conquer trust.' . . . Nay, in the infinite universe man may now feel, for the first time, at home. The worst fear is over; the true security is won. The worst fear was the fear of spiritual extinction or spiritual solitude; the true security is in the telepathic law."

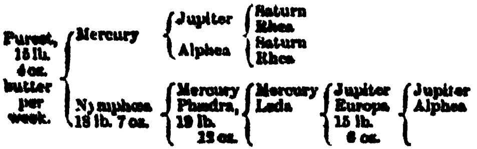
DAIRY CATTLE

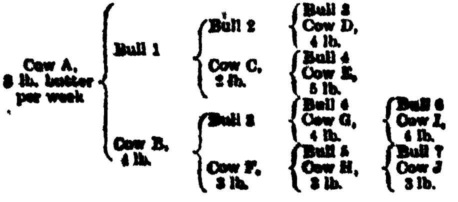
Importance of Careful Breeding. Our Principal Native Breeds, their Characteristics and Yields of Milk and Butter

By Professor JAMES LONG

THE pure breeds of dairy cattle which may be termed British are without question superior to those of any other country; indeed, with the exception of the black cattle of Holland, generally described as Dutch, the Schwyz of Switzerland, and the dairy cow of Normandy, all of which are excellent, we know of no cattle in the world which are approximately equal to the best of our native breeds. The foreign varieties that we have named, however, although large producers, yield milk which is only of moderate quality, and this especially applies to the Dutch cattle. Denmark possesses two varieties of dairy cow, the Jydsk and the Angeler, both useful and economical, while the Belgians own an excellent race in the Flamande; but these, again, can scarcely compare with the cattle of the British Isles, or with the best of France and Switzerland.

Improvement of Breeds. Unhappily, in all countries the majority of the cows kept by farmers are of impure blood, chiefly crosses or "scrubs," which have been carelessly bred, and in many cases carelessly reared. Whether purity of breed be maintained or not, in order to achieve success in the dairy farming industry it is essential not only to maintain, but constantly to improve the milk-producing qualities, and this can only be accomplished by breeding farm stock, both sire and dam, which is of essentially deep and rich milking blood. This fact may be illustrated in the following way:





Thus the cow Purest, bred from the bull Mercury (a son of Jupiter and Alphea, both of high butter-producing blood, as the pedigree shows) and the cow Alphea, which had already produced high butter-making stock when mated with Jupiter, produced 18¼ lb. of butter per week. Again we see by the second pedigree that by continually using cows which were small producers and different bulls, neither of which had any "butter blood," we get produce as in "Cow A," which shows a diminished yield of only 3 lb. per week. Whereas if these cows were mated in each generation to a bull with milking blood in his veins, they would systematically produce offspring which would inherit in a more or less marked degree the qualifications which their sires possess. It is for a similar reason that the constant employment of Shorthorn bulls, which have practically no inherent value except for the production of beef, while improving the size, form, and meat-producing qualifications of the stock to which they become sire, fails to impart the milking property which is so essential on the dairy farm. On the great majority of farms calves are bred from time to time which are of little or no economical value for breeding or dairy purposes. Such animals should be converted as quickly as possible into veal, and this practice is more profitable when they arrive in the spring, and can be allowed sufficient milk at a time when its value is lowest in the market.

The Good Milking Cow. It is desirable, however, that we should not be mistaken as suggesting that milk is the only qualification in a cow. She possesses an intrinsic value apart from her deep and rich milking properties, and this is especially the case among the larger breeds, whose end is the shambles. A good milker, therefore, should possess good feeding properties, a gentle disposition, a mellow skin, square build, which combines breadth across the hips and between the buttocks, depth of body, and length, although the milker, contrary to the beef-producer, is finer in the shoulder, neck, head, and horn. Size and constitution are largely obtained by the liberal feeding of the calf, and a lesson in this direction may be advantageously taken from those breeders of stock bulls who allow their bull calves to suckle their dams, or to drink whole milk until they have completed their first year.

Our Native Breeds. The following are the chief varieties or breeds of dairy cattle in the British Islands. We have already briefly described them in the lesson on British Breeds of Cattle on page 2235, and the student should refer to the details there given, to which the following remarks are supplementary. The pedigree Shorthorn is not included, inasmuch as—although there are occasionally fine milkers—the breed is peculiarly a beef producer, as previously stated. There are also two varieties of the Devon, the one bred for meat production, the other, peculiar to the south of the county, a milker of high type [8]. Similarly there are strains of Red Polls in East Anglia which are respectively first-rate as milkers or as beef-makers. The remaining breeds are essentially milking cattle, and in most cases of little value for meat production, whether fed as young stock or fattened when their milking days have ended.

* Average at Park Royal, 1905.

The Dairy Shorthorn. This is, perhaps, the most popular of dairy cows with the farmer. It is in this country regarded as a general purpose cow, the largest producer of milk, and capable on an emergency, or when milk production fails, of producing a heavily-meated carcase. There are Dairy Shorthorns in this country of the highest type—superior to any general purpose cow in existence—and we believe that it would be possible by careful selection not only to beat the choicest stock of any other known breed in the world for weight of milk and butter, but, by breeding from the best to be found, to produce animals which would equal the Jersey from the point of view of the quality of milk. Although the average fat percentage is not high, there are in every important competition, such as the annual contests at the National Dairy Show, Dairy Shorthorn cows whose milk contains from 4 to 5 per cent. of fat. Hence, the inherent capabilities of the breed are much greater than they are generally supposed to be.

The Dairy Shorthorn cow has deep, straight, and wide buttocks, a long, narrow head, surmounted by fine horns, usually curved inwards, a white muzzle, slender shoulders, a capacious abdomen, and a large, fine skinned, silky udder, provided with fairly large teats, placed wide apart each way, and carried well forward under the abdomen, and well backward between the buttocks. The udder should not hang, but in a good cow it is symmetrical, usually semi-globular, distended before milking, and shrunken immediately afterwards. A fine animal presents a massive appearance from behind, and a somewhat wedge-shaped form from the front. The calves grow with rapidity, and if the feeding be well maintained from birth, they provide splendid meat, known as baby beef, at two years old, instead of four years, as was the case a quarter of a century ago when cattle were kept until they became oxen. The best Shorthorn dairy cattle are found in Cumberland and Westmorland, parts of Lancashire and Yorks, and the North of England generally; in Derbyshire and Bucks there are also many fine cows of this type. In other counties the local breeds often predominate, but in all parts of England, except where poor land prevails, Shorthorns are found in the hands of a large percentage of dairy farmers. In the United States the pedigree Shorthorn is one of the popular breeds, but the Dairy Shorthorn cow, as we understand it, is almost unknown, and the great competitions in Chicago and St. Louis have proved that American farmers have little knowledge of the high value of our great native milking cattle. The following tables show their great capacities

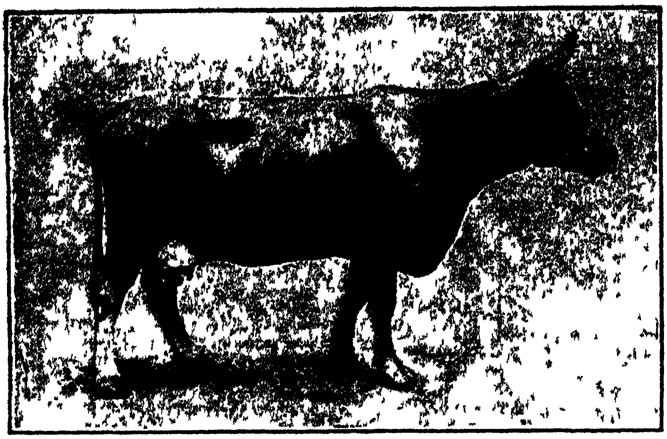
No. of Cows.	Pounds of Milk per Cow.	Per cent. Fat	Per cent. Other Solids.
147	48·3	3·73	8·9

Between 1895 and 1900, 106 Shorthorns were tested for butter at the Dairy Show. They averaged 50½ days in milk and 1 11 oz. of butter per day, requiring 28·8 lb. of milk for the production of each lb. In the four following years the averages were almost identical.

At the Royal Show at Derby, in June, 1906, Mr Evens's Lincoln Red (Burton, 4st.), 6 years old, gave 68 lb of milk, and Mr. R. Shelton's Shorthorn, Lady Mainstay, 8 years old, 7 gal. of milk in 24 hours—the latter producing 3 lb. 4 oz. of butter.

The Devon. The Devon dairy cow [8] is mellow fleshed, and in many instances symmetrically formed, but she is less perfect in this respect than the Devon of the showyard, which is bred for beef production, and wanting in those finer points which characterise the perfect dairy cow. Her milk is rich, and in many herds the yield is large and the fat percentage high, for which reason she is well adapted to the production of what is known in the West as clotted cream. She is an exceptional butter cow, but is used in Somerset by many farmers in their cheese-making herds. We may fairly assume that a herd of useful cattle will produce more than 4 lb. of butter per 100 lb., or 10 gallons of milk.

At the Royal Show at Derby (June, 1906), Mr Wm. Vosper's Primula Second, gave 56 lb. of milk producing 2 lb. 4½ oz. of butter in 24 hours, and at the London Dairy Show, in October, 1904, the cow Primrose gave 56 lb. 2 oz. of milk.



3 SOUTH DEVON COW

Vinton

The Red Poll. A good milking cow of this breed possesses a long head, quite devoid of coarseness, somewhat slender neck and shoulders, a capacious abdomen, square quarters, deep body, breadth across the hips, and a somewhat light fore-quarter; the udder resembles that of the Shorthorn. The following measurements are of a first-prize cow of that breed Height of hips, 50 in.; length, 82 in.; girth behind the shoulder, 76 in.; width across hips, 20 in.; hip bone to tail, 17½ in. Although the average quality of the milk is exceptional, there are many cows which produce milk containing still larger proportions of fat.

BUTTER PRODUCTION AT THE LONDON DAIRY SHOW.

From 1895 to 1900, 30 cows were tested They averaged 60½ days in milk, and 1 lb. 4¾ oz. of butter per day. In the following four years the weight of butter varied from 1 lb. to 1 lb. 8½ oz., requiring from 25½ lb. to 30¼ lb. to produce each lb.

40	40·7	3·65	8·9

The Ayrshire. This characteristic breed, so unlike any other variety in these islands, from the point of view of horn, form, and colour, is peculiarly Scotch, and cows are commonly brought by Scotch settlers to England, while they are frequently exported to Norway and Sweden, where they are much esteemed. The Ayrshire is a hardy cow, adapted to feed on the mountain-side, and to make the most of a coarse ration. Although weighing fairly well, she is smaller in frame than the figures suggest. In addition to the remarks made on page 2236, we would call attention to the fact that in no breed do we find the shoulders and neck so slender, or the body taper so gradually from the fore to the hind quarters [see illustration on page 2237]. The abdomen is large, the loins thick and deep, and the udder exceptional in its form. Instead of hanging or being globular, it is comparatively flat, sometimes no deeper than the base of the abdomen, but it is broad and long, and provided with four small teats, which fit it for female rather than for male milkers The breed should be more generally encouraged in England, although it is probable that English farmers object to it on account of its being but little adapted to the production of beef. The Ayrshire is found in perfection in the South-West of Scotland, chiefly in the two great cheese-producing counties of Ayrshire and Wigtonshire, where herds containing 250 head may sometimes be found, since it is better adapted for cheese-production or milk-selling than butter-making. A London champion cow measured as follows: Height at hips, 50 in.; length, 84 in; girth behind shoulder, 74½ in.; width across hips, 18 in.; hip bone to tail, 18 in

In the milking trials of 1899 four Ayrshires averaged 47½ lb. of milk containing 3·7 per cent. of fat and 9·2 per cent. of other solids. In 1901 four cows averaged 42·3 lb. containing 3·4 per cent. of fat and 8·9 per cent. of other solids.

In the years 1896 to 1900, eight Ayrshires averaging 52 days in milk averaged 1 lb. 13½ oz. of butter, each lb. requiring 26·35 lb. in its production.

The Jersey. The Jersey is at once the most elegant of our native breeds, and the most beautiful in colour, which varies from fawn and golden fawn to silver grey and mulberry [see illustration on page 2237]. She is a small cow, less fleshy than any other British variety; her skin, which should be thin and silky, covers its bony structure with little flesh behind it. Many judges incline to this want of fleshiness, and in some cases a belief is held that the fleshy cow is not a meritorious milking cow. Dr. Watney, however, the most successful of all competitors in butter-making competitions, has proved by constantly beating all rivals that this theory is not correct, for he maintains his cattle in a comparatively meaty condition, and turns them into pastures as luxurious as those upon which the pedigree Shorthorn breeders of the past obtained the high condition in which their stock was usually shown. The Jersey has a particularly fine head and muzzle, which, like her tongue, is black, a small delicately formed, crumpled horn, curving inwards, yellow at the base, and black at the points. The skin is mellow and oily, the shoulder almost imperceptible, the back straight, the ribs well sprung, the hips wide, the belly capacious, and the buttocks wide apart, the gap being filled with the back of the large and globular udder, which is more characteristic of this breed than of any other; the teats are of medium size, well placed, and wide apart. The milk vein is prominent, the tail black and long, and the skin yellow and rich in the most exposed parts, as the ears, inside the thighs, and the udder. The Jersey is a remarkable milk and butter producer, and the few selected examples will furnish some idea of her capacity. Baron's Progress, London champion (1889) gave milk containing 7·94 per cent. of fat in the morning, and 8·55 per cent. in the evening, producing 3 lb 5 oz of butter in a single day.

Between 1895 and 1900, 126 Jerseys, averaging 99 days in milk, produced an average yield of 1 lb. 10¼ oz. in the 24 hours, 19·15 lb. of milk being required in the production of each lb. In 1903, 20 cows averaged 1 lb. 11 oz. of butter, each lb. being obtained from 18·12 lb. of milk In 1904, 12 cows in milk 117 days gave an average yield of 1 lb 13¼ oz. of butter, each lb. being produced from 19·6 lb. of milk.

No. of Cows.	Pounds of Milk per Cow.	Per cent Fat.	Per cent Other Solids.
131	31·4	5·2	9·2

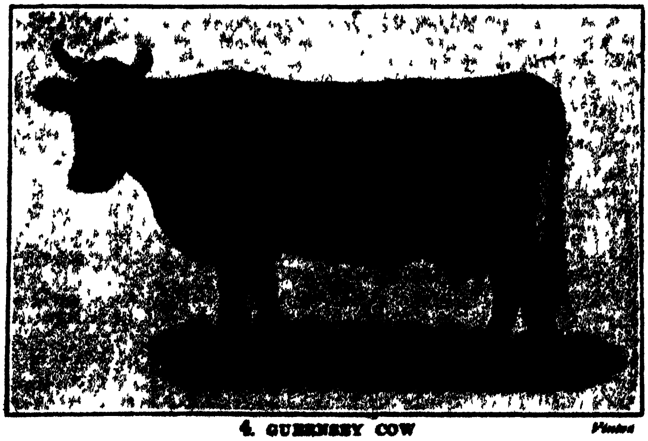
Not only is the milk of the Jersey rich, but it is remarkable for the large size of its fat globules, as well as for the extraordinary richness of its colouring, which, like that of other breeds, is more marked when the cows are on the pastures in summer. Much has been done in the Island of Jersey, from which all our stock is derived, as well as in England and America. In the latter country there are many public tests of remarkable cows, and the pedigrees of these animals are often accompanied by figures showing the actual yield of butter by the dams and the grandams during a given period. As the Jersey has little economical value apart from her milking powers, it is more than essential that this should not only be maintained, but developed by the adoption of the principle of selection.

The male calves of the Jersey, unless of very first-rate stock, are of little or no value, and the remark applies equally to heifer calves the produce of inferior cows and bulls. In every important exhibition animals are exhibited which have been purchased in the Island of Jersey from breeders who realise high prices for cattle able to win. The English Jersey is usually a bigger, coarser, and stronger cow than those bred in the island. She is a hardy animal, essentially profitable so long as she continues to milk, but at the end of her days her carcase carries little meat. Jersey milk is seldom placed on the market, for the reason that the dealer is unwilling to pay for it in proportion to its value. It not only produces more butter per 100 lb., but more cheese, and, contrary to the belief of the practical man, it produces better cheese, while the cream is far superior in texture and flavour to that of any other breed, the Guernsey excepted.

Dr. Watney's herd, members of which have reached 550 lb of butter in a year, has reached an average yield per cow of 450 lb

Measurement of Baron's Progress Height of hips, 50 in; length, 87 in, girth behind shoulder, 72 in.; width across hips, 56 in; hip to tail, 20 in.

The Guernsey. This famous cow [4] is one of the chief products of the island from which its name is derived. Her colour is orange, or orange and white She is heavier, larger, and coarser than the Jersey, and her lines in consequence less finely drawn. The quality of her milk is practically equal to that of the Jersey It produces butter and cream of similar character and colour, and is equally well adapted to the manufacture of cheese. The average Guernsey is of a fleshier type than the average Jersey, but the lightly-clad cows, when symmetrical, are preferred by the judges in the showyard. The skin is fine and soft, the body deep, the loins wide, and the fore-quarter slender in the best examples; but, taking the breed as a whole, it is less elegant than the sister variety, although occasionally cows closely approximate in quality to the best Jerseys. The calves are better adapted for veal production than those produced by Jersey cows, and although some admirers have produced excellent steers, it is doubtful whether a net profit has been realised upon their sale. Occasionally wonderful producers of milk and butter have appeared on the scene, and the following instances show that there is inherent power in the breed, that is less ardently cultivated than the Jersey, which in this country,



4. GUERNSEY COW [illegible]

as in America, has an exceptional society of admirers behind it.

In the United States, Guernseys which have been officially tested have in many cases given from 1,200 to 1,400 gallons of milk, producing from 620 lb. to 775 lb. of butter in a year, while in the Island averages of 1,200 gallons in small herds are not uncommon.

Between 1895 and 1900, 23 Guernseys, averaging 71½ days in milk, averaged per day 1 lb. 9½ oz. of butter, each lb. being obtained from 21·8 lb. of milk. In later years these figures were both increased and diminished, for the number of competitors was small.

AVERAGES AT THE DAIRY SHOW MILKING TRIALS, 1899–1904

No. of Cows	Pounds of Milk per Cow.	Per cent. Fat.	Per cent. Other Solids.
42	31	4·5	9·1

The following measurements are of a 2½-year-old heifer which was a London champion: Height of hips, 50 in.; length, 86 in.; girth behind shoulder, 72 in.; width across hips, 18 in.; hip to tail, 18 in.

The Kerry [see page 2237]. The Kerry cow is the pride of the dairy of Southern Ireland, where, however, it is not seen to the best advantage. Its small size is no doubt owing to the fact that it has been practically "made" on the mountains of the south-west, where herbage is extremely scanty, and the means of the owners as extremely limited. The result is that, apart from diminutive size, it remains a milker of a very low order until its venue is changed and it is supplied, like other cattle, with liberal quantities of proper food. When fed in the normal manner it is one of the best milkers in the world in proportion to its weight. The writer once attended the great Kerry Fair, at Kenmare, where, from some few thousand animals, the animal that was believed to have been the best of the bunch was selected and purchased by a fellow visitor for a five-pound note. Prices, however, are different in England, where the Kerry is much superior. The Kerry is black, or black with a little white. She is low in stature, but rather lengthy and deep in body, yet she is as graceful as she is gentle in disposition. The head is well formed, and the horns symmetrically curved. The properties of the breed adapt it to the requirements of private owners, as it will supply sufficient milk for a household, and yet the Kerry is not a butter cow of high order, for the milk, although fairly rich, does not produce butter of the finest type as regards texture, colour, and flavour when compared with the Jersey or the Guernsey.

The cow Babraham Belle has produced about 1,100 gallons of milk per annum; while at the Derby Royal Show, Lady Greenall's Walton Joyous, 4 years old, gave 47 lb. 14 oz. of milk in 24 hours.

In 1902, the only year in which the London competition has been normal, few cows having been entered, two Kerries, averaging 46½ days in milk gave per cow 1·7½ lb. of butter, each lb. being obtained from 21½ lb. of milk.

5 DEXTER COW

The Dexter. The Dexter [5] has no counterpart among any British breed as regards either size or form. It is wholly black or red; a little white on the udder, along the inside of the flank, or underside of the belly, or on the tassel of the tail is allowable. The head is broad and short, tapering to the muzzle, which is large; the neck is short, deep, and thick, the shoulders wide apart, the hips wide, the quarters deep and well sprung; the body well ribbed, the under loin straight and the udder placed well forward, showing breadth behind, the teats being well placed and of medium size. The legs are short and strong, and the body is as close to the ground as possible. The horns are short and moderately thick, having an inward and slightly upward curve. The skin is soft and mellow, but not too thin, while the hair is fine, abundant, and silky. The bulls should not exceed 900 lb. in weight, and the cows 800 lb. The real origin of the Dexter is not known, but it is believed to be the result of breeding from specially selected Kerries. Mr. Hordern, secretary of the English Kerry and Dexter Society, estimated the average yield of both Kerry and Dexter cows at 2½ gallons a day for heifers and 3½ gallons for cows, but we must regard these figures as applying to selected stock only.

The cow La Manche Beatrice, having calved in July, gave 4 gallons daily in October, this containing 4 per cent. of fat; Red Rose gave between December and September, 1,270 gallons of milk; and Mr. Robertson's Edna, 6 years old, 41 lb. 14 oz. in the Derby competition.

Management of the Cow. The student will find our general remarks on the Breeding and Management of Cattle on pages 2238–40. We have therefore confined ourselves to the special treatment to be pursued in connection with the milking breeds.

When a cow has been purchased she is in practical dairying, usually in milk or in calf, or both. If she be dry and pregnant, it should be possible to recognise the presence of the calf by pressing with the back of the index finger and the ball of the thumb rather low down in the abdomen below the hips on the right side. The fact of a cow being dry is presumptive evidence that she has been dried for calving, but the calf may be felt before drying off by an expert as early as the fifth and sixth month after service. A cow in season indicates the fact by her excitability, and by other signs which every stockman understands. The skilled are aware what course to pursue, but in the case of the unskilled we strongly urge that when it is intended to breed from a cow thought should be given to the matter before deciding by what bull she should be crossed. It is far more economical to employ a suitable bull of a deep milking strain, and to pay a guinea for service, than to use a nondescript bull without any payment whatever. In the ordinary way, a milking cow should be dried six weeks before she is due to calve. In drying a cow, the milker commences by omitting a daily milking for a few days, and then by omitting to milk altogether. Some cows continue, in spite of all precautions, to milk right up to calving, with the result that the fœtus is starved, and on its appearance is usually weak, fragile, and undersized. A week or two before calving—or when, owing to her breed or history, milk fever is anticipated—a cow of a fleshy breed should be scantily fed that her condition may be reduced. If she be turned out, a poor pasture will serve the purpose best, without any addition to her ration. If she is being stall-fed, cake and meal should be omitted, a light ration of hay alone being provided, and she should have plenty of exercise.

Calving. When calving is near the cow should be watched and kept untied night and day, either on a pasture or in a loose-box. Some farmers would milk her every night to prevent her calving before the morning, but this plan is not infallible. Sometimes, after calving, the "placenta," or after-birth, refuses to pass. This is a troublesome and sometimes dangerous affair. A drink may be obtained to help the animal, while to the exposed portion of the "cleansing" a thin cord should be attached with a light weight at the end that there may be gentle and continuous force exerted which will induce it to disattach itself. During the retention of the placenta, and to prevent poisoning by its decomposition within the animal's body, the passage should be daily disinfected with carbolic acid at the rate of 1 part to 50 of water. In some [illegible], where the attachment is slight, the after-birth may be gently removed, or torn away by the hand. Cleanliness, at all times important, is doubly so at this period. In all cases the after-birth should be buried.

It sometimes happens that after calving one of the teats of the udder is blocked, and refuses to pass milk. This is sometimes owing to a chill, sometimes to the carelessness of a milker before calving. It will need careful and gentle manipulation, and it may be necessary to strip it, or attempt to strip it, every couple of hours through the day in the effort to remove the material or cause of stoppage. The loss of a teat is serious, for if it does not actually involve the loss of a full quarter of the milk which the cow should give, it diminishes her saleable value. Should hand manipulation fail, the calf should be tried. In the ordinary way, a calf will succeed where man does not, suction being powerfully brought to bear. Should there be no good result from either course, a silver tube must be obtained, and after lubricating with oil, very carefully introduced into the duct of the teat. This will usually pass sufficiently far to enable the milk to flow, but the passage may close again unless the greatest possible care be exercised. Another trouble is the hardness of the udder, which may arise from one of various causes. Here, too, the calf's assistance is often important, and although it is the practice of many breeders to remove the calf at birth, and to feed it from the pail, it had better be left with its dam in such a case, that by its repeated sucking and punching, the udder may return to its normal condition. Failing the calf, hand rubbing with oil or goose grease is often found effectual, but in all cases the udder should be stripped of its milk every three or four hours.

Colostrum. The first milk drawn from a newly-calved cow is of much deeper colour than normal milk. It is known as *colostrum*, and is unquestionably valuable for the calf, upon which it acts medicinally. Colostrum is extremely rich in solid matter, especially casein and albumin. The solids may reach 25 to 28 per cent. against 13 in normal milk, while the casein and albumin may reach 15 to 20 per cent., against 4 per cent. in average milk.

Abortion, or slipping of the calf, is one of the accidents and misfortunes of the dairy herd. A cow purchased in the market or elsewhere may be infected, and if the fact be unknown, may remain with the herd in her new home, and infect the cows around her [see page 2623]. No trouble should be regarded as too great in a case of this kind, for abortion in the herd has often ruined a farmer. A cow which has aborted should be fed for the butcher, as there is some risk of infecting the bull, and through him the whole herd.

Breeding. Where a farmer breeds his own stock, he must decide at what age and under what conditions his heifers should be mated. A heifer which is undersized, raw, and still growing, had better wait until from 19 to 21 months, but large-framed beasts, which are practically mature enough for breeding, may undoubtedly be introduced to the bull at 18 months. A heifer should never be retained for breeding if she be unhealthy, or, indeed, if she be not robust. It is far wiser to feed her for the butcher. Much is accomplished by good feeding from birth, maturity is hastened, strength is imparted, and an animal may be brought into the dairy as a profitable servant at the age of 2¼ years instead of 2¾ years or later. There are too many who fail to feed well, and who allow their young stock to graze upon poor pastures in the belief that they are saving money by the practice. Ungenerous feeding is, however, uneconomical. In the case of the males of a herd, a young bull may prove unfertile from time to time owing to the scanty way in which he has been fed.

In the vast majority of cases cows calve in spring, but the farmer is able to control the period of calving in accordance with the value of the calf or of the milk. The cheesemaker requiring milk from April to September prefers the spring calving cow; the milk seller, who caters for winter prices, often prefers the autumn calver, that he may obtain a larger yield at a time when it returns him the most money. It is important, therefore, that where cows are to calve at given periods, the bull should be confined to a box and yard, and only used when the cows are in season and at the right date. Where the cows calve in spring labour is reduced together with the cost of feeding, for the herd, being on the pastures, are pretty much left to themselves. In winter, however, the milking cow is stall-fed, and this not only involves greater cost, but demands greater attention at the hands of both owner and men. As we shall see, however, some hand-feeding in summer is important, and, indeed, imperative.

Points a Purchaser Must Look for. It is important in purchasing a cow that no mistake should be made as to her value. There is no lesson in this matter which can compare with experience, but a few words will help even the experienced buyer. The animal [6] should be large for her breed, with a capacious belly, breadth across the hips, a straight back, depth of loin, width between the buttocks, fine shoulders and neck, a long, fine head, powerful muzzle, and fine shapely horns characteristic of her breed. A short, thick cow with a deep brisket, coarse head and neck, heavy shoulders, and great fleshy character should be rejected, especially if the udder be small and narrow. She should be healthy, quiet, gentle, chewing her cud when at rest—a very good sign of health; her horns clean and without many wrinkles, her teeth sound (both teeth and wrinkles on the horn indicate age), and provided with a well-formed large udder with a silky covering much shrunken after milking. The size of the udder is not an absolute guide to milking power, and therefore in purchasing from a private buyer on the farm it is wise to see selected cows milked morning and night, and to take the precaution not to inform the seller when a visit for the purpose will be made, or the animals may possibly be "stocked" for the purpose—*i.e.*, unmilked at the previous milking time. A good cow milks well to the last; nevertheless, a very heavy yield with one calf may be followed by a much lighter yield with the next, although later the return is almost certain to be good. There is no empirical method of selecting a good milker. The best judges are often deceived by appearances. A healthy cow has warm ears, a loose, mellow skin, horns warm at the base, and dew on her nose. Details as to teeth, with two diagrams, are to be found on page 2239. It should be noted that a cow always grazing pushes her teeth through more rapidly, whereas fed in the stall she has less use for her incisors, which may in consequence appear later.

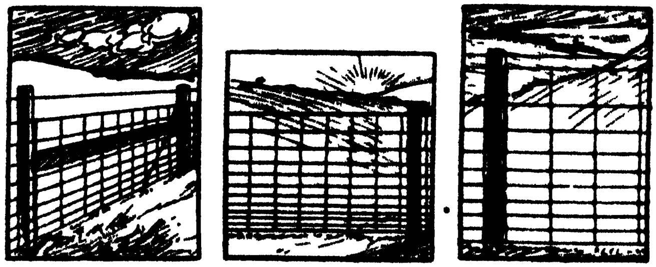
Care of Stock. Although the practice is most uncommon, cows should be daily groomed, scraped in winter, and washed, if necessary, to keep the flanks and buttocks clean. The average cow in winter is plastered with the manure on which she lies; this dries and cakes, and disfigures her, until she loses her coat, apart from which the practice is filthy, and contributes to the contamination of the milk. A cow which is never cleaned may be attacked by ringworm, and is almost invariably covered with parasites; her coat is the abode of dirt, and the milk she yields is daily tainted in consequence. Apart from grooming, the coat should be washed at least once a week with soap and water, to which a small quantity of carbolic acid has been added. One part in fifty will destroy parasitic life. Should ringworm appear in cow or calf, immediate and persevering attention should be given, few complaints being more obstinate. The edges of the crust of the growth may be removed a little at a time, and the whole daily rubbed with carbolic or mercurial ointment, which, however, fails to penetrate the crust itself.

The Byre. The buildings in which cows are stalled, milked, and fed vary in design. They have been described on page 2997.

The cows may be tied to the stalls in one of many ways. A common plan is to affix a vertical iron rod right and left with screws at each end to each partition. A chain is attached to this rod by a ring that it may slide from top to bottom, and thus each cow is fastened when the chain is passed around her neck to the partition next to which she stands, and is able to feed from the manger without too close contact with her neighbour. Food receptacles, however, whether manger or rack, are provided in numerous forms, and the remark equally applies to the various methods of changing the cows, especially in the United States, where they are in many cases most ingenious. An advantage of the firebrick manger is that if a tap be fixed at one end, and a pipe and plug at the other, the whole may be flushed out with water and cleaned, while, when necessary, it may be partially filled with water for the cows to drink. The walls of the cowhouse should be periodically lime-washed, and the floors disinfected daily; where the latter are made of burnt clay or firebrick, and grouted in cement, they should also be flushed with water. In winter the stalls may be littered with straw—oat straw is best, especially as a portion will be consumed by the cattle—with peat moss, or even with sawdust or shavings, if other materials be not obtainable, although the latter do not make the best or most desirable of beds.

It is essential that boxes should be provided for calving cows, calves, and sick cattle, all of which should be well lighted and ventilated, but kept free from draughts.

Storing and Preparing Cattle Fodder. A food store and mixing apartment where a number of cows are kept is required, and it is a good plan to construct this in the centre of the cattle building. The floor should be of concrete, and arranged so that the pulped roots, the chaff, the cake, and the meal or grains used may be close at hand ready for mixing in a heap morning and night. The mixture is usually allowed to remain heaped for twelve hours that it may ferment. Being thus warmed, it is either carried in tubs or baskets, a galvanised iron barrow, or a tramcar, direct to the cattle.



7. TYPICAL MODERN FENCES

Where many cows are kept the small steam or oil engine described on page 2999 may be used with advantage. There should be a loft or store overhead, and here the chaff-cutter may be fixed, the hay or straw being delivered from the outside of the building and the chaff as it is needed passed below through a trap-door in the floor. A belt attached to the shafting which drives the chaff-cutter will serve to drive the pulper and the corn mill; hence if a store for roots be conveniently placed into which they may be delivered by the carts from the field, and if the grain to be ground be stored in the loft, the food may be conveniently prepared and mixed as occasion requires.

When and How to Milk. Cows should be regularly milked, whatever the hours fixed may be; but it has been shown by experiment by milking at three periods—6.30 a.m. and 2.30 p.m., 6.30 a.m. and 4.30 p.m., and 6.30 a.m. and 6.30 p.m.—that although the yield was practically the same in each case, the mixture was richer when drawn at the first two periods. Except when milked twelve hours apart, or thereabouts, the milk of the evening is always richer than that of the morning. Milkers should be encouraged to milk with dry hands, otherwise the practice of dipping the fingers into the pail is regularly followed. The practice is not only disgusting, but contributes to the non-keeping power of the milk, which is thus contaminated. Cows may be trained to be milked in the fields—as in Holland, where they are frequently tied to posts, or in Normandy, where they stand quietly for the purpose. In each case the necessity for bringing the milk home is involved. The Dutchman brings it in his boat, the Norman dairymaid on her head, or in the panniers on the back of an ass.

When the milkers enter the cowhouse early on the winter's morning, the cows may be supplied with a little sweet hay or, if the owner prefers, with their morning's mixed ration. The udders are then cleansed, the milkers wash their hands, don their overalls, and draw the milk in pails which have been cleansed overnight and left in the air. After milking, and when the food has been consumed, the cows may be turned out either to grass and drink, or, when the weather is severe, for exercise and drink. After breakfast the men proceed to clean out the stalls, gutters, and houses, and then to prepare the ration for the following day. In summer the cows remain in the fields, but attention should be given to gates, fences [7], the water supply in ponds or streams, to possible gaps in hedges, and, where forage crops, such as vetches, rye grass, trifolium, clover, lucerne, cabbage, or maize are provided, to the cutting of the food and its conveyance either to the pastures where the cows are grazing, or to the mangers. It will usually be found essential to allow the forage mown in the morning to remain until the next day before it is supplied, that it may lose part of its moisture, otherwise hoven [see page 2623] may follow, especially when this form of feeding is commenced and when the food is young and succulent.

Necessity for Keeping Records. The system of recording the milk yield of each cow should be followed on every farm. There is no other method of ascertaining her intrinsic milk value. As the milk is drawn from each animal the pail should be placed upon a scale, the net weight ascertained, and marked on the record sheet on the wall. A glance at such a sheet daily will suffice to satisfy an owner, or to indicate when the yield suddenly falls off in a particular case, whether the cow be in season or suffering. The practice of measuring is misleading, and should never be followed; weight is the only certain factor, and, roughly, a gallon may be estimated as weighing 10 lb.

RENAISSANCE ART

Architecture and Sculpture of the Renaissance. The Work of Michelangelo, Donatello, Ghiberti, and Della Robbia. Other Great Renaissance Masters

HISTORY OF ART
continued from
page [illegible]

By P. G. KONODY

THE history of the early Renaissance is inseparably connected with the history of Florentine art. It is, indeed, difficult to follow the evolution of the revival in the three sister arts separately, since the giant minds of that period did not restrict their colossal activity to a single sphere, and mastered the terms of many arts. We have already seen how Giotto achieved greatness in painting, sculpture, and architecture. Others there were in the fifteenth and sixteenth centuries who were goldsmiths and sculptors and painters; there was no art that Michelangelo did not master, and Leonardo da Vinci combined the functions of military engineer, musician, poet, writer of scientific treatises, and stage manager of glorious spectacles with those of painter, sculptor, and architect. There was a constant interchange of ideas, and each art left its mark on the sister arts; each step forward in the one was reflected by the others.

The Renaissance House. In architecture, the ideal form of the private dwelling was the greatest achievement of the Renaissance, and of Filippo Brunelleschi (1377 to 1466) its creator. The Gothic house was a kind of miniature fortress, with a narrow, high street front, as few apertures as possible, and narrow, irregular passages, rooms, and winding stairs. With the growing wealth and luxury of Florence, and increased security of life, a new type of building had to be evolved, a palace that should express the new conditions, the wealth and power and taste of the merchant princes who ruled the city. Spaciousness, comfort, air and light were the primary considerations which led to the adoption of a wide street front, clearly articulated but not over-decorated, a spacious ground plan with only few storeys and suites of large well-lighted rooms. The beauty of the façade is based on noble proportions, on the relation of the massive "rustica" masonry—composed of rough-hewn blocks finished off only at the joints—to the window openings, which are generally divided by columns or mullions, and the classic cornice or attic.

The most striking feature of the Florentine palace is the handsome inner court surrounded by slender colonnades, which are sometimes arranged in two tiers. The charm of the façade lies in the play of light and shade of the strong southern sun on the roughly hewn masonry, the arches and pilasters of the windows, and the boldly jutting cornice. Brunelleschi's Pitti Palace [illegible], Michelozzo's Riccardi Palace, and the wonderfully impressive Palazzo Strozzi [68], the plan of which is, with little show of reason, attributed to the sculptor Benedetto da Majano, are the noblest instances of the Renaissance Palace, not only in Florence, but in the whole world. In Venice, the Palazzo Vendramin, graceful in form and resplendent in coloured marble casing, shows the adaptation of Venetian decorative devices to the style born in Florence, whilst, if we turn from secular to ecclesiastic architecture, in the façade of the Certosa di Pavia, begun in 1473 by Ambrogio Borgognone, with its wealth of marble incrustation, reliefs, niches, statues and medallions, the dignity of the style has given way to playful exuberance.

Churches. The great Cathedral of Florence, which had undergone many modifications in the two centuries of its building, received its imposing cupola by Brunelleschi, who thus solved a problem which had baulked the efforts of all his predecessors; but in spite of this dome it remains in its essential features a Gothic building. The churches of S. Lorenzo and S Spirito, and the graceful Pazzi Chapel, are the three most important Renaissance churches built by this master. Alberti, the designer of the façade of S Maria Novella, in Florence, and the inventor of the volutes masking on the exterior the junction of the nave and the lower aisles, went further than Brunelleschi in his adherence to the classic orders; he lacked the other master's inventive genius and sense of elegant proportions, and tried to make all architectural forms fit in with his favourite theories.

In the sixteenth century the powerful and liberal patronage of the Popes attracted the leading artists of the whole of Italy, and made Rome the centre of artistic activity. Here, on classic soil, architects were enabled to study the ruins of antiquity and to formulate their knowledge into a scientific system. True enough, the classic forms continued to be a mere outer garment which clothed the buildings that were adapted to modern requirements, but they were applied with better understanding of their functions, with increased sureness and purity. In the palaces the storeys were clearly divided by cornices, the windows framed by pilasters and surmounted by triangular or curved pediments of purely classic proportion. As regards the use of the "orders," the superimposed storeys led the eye from the heavier Doric, through the Ionic, to the graceful Corinthian. In church architecture the mighty dome, in conjunction with a barrel-vaulted nave, became the firmly established type of the later Renaissance.

Masters of the Renaissance. Bramante, who has left much of his early work in and around Milan, played in Rome the same part that Brunelleschi had played in Florence. He is the initiator of the second period, the first of the many builders who helped in the erection of St. Peter's, and the architect of the beautiful Cancelleria [67] and Giraud Palaces. The great Raphael's chief building is the Palazzo Pandolfini, in Florence, where the alternating triangular and semicircular pediments over the windows are introduced for the first time. Antonio da Sangallo, the builder of the Farnese Palace in Rome; Baldassare Peruzzi, the scene of whose captivity was Siena; Giulio Romano, who worked in Mantua; Sansovino, the designer of the library of S. Marco and of the Zecca, or Mint, in Venice, are among the leading masters of the late Renaissance which culminated in the work of Michelangelo. In his striving for a grand general effect, without much concern with detail, he introduced the germ of the lawlessness which set in after his death and led to the exaggerated forms of the Baroque style. The gigantic cupola of St. Peter's in Rome [66], and the Medici Chapel in Florence are his most famous architectural works.

67. THE CANCELLERIA PALACE, ROME

Sculpture. In sculpture, as in architecture, Florence was the centre of the early Renaissance, but chronologically a Sienese master, Jacopo della Quercia, stands between the Gothic Orcagna and the first great sculptor of the new epoch, Ghiberti. Though in many ways still addicted to Gothic mannerisms, Jacopo is, in his boldness of vision and vigorous treatment of the human form, a true child of the Renaissance, and stands nearer to Michelangelo than any of the intervening Florentines. Ghiberti's greatest work is the gates of the Baptistery in Florence [69*E*], of which Michelangelo said that they were worthy to be the gates of Paradise. In comparing them with Andrea Pisano's, one is immediately struck by the inimitable sense of beauty that pervades the later artist's work; the exquisite finish which betrays the goldsmith's training; the wonderful grouping of the figures in receding planes, and the corresponding variations in the relief treatment, from the foreground figures, which stand forth in their full roundness, to those in the far background, which are indicated by scarcely more than a few lines. In fact, Ghiberti was the first sculptor who made use of linear perspective in relief work, and his work is almost pictorial in character.

Alinari

68. THE STROZZI PALACE, FLORENCE

Greatest Sculptor of the Renaissance. Donatello is acknowledged to be the greatest, as he was the most productive, sculptor of the Renaissance. He lacked, perhaps, the pure sense of beauty of Ghiberti, but there is in his work something greater than formal beauty — the beauty of character, which renders the very harshness fascinating. Everything he wrought, in marble or in bronze, is full of expression and life, character and movement. [See 29, page 1511.] And his leaning towards extreme realism was tempered by his knowledge and love of the antique. He worked from the living model, but had before his mind's eye the masterpieces of classic art. This is especially apparent in his bronze "David" at the Bargello, in Florence [69*A*], the first nude bronze of modern times. There is nothing less than classic beauty in the graceful, well-balanced attitude and the well-shaped legs, whilst the thin, angular arms are copied from the living model. And yet the figure is quite homogeneous; it has the thrill of life, and in its very deviations from the classic ideal conveys the idea of the immature shepherd youth and giant-killer. And Donatello approached every successive task in the same objective spirit, dealt with each on its own merits, infused pulsing, throbbing life into cold stone or bronze. His "Gattamelata," in Padua [69*B*], is the first equestrian statue since classic times, and has never been surpassed in impressiveness and dignity save by Verrocchio's "Colleoni" [31, page 1674] in Venice. [See 69*F*.]

The third great master sculptor of the early Renaissance was Luca della Robbia, the founder of a whole dynasty of workers in glazed terra-cotta, and at the same time one of the leading sculptors in marble. Of all the early Renaissance sculptors, Luca was the one that came nearest to the Greek spirit of calm serenity, though in subject matter he was further from the antique than any of his contemporaries. Motherly love and tenderness

70. THE PITTI PALACE, FLORENCE *Alinari*

and happiness were his favourite themes, and have perhaps never found more beautiful expression in plastic art. Of his marble works the most famous is the singing gallery, in Florence [69*D*].

Donatello was followed by a whole school of great marble workers who devoted themselves chiefly to tomb monuments and portraiture. The tomb of the period was generally conceived in the form of a recumbent figure of the dead on a sarcophagus in a niche, the architectural setting being in perfect harmony with the purely sculptured part, and richly decorated. Desiderio da Settignano, Mino da Fiesole, Rossellino, Benedetto da Majano, and Pollajuolo must be mentioned among the leading masters of the fifteenth century. Verrocchio, who excelled in bronze work, and is the creator of the world's greatest equestrian statue—the Colleoni monument in Venice—has left comparatively few works, but exercised an enormous influence as a teacher. Leonardo de Vinci was one of his pupils, and the first suggestion of the enigmatic type of face, which is always associated with Leonardo's work, can be found in Verrocchio's bronze "David" at the Bargello, in Florence.

Michelangelo. Sixteenth century sculpture is overtowered by the mighty genius of Michelangelo, whose work is the embodiment of the highest ideals of the late Renaissance. To the close of his earlier period belongs his colossal "David," that wonderful figure of a youthful well-proportioned giant, which the master chiselled out of a spoilt block of marble.

In his later work Michelangelo to a certain extent broke away from the Greek ideal, as he had broken away from everything that had gone before him, to find an adequate expression for his passionate spirit. As a poet for the sake of emphasis is allowed to change the natural proportion of speech, so Michelangelo in sculpture departed from strict truth to nature, exaggerating certain actions or muscles or limbs, for the sake of accent and increased impressiveness. At the same time he knew, like no other master, how to vary the texture of the surface to secure the desired effects of light and shade. The tombs of Lorenzo [69*C*] and Giuliano de Medici, with the attendant figures of "Night and Day," "Dawn and Twilight," mark the height of his achievement.

Between the early Renaissance and Michelangelo stands Andrea Sansovino, the creator of the Cardinal Sforza tomb at S. Maria del Popolo, in Rome, a monument which shows Andrea's complete mastery of classic forms, though the sarcophagus with the recumbent figure is overwhelmed by the architectural setting and subsidiary figures. His pupil, Jacopo Sansovino, has left many beautiful works in Venice. Of the other masters of the period only Giovanni da Bologna and Benvenuto Cellini did not succumb to the influence of Michelangelo, which proved baneful to all others who succeeded him, and contented themselves with turning his style into mannerism by absurd exaggeration of distorted proportions. Baccio Bandinelli is the typical sculptor of this period of decline.

Giovanni da Bologna's bronze "Mercury," with its fine expression of swift upward movement and its brilliant adaptation of the modelling to the material, is the work by which this master will be best remembered, whilst Benvenuto Cellini, the sculptor goldsmith, whose chief fault was that he treated monumental sculpture in the spirit of the goldsmith, and his goldsmith work in that of the sculptor, has left the world the famous "Perseus" in the Loggia de' Lanzi, in Florence.

A special branch of sculpture, which reached its highest development in the early days of the Renaissance, is the art of the medallist. Vittore Pisano, who flourished in Northern Italy in the early fifteenth century, was the first great medallist, and remained unsurpassed.

FOREIGN BILLS AND EXCHANGES

Continued from page 2571

Consignments Inward and Outward. Mutual Indebtedness of Countries. Par and Course of Exchange. Gold Movements. Bill Market

By J. F. G. PRICE

IT is now more than three years since the attention of the people in the United Kingdom was particularly drawn to the whole question of our trade with foreign countries. This is not the place in which to enter into a discussion of the merits of the two fiscal systems which for some time were argued by leading men on both sides, but if the raising of the subject has had the effect of making our manufacturers and merchants alive to some of the defects in their methods of conducting their foreign trade a great deal will have been accomplished.

Imports and Exports. The importance of the subject is not likely to be underestimated, but it may be mentioned that in 1905 our foreign trade amounted to £973,000,000, of which £565,000,000 represented imports and £408,000,000 exports. The difference in value between the imports and exports is known as the balance of trade, and it was formerly held that in order that a country should be in a prosperous condition the exports should always exceed the imports. This idea no longer holds the field in its original shape, attention being now directed more to the nature of the articles making up the total than to the totals themselves—*i.e.*, whether they consist of raw or manufactured goods. Considerations of space forbid a lengthy explanation of the methods of conducting the foreign trade of the country generally, and our purpose here is to deal with the matter from the view of accounts.

There are three principal methods of selling goods—*viz.*, direct, at auction, and on commission. The method with which we shall now deal is the one last mentioned, since the first has already been the subject of our various examples hitherto, and the second is really covered by the others. Most of the goods exported by our merchants are in execution of orders received from abroad—*i.e.*, they are sold before they leave this country; but other transactions are entered into where no sale has taken place before the goods are exported, and where the object in sending them is to endeavour to find a buyer in the place to which they are sent. The goods are despatched to an agent in the town or country in which the merchant hopes to find a market for them, arrangements having first been made with the agent as to the terms upon which he will act. These terms are generally reimbursement of his out-of-pocket expenses, and a commission by way of a percentage upon the selling price of the goods.

Consignments Outward. The goods sent out by a merchant in this manner are termed in his books a *consignment outward*, while the same goods are referred to in the books of the agent who receives them as a *consignment inward*. The merchant, who is known as the *consignor*, keeps an account in his books of the cost of the consignment, both as regards the price of the goods and the expenses incurred. He does this because he desires to know the outcome of each consignment, whether it results in a profit or a loss, so that he can form an opinion whether it would be advisable to send further consignments to the same place or to the same agent. When a large consignment business is done a special book is kept in which to record all goods sent out in this way. The book is treated in the same manner as a sales book, the entries in it being posted periodically to the ledger. When there is only an occasional transaction of the kind the entry can be passed through the journal, debiting the consignment account and crediting goods account.

Consignment Accounts. A ledger account is required for each consignment, to record the separate results as well as the net result of the whole. The consignments are, therefore, numbered or given distinguishing titles according to either the place to which they are sent or the consignee's name. If accounts of consignments outward are distinguished by the names of the consignees it must be borne in mind that they are merely subsidiary goods accounts and not personal accounts upon which the consignees are liable. The first entry on the account is on the debit side, and consists of the price of the goods. As payments are made in connection with the consignment, the account is debited and cash credited. Any liability incurred in connection with it is debited to the account and credited to the person or firm to whom the amount of the liability is due.

A *pro forma* invoice is made out and sent to the agent, with instructions as to the minimum price at which he is to sell. If he is successful in his efforts and disposes of the consignment, he prepares and forwards to the consignor a statement called an *Account Sales*. This shows the gross amount realised, details of his expenses and commission, and the net amount due to the consignor. This amount he remits to him in the manner dealt with later.

The consignor enters the amount of the net proceeds as shown by the account sales on the credit side of the consignment account, the balance on which will then represent his profit or loss on the venture. The reason for this is that the total cost, both in goods and expenses, will appear on the debit side, and the net amount realised on the other. The difference is, naturally, the gain or loss.

The consignee terms the goods a *consignment inward*. If he acts as agent for a number of merchants, or has many consignments from one merchant, he keeps a special book in which he records particulars of all goods so received. This record will usually be merely a memorandum, and no entry will be made in a book of account upon the receipt of the consignment. The reason for this is that the goods do not, on the one hand, belong to the consignee, and therefore cannot be debited to the goods account; while, on the other, the consignor is not his creditor for the value of the goods, since the consignee has not bought them and is not liable for the price. He is only responsible for their safe custody and for the proceeds if he effects a sale. If he is not successful in this he can return the goods. As a rule, then, no account is opened by a consignee when he receives goods on consignment, but as soon as he pays anything or incurs any liability in respect of it he records the fact in his account books. He does this by opening an account in his ledger in the name of the consignor (not a consignment account, but a personal account), and debits the amount paid or the liability incurred. The reason for this is that the amount is due from a definite person, and he naturally debits that person and not an impersonal account. At the same time, he credits cash or the person to whom the amount is due.

When a sale is effected the consignee debits the person to whom the goods have been sold and credits the consignor, because the amount then becomes due to the latter, subject to the payments or charges which may have been made on his account. The consignee then calculates his commission and debits the amount to the consignor, who, of course, is liable to pay it. The balance on the consignor's account will then represent the amount due to him, since he has been debited on one side with all payments made or expenses incurred on his behalf and with the agreed commission, while he has been credited, on the other side, with the gross proceeds of the goods. The consignee then remits the balance due, usually by a bill of exchange, and the method by which he does so is explained later. When the purchaser of the goods pays for them, cash is, of course, debited and the payer credited. This will close the transaction in the consignee's books.

For the purpose of making the course and result of the operations clear to the mind of the student, a series of transactions will be dealt with and the ledger accounts shown in the books of both the consignor and the consignee. W. Brown, of London, ships to J. Bonhomme, of Bordeaux, ten bales of 400 yards each of cotton goods at 8d. per yd. and pays £15 for freight, £2 13s. 4d. for insurance, and £6 5s. 3d. for cartage and miscellaneous charges. Bonhomme receives the goods, and pays £3 for storage, £1 for insurance, £10 for Customs duties and landing charges, and £3 for miscellaneous expenses. He sells four bales at 1s. per yd., and the other six at 1s. 0½d. per yd. His commission is 2½ per cent. on the proceeds. Bonhomme's payments and transactions, taking place in Bordeaux, will naturally be in French currency, but for the sake of simplicity they are given in the accounts in sterling.

They are, however, for the guidance of the student shown in the account sales on the next page in French currency just as they would appear in the statement as rendered by Bonhomme It will be observed that the balance shown by account sales to be due to W. Brown is stated therein both in French currency and in its British equivalent

The following would be the accounts in the two ledgers:

Foreign Exchanges. The words relating to the payment of the balance due to the consignor, as shown on the account sales, brings us to the general question of the foreign exchanges. The consignee, being a Frenchman, naturally keeps his books in the currency of his own country, and renders accounts to his English consignor in the same way, merely remitting the ultimate balance due in English money. We have now to inquire how he does this, and how he arrives at £182 17s. 6d. as being a fair equivalent of 4,608 fr. 45 c. He could, no doubt, have purchased English gold and silver coins to the amount he has to remit, but obviously this would be a clumsy and costly method of discharging the liability, and is no more adopted in practice between foreign countries and England than it is between two towns in the same country.

The remittance, as stated in the account sales, is made by a bill of exchange, and the bill is obtained by the consignee finding somebody in Bordeaux who has a debt due to him from a person in England and purchasing the right to receive payment of such debt. Let us take a simple illustration to see how this is brought about, and how the indebtedness of two persons to two others, on perhaps many transactions, can be settled by one payment. A in Bordeaux buys goods from B in London, while C in London buys goods from D in Bordeaux. We will assume that the amount is the same in both cases. D draws a bill upon C for the amount the latter owes him. A becomes aware of this and buys the bill from D for its fair equivalent in French money. Having obtained the bill he sends it to B in London, who presents it to C, and in due course receives payment from him.

Par of Exchange. We now come to the question of what is a fair amount in French money to pay for a given amount of English money. To obtain the answer we must know the state of the currency of each country, what is its standard coin and of what metal it is composed. In England, of course, the standard coin is the gold sovereign. It contains a certain quantity of alloy for hardening purposes, the proportion of pure gold in the sovereign being eleven parts in twelve. In France the standard coin is the franc, but as this is a silver coin the value of French money as compared with English is measured by the 20-franc piece, which is of gold. The fineness of this coin—*i.e.*, the proportion of pure gold in it, is nine parts out of ten. There is thus a small difference in favour of the English currency in the proportion of pure gold in the coins of the two countries; and although it is trifling in one coin it becomes of great importance when large amounts are involved, and has to be taken into account when stating the quantity of French coins which are required to make up the value of the English sovereign.

A further point which has to be taken into consideration in fixing the relative values is the difference in the weight of the sovereign and of the 20-franc piece. The sovereign weighs 123·27 gr., the 20-franc piece 99·56 gr. Obviously, then, we shall require more than 20 francs for one sovereign, and after taking both weight and fineness into consideration, it is found that the English pound is equal to 25·2215 francs, or, roughly, 25 fr. 22 c. This is known as the *par of exchange* between France and England, and is the basis upon which settlements of account between the two countries take place.

But although it is the basis, there are many considerations which help to raise or lower the rate. Owing to the very considerable trade between England and France, there are always thousands of debts outstanding between the traders in the two countries which have to be settled in some way. This mutual indebtedness is made the means of satisfying the claims on both sides without any coin passing to and fro. Of course, it happens that gold is imported from or exported to France as well as other countries, but the quantity bears no relation to the volume of trade between those countries and England. There being, thus, many people in England indebted to others in France, while there are people in France indebted to others in England, it is clear that if a transfer of the debts could be arranged so that the English debtors could pay the English creditors, while the French liabilities were discharged in a similar manner, an immense saving of trouble and expense would be brought about, while the claims on both sides would be satisfied. This

Bordeaux, 1st September, 1905
Jean Bonhomme
Bill at 3 months herewith @ 25.20 = £182 17 6

The consignee terms the goods a *consignment inward*. If he acts as agent for a number of merchants, or has many consignments from one merchant, he keeps a special book in which he records particulars of all goods so received. This record will usually be merely a memorandum, and no entry will be made in a book of account upon the receipt of the consignment. The reason for this is that the goods do not, on the one hand, belong to the consignee, and therefore cannot be debited to the goods account; while, on the other, the consignor is not his creditor for the value of the goods, since the consignee has not bought them and is not liable for the price. He is only responsible for their safe custody and for the proceeds if he effects a sale. If he is not successful in this he can return the goods. As a rule, then, no account is opened by a consignee when he receives goods on consignment, but as soon as he pays anything or incurs any liability in respect of it he records the fact in his account books. He does this by opening an account in his ledger in the name of the consignor (not a consignment account, but a personal account), and debits the amount paid or the liability incurred. The reason for this is that the amount is due from a definite person, and he naturally debits that person and not an impersonal account. At the same time, he credits cash or the person to whom the amount is due.

When a sale is effected the consignee debits the person to whom the goods have been sold and credits the consignor, because the amount then becomes due to the latter, subject to the payments or charges which may have been made on his account. The consignee then calculates his commission and debits the amount to the consignor, who, of course, is liable to pay it. The balance on the consignor's account will then represent the amount due to him, since he has been debited on one side with all payments made or expenses incurred on his behalf and with the agreed commission, while he has been credited, on the other side, with the gross proceeds of the goods. The consignee then remits the balance due, usually by a bill of exchange, and the method by which he does so is explained later. When the purchaser of the goods pays for them, cash is, of course, debited and the payer credited. This will close the transaction in the consignee's books.

For the purpose of making the course and result of the operations clear to the mind of the student, a series of transactions will be dealt with and the ledger accounts shown in the books of both the consignor and the consignee. W. Brown, of London, ships to J. Bonhomme, of Bordeaux, ten bales of 400 yards each of cotton goods at 8d. per yd. and pays £15 for freight, £2 13s. 4d. for insurance, and £6 5s. 3d. for cartage and miscellaneous charges. Bonhomme receives the goods, and pays £3 for storage, £1 for insurance, £10 for Customs duties and landing charges, and £3 for miscellaneous expenses. He sells four bales at 1s. per yd., and the other six at 1s. 0½d. per yd. His commission is 2½ per cent. on the proceeds. Bonhomme's payments and transactions, taking place in Bordeaux, will naturally be in French currency, but for the sake of simplicity they are given in the accounts in sterling.

They are, however, for the guidance of the student shown in the account sales on the next page in French currency just as they would appear in the statement as rendered by Bonhomme. It will be observed that the balance shown by account sales to be due to W. Brown is stated therein both in French currency and in its British equivalent.

The following would be the accounts in the two ledgers:

Foreign Exchanges. The words relating to the payment of the balance due to the consignor, as shown on the account sales, brings us to the general question of the foreign exchanges. The consignee, being a Frenchman, naturally keeps his books in the currency of his own country, and renders accounts to his English consignor in the same way, merely remitting the ultimate balance due in English money. We have now to inquire how he does this, and how he arrives at £182 17s. 6d. as being a fair equivalent of 4,608 fr. 45 c. He could, no doubt, have purchased English gold and silver coins to the amount he has to remit, but obviously this would be a clumsy and costly method of discharging the liability, and is no more adopted in practice between foreign countries and England than it is between two towns in the same country.

The remittance, as stated in the account sales, is made by a bill of exchange, and the bill is obtained by the consignee finding somebody in Bordeaux who has a debt due to him from a person in England and purchasing the right to receive payment of such debt. Let us take a simple illustration to see how this is brought about, and how the indebtedness of two persons to two others, on perhaps many transactions, can be settled by one payment. A in Bordeaux buys goods from B in London, while C in London buys goods from D in Bordeaux. We will assume that the amount is the same in both cases. D draws a bill upon C for the amount the latter owes him. A becomes aware of this and buys the bill from D for its fair equivalent in French money. Having obtained the bill he sends it to B in London, who presents it to C, and in due course receives payment from him.

Par of Exchange. We now come to the question of what is a fair amount in French money to pay for a given amount of English money. To obtain the answer we must know the state of the currency of each country, what is its standard coin and of what metal it is composed. In England, of course, the standard coin is the gold sovereign. It contains a certain quantity of alloy for hardening purposes, the proportion of pure gold in the sovereign being eleven parts in twelve. In France the standard coin is the franc, but as this is a silver coin the value of French money as compared with English is measured by the 20-franc piece, which is of gold. The fineness of this coin—*i.e.*, the proportion of pure gold in it, is nine parts out of ten. There is thus a small difference in favour of the English currency in the proportion of pure gold in the coins of the two countries; and although it is trifling in one coin it becomes of great importance when large amounts are involved, and has to be taken into account when stating the quantity of French coins which are required to make up the value of the English sovereign.

A further point which has to be taken into consideration in fixing the relative values is the difference in the weight of the sovereign and of the 20-franc piece. The sovereign weighs 123·27 gr., the 20-franc piece 99·56 gr. Obviously, then, we shall require more than 20 francs for one sovereign, and after taking both weight and fineness into consideration, it is found that the English pound is equal to 25·2215 francs, or, roughly, 25 fr. 22 c. This is known as the *par of exchange* between France and England, and is the basis upon which settlements of account between the two countries take place.

But although it is the basis, there are many considerations which help to raise or lower the rate. Owing to the very considerable trade between England and France, there are always thousands of debts outstanding between the traders in the two countries which have to be settled in some way. This mutual indebtedness is made the means of satisfying the claims on both sides without any coin passing to and fro. Of course, it happens that gold is imported from or exported to France as well as other countries, but the quantity bears no relation to the volume of trade between those countries and England. There being, thus, many people in England indebted to others in France, while there are people in France indebted to others in England, it is clear that if a transfer of the debts could be arranged so that the English debtors could pay the English creditors, while the French liabilities were discharged in a similar manner, an immense saving of trouble and expense would be brought about, while the claims on both sides would be satisfied. Bordeaux, 1st September, 1905

Jean Bonhomme

Bill at 3 months herewith @ 25.20 = £182 17 6 is, in effect, exactly what takes place, and the means by which it is effected are bills of exchange.

Foreign Bills. For practical purposes foreign bills of exchange are treated as a commodity, and there is a regular market in them as in other articles of commerce. The dealers in this market are known as *bill brokers*, and they make it their business to buy and sell bills drawn on persons in this country by creditors in other countries, and vice versâ. If, therefore, a person in London desires to satisfy a debt to another in Paris or Berlin, he approaches a bill broker and ascertains the price he will have to pay for a bill for the amount he requires. The principal bill brokers, bankers, and merchants meet twice a week at the Royal Exchange and fix the rates for bills on the various countries. The basis of the rate is, as stated above, the par of exchange; but there are many causes operating to affect the market rate. The principal of these is the condition of trade between the two countries. If there is, on balance, a considerable indebtedness from England to another country, there will necessarily be a strong demand in London for bills payable in that country, and the prices of bills of exchange, like those of other commodities, are affected by the laws of supply and demand. The result will be that the English trader will have to pay a premium for the bill he requires, but the premium will be stated in such a way as to somewhat confuse the student in the absence of explanation.

The par of exchange between London and Paris is, as stated above, 25 fr. 22 c. for £1. The rate is said to be above par in London when the exchange is quoted below 25·22, the reason being that in exchange for a sovereign it will be possible to obtain only, say, 25 fr. 15 c., and thus, to discharge an indebtedness in French money a higher price than the actual mint value will have to be paid in English currency.

Gold Points. But there are certain points above or below which the rates with other countries do not rise or fall. These are known as the *gold points*, and indicate the rates at which it would be more profitable to import or export gold coin or bullion to discharge debts rather than buy bills at prices outside those limits. The gold points depend upon the cost of transmitting the gold, plus insurance and other expenses, and the margin, therefore, varies according to distance and other circumstances. In the case of London and Paris, the point at which it would pay to export gold to France is 25·12½—*i.e.*, if it were found that the price of bills was 25 fr. 10 c. a merchant could send bullion cheaper than he could obtain bills. The importing point is 25 fr. 33 c., so that a merchant in Paris would send gold to England if bills on London were above that rate. Although these are theoretically the points of gold movements, it might not follow that gold would be transferred if the rates of exchange exceeded these limits, for the cost of transmission fluctuates slightly, and might do so sufficiently to prevent shipment.

Foreign Bill Procedure. The procedure with regard to foreign bills of exchange differs from that in the case of inland bills. The form of the bill is different, and, as a rule, the wording is as follows:

London, 1*st July*, 1906.

Exchange for Fcs. 7,550.

STAMP
1/6

At three months after sight of this first of exchange (second and third unpaid) pay to the order of M. Jules Perier seven thousand five hundred and fifty francs and place same to our account as advised.

Williams, Jenkins & Co.

M. F. Chardenal, Marseilles.

Foreign bills are drawn in the currency of the country of the drawee, and are prepared in sets of three. The three parts are in identical terms, except that each is expressed to be payable only in the event of the others being unpaid. The chief reason for drawing the bills in sets was originally with a view to their reaching their destination safely, and that is one reason why they are still so drawn. Another reason is the facility which the method affords for negotiating the bill. The drawer, a merchant carrying on business, say, in Bombay, draws on his debtor in London, and sends over two parts of the bill for acceptance by different mails. He keeps the third, and if he finds subsequently that it would be of advantage to him to have cash immediately, he takes the bill to his banker, and discounts it with him, endorsing it in the usual way. The banker then sends the endorsed part, which, of course, has not been accepted, to his agent in London, who obtains one of the other parts from the drawee duly accepted. The accepted and endorsed parts then form a complete bill, and will be collected when due. The drawee must be careful not to accept more than one part, for if he should do so, and both accepted parts got into the hands of holders for value, he would have to pay both.

Frequently when a creditor in one country draws on his debtor in another, he sells the bill as soon as it is drawn, and the name then inserted in the body of the bill as the payee is that of the person who buys it—generally a banker or bill broker. It will be perceived from this that foreign bills are sold or discounted by the drawers before they have been accepted. This is what actually takes place in many cases, and bills frequently pass through several hands before they are presented to the drawee for acceptance.

Acceptance for Honour. In order to guard against the risk of the drawee refusing to accept the bill when it is presented to him for that purpose, the drawer or any subsequent holder may write on the bill, "In case of need with Blank & Co." This means that in case of the bill being dishonoured owing to its not being accepted by the drawee, the firm named will accept the bill to protect the honour of the drawer or subsequent holder as the case may be. Before they will do so, however, a form has to be gone through, known as *protesting the bill*. This consists in the bill being formally presented for acceptance by an officer known as a Notary Public, who afterwards makes a declaration in a stated form that he has done so. When a bill is accepted in this way it is known as an *acceptance for honour*.

The banker, or bill broker, who buys a bill from the drawer treats it as part of his stock-in-trade, and either holds it until maturity, or sells it before it is due to somebody who wishes to pay money in the place where the bill is payable.

Payable After Sight. It will be observed that the bill set out on last page directs payment three months *after sight*. This means that the time mentioned in the bill will not begin to run until it has been accepted or sighted by the drawee. Foreign bills are frequently drawn after sight rather than after date, owing to the time which elapses before the drawee receives them for acceptance. When this is the case the bill is presented for acceptance as soon as possible after it is drawn, and the date it is accepted is included in the form of acceptance.

To return to the transaction out of which this short explanation of the principles of foreign exchanges and bills arose. We know that the course M. Bonhomme would take would be to buy from his banker in Bordeaux a bill on London for the amount he has to remit, the price being calculated at the rate of the day. Having obtained it, he sends it to Mr. Brown, who will probably have to first obtain acceptance of it, and then either hold it till it matures or else at once discount it.

Bank Drafts. Another method of making remittances abroad is to purchase a bank draft, which is an order by a banker upon an agent or a branch for the payment of a stated sum of money to the person named in the draft. The drafts can be made payable either at once or at a future time, but in practice they are nearly always sight drafts—*i.e.*, payable at sight or on demand in just the same way as a cheque. They are largely used when remittances of cash have to be made between countries.

English houses which are doing a large business with a manufacturer or merchant in a foreign country will frequently receive the invoices of the goods they buy made out in the currency of the country. The indebtedness will, of course, have to be discharged to the full amount of the invoices. When invoices are received in this form it is necessary for the English house to keep the account with the foreign merchant in both sterling and the foreign currency, the former in order to bring the transactions into line with the other accounts of the business, the latter to know exactly how they stand with the creditor. The method adopted is to fix a rate of exchange at which all invoices received are converted into sterling, the amounts being shown side by side in the ledger accounts. When remittances are made, drafts in the foreign currency are purchased at the rate of exchange of the day, and the cost in sterling and the amount of the draft are entered side by side on the debit side of the account. Finally, a draft is remitted for the difference shown by the currency columns, which will then exactly balance. This result will, however, probably not be obtained in the sterling columns, owing to the varying rates at which the drafts have been purchased. The difference on this column is treated as a profit or loss on exchange, and is carried away to the profit and loss account. The account given on this page shows the working of this method.

Dr. JONATHAN & CO., BALTIMORE Cr.

Date	Particulars	Fo.	$ c.	£ s. d.	Date	Particulars	Fo.	$ c.	£ s. d.
					1906				
Jan. 8	To Cash @ 49½	65	250 00	51 11 3	Jan. 1	By Goods ..	41	250 26	52 2 8
„ 31	„ „ @ 49⅝	75	150 00	31 0 4	„ 28	„ „ ..	63	180 48	37 12 1

	„ Gain on Exchange .			1 7 11	„ 18	„ „ ..	130	120 50	25 2 1
			957 00	£199 7 5				957 00	199 7 5

The fixed rate adopted in this instance for converting the dollar into English money is 50d. per dollar, and the invoices are posted in both currencies, as shown above. Remittances of bank drafts on Baltimore were made on January 8th and 31st, and on February 28th, the drafts being purchased at different rates, as quoted in the account. After making these remittances, there was a balance of 257 dollars due to the American firm, the cost of a draft for which was £53 4s. 2d. The invoices having been converted at a different rate from those at which the drafts were purchased, there is naturally a difference between the sterling columns. This, as stated above, is transferred to the profit and loss account, and if there are many accounts with such differences on them, a special exchange account is opened, and the balance thereof transferred to the profit and loss account at the periodical balancing of the books.

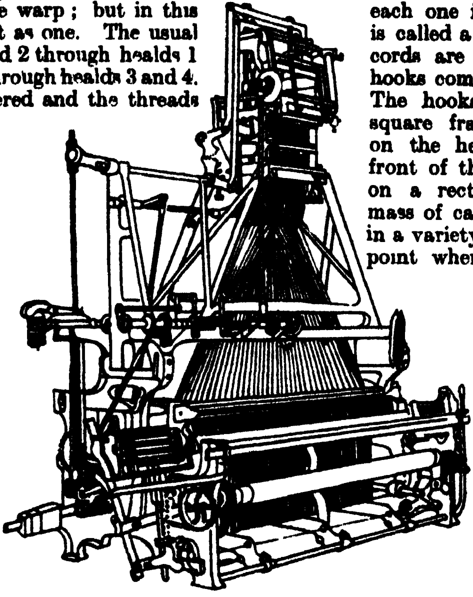
THE FUNCTION OF THE LOOM

Different Methods of Controlling Warp: Healds, the Jacquard, the Tappet, and the Dobby. Loose Reeds. Shuttles; Rising and Circular Shuttle-boxes

By W. S. MURPHY

HAVING viewed the general structure of the loom, we now turn to the various parts with which the weaver manipulates the warp and weft.

The *healds* are those horizontal frames which carry the warp between them and form the *shed*, or opening for the passage of the weft shuttle. For convenience, healds are sometimes called *leaves*. A plain web requires only two leaves, because the one half of the warp crosses the other in regular sequence. When we consider the putting-in of the web, the drawing-in of the threads will be reviewed. For our present purpose we take the loom as ready to work. Many plain looms are equipped with four healds, to lighten the weight of the warp; but in this case, the pairs of healds act as one. The usual way is to put threads 1 and 2 through healds 1 and 2, and threads 3 and 4 through healds 3 and 4. Sometimes the order is altered and the threads are healded 1 and 3 and 2 and 4; but the variation in the order does not matter very much, except for special reasons. It is very different, however, when twills are to be woven. Say that we have a four-end twill to put on the loom, then we require four healds to divide up the warp, because the four sections of the warp act differently. The rule is that every thread in each heald must act in precisely the same way throughout the whole web. Four ends may be easily followed; but when eight, ten, or twelve have to be dealt with, some complexity arises, which only studious care can prevent from causing confusion. It is obvious that the number of healds which a loom can carry is limited, and yet we desire to keep the bounds of our variations as wide as possible. By means of ingenious devices and patient labour, the hand loom weavers were able to produce marvellous varieties in colour and pattern; to them every fresh web was a new problem. But in the factory we cannot proceed upon lines so uncertain. Up till the advent of the Jacquard apparatus into this country, fancy weaving was done mostly on the hand loom; but that wonderful contrivance changed the situation entirely, and opened a career for the power loom far grander than ever the hand loom, with even the harness apparatus, could claim.



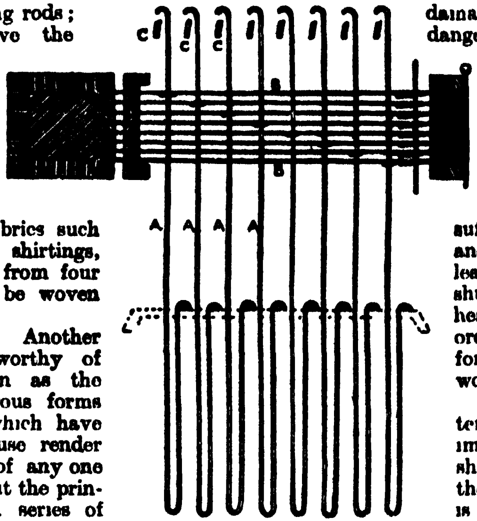
169. JACQUARD LOOM

Jacquard. This machine presents some difficulties to the learner at first; but, if taken in detail, and each part noted with care, the whole should appear plain. Looking at the jacquard loom [169] we see that over the face of the warp is spread a mesh of cords, which, at first sight, seem to baffle understanding; but these are simply the heald cords stretched out and applied in this way. As every heald cord holds its own particular thread, so these cords have eyelets which each hold a warp of thread. The cords converge, and each one is knotted on to what is called a neck cord. The neck cords are short, and loop round hooks coming down from above. The hooks extend up within a square frame seated above all on the head of the loom. In front of the frame and revolving on a rectangular cylinder is a mass of cards, pierced with holes in a variety of patterns. At the point where the cylinder brings a card in front of the frame is a board pierced through by a mass of needles, to the depth of a quarter of an inch. Now look inside the frame [170]. At the inner extremity of the projecting needles (B) is a box full of springs which allow the needles to give way to pressure, but send them back again as soon as the pressure is removed. In the middle the needles are joined to the hooks (A), which, as we have seen, are attached to the cords looped round the warp threads. On the heads of the hooks are other hooks, which curve into a series of bars called the *griffe* (C). As the loom works, this griffe moves down and up, like the treadles of a common loom. If all the hooks were left in place, the bars of the griffe would lift them up bodily, and so elevate every thread of the warp. We do not want anything of the sort. Governed by an action of its own, the cylinder brings round the cards to the needle board, and the cards press back those needles which have no perforations opposite to them. The needles, being pressed back, send the hooks to which they are joined out of the way of the griffe; the griffe, in its passage upwards, lifts only those hooks which the perforations of the cards have allowed to remain in position. These hooks pull up the corresponding warp threads, and the shed designed is made.

One needs little consideration to understand what a wonderful instrument the jacquard has placed in the designer's hands. By its means we can manipulate every individual thread in the warp in any way desired. The cards are pierced according to design, one perforation for every warp thread to be called up. Some designs require as many as 20,000 cards.

The Tappet. Other methods of manipulating the warp have been devised. One of the earliest and simplest was the *tappet* motion, consisting of treadles, tappets, jack-levers, square shafts, and half-moon levers The wheel-shaped tappets move on the treadles, the ends of which are connected with the jack levers by long rods; the jack-levers move the square shafts extending across the loom, and set in motion the half-moon levers, which, being connected by cords with the healds, perform the shedding motion. Fabrics such as doeskins, cotton shirtings, and twills, requiring from four to eight healds, can be woven very well by tappets.

The Dobby. Another shedding machine worthy of note is that known as the dobby. The numerous forms of this contrivance which have been brought into use render detailed description of any one almost needless But the principle is general. A series of pegs act on a set of blades, which perform the same office for the pairs of levers controlling the healds from above and below as the needles of the jacquard to the wires. When the peg puts a lever out of position, the heald is depressed; when the blade remains in position, the heald is elevated, and with it, of course, the warp it controls. A modification of the dobby is seen in the velveteen loom [171].



170. DIAGRAM OF JACQUARD

The Reed. Though nothing more than a series of flat wires set under the slay, the reed is not a simple instrument. In the plain loom we have no more to do than put two or three or more threads from the healds through between each pair of reed wires, or in each *dent*, as the opening between the wires are named. But the moment we begin to depart from the plainest of plain cloth our troubles with the reed begin. Take two twills for example. Say one flushes two ends and two picks alternately, and the other flushes three picks and three ends. If both were reeded the same, the former would be too thin, or the latter would be too thick. Reeds vary in closeness, some having 10 and others as many as 16 dents to the inch. Thickness of thread also has to be considered in reeding. All this is a matter of calculation, however, easily arrived at by arithmetic.

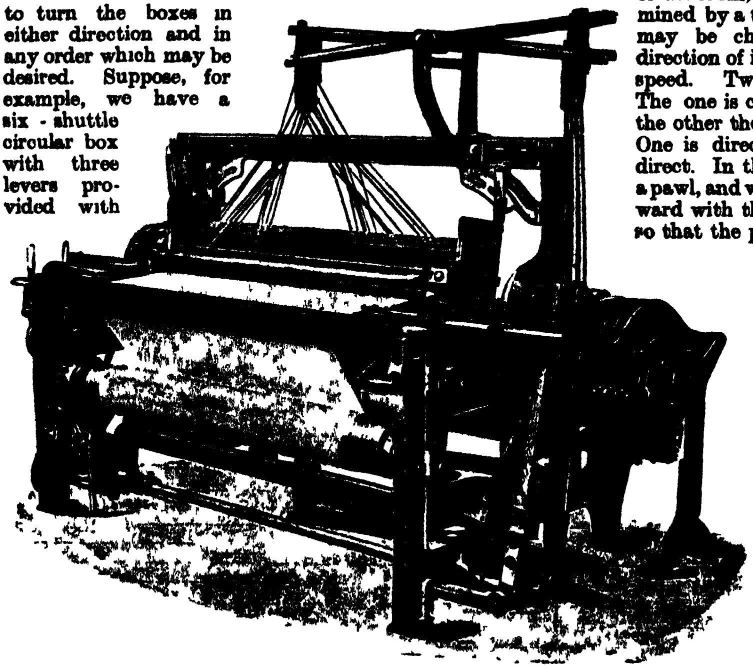
Searching for ways of carrying out novel designs, the designer has hit on a method of utilising the reed in the formation of crinkled cloths. Behind the reed, and timed to act at the moment when the reed is being thrown back, a series of little nippers comes up and grips on to a range of warp threads just for an instant, holding them back while their fellows go forward, thus putting a series of drawn threads through the fabric. Other small services are imposed on the reed, but these are of minor value.

Loose Reeds. Should the shuttle by any accident be turned from its course, and tangle in the warp, the coming of the reed will smash it through the warp and cause damage. To guard against this danger there have been several kinds of loose reed invented. The best is the simplest. Instead of fixing the reed solid in the slay, the lower side is held by a spring clasp, which tightens at the moment of the stroke of the slay just sufficient to give the stroke, and slackens so as to offer the least resistance possible to the shuttle at any other time. For heavy goods, however, the ordinary fixed reed is best; for light cloths the loose reed works very well.

Shuttles. Numerous attempts have been made to improve on the common fly-shuttle, but the form has, in the main, kept unchanged. It is true that the stiff wooden pirn, with its screw, has given place to the weft cop, with the consequent alteration in the method of securing it in the shuttle Some shuttles have a spring lid, others let the weft out from the centre of the cop; but most have merely a peg at the end, where the screw-pin used to be. The chief property of a shuttle is that it will let the weft come away easily and fly straight. In these essential qualities the old form of shuttle excels all others.

Shuttle-boxes. When the power loom came into general use, the first demand was for a shuttle-box which would change the shuttles automatically. Without the ability to change the shuttles swiftly, vari-coloured weaving was an impossibility. Kay the younger had already shown the way with his springing change shuttle-box, and subsequent inventors took the hint. Now we have two systems, or methods, for changing the shuttles. The one is by what are called *rising boxes*, the other is the *circular box*.

By means of springs adjustable to the requirement of the design, the shuttle-boxes sit one above the other, and change places with marvellous rapidity. Before beginning to weave, the plan of the rising boxes is arranged on the jacquard principle, so that each shuttle comes up in turn, as needed by the pattern. On fancy cloth and gauze looms, the six boxes are placed at both ends of the lay, the 12 shuttles affording special opportunity for fine weft effects. Circular shuttle-boxes move with less noise, and possess other points of merit. The shuttle-boxes are fixed round a centre, the revolving motion being conveyed through levers and cams acted on by the motions of the loom. When first introduced the circular boxes could be moved in one direction only, and in direct succession. By a rearrangement of the gearing we have been enabled to turn the boxes in either direction and in any order which may be desired. Suppose, for example, we have a six-shuttle circular box with three levers provided with forward and backward catches, each actuated by a cam of different size, so as to make the box turn one-sixth, one-third, or one-half of a revolution, we have the power to make the shuttles come up in any order we please. The rest of the mechanism is too intricate to be shown at present.



171 VELVETEEN LOOM

Letting Off and Taking On. We have now come to the extremities of the loom—the warp and the web beams. The relations between the two are very intimate, though they are as far apart as possible. The warp must be let off in such measure as the taking up of the cloth beam requires. Not only so, but it should keep the warp even and tension uniform. In their mutual relation, the cloth beam is the active and the warp beam the passive agent. It is the former which draws. The latter, therefore, needs little more than the means of holding back. As a rule, the warp beam is weighted, the weight being proportioned to the character of the cloth and various other circumstances which can hardly be defined in any theoretic way.

Cloth Beam. The management of the cloth beam is not so simple; it must be regulated in a stringent fashion. Consider how many different variations the cloth beam has to meet. We may want to spread the weft over a wide surface, varying the number of picks to the inch by 20 or more. Or it may be that the cloth is to be heavy with weft. Then the weft may be thin or thick, single or double. For every variation the cloth beam must have a certain rate of movement. This movement is derived from the action of the loom, and the rate is determined by a train of wheels which may be changed either in the direction of increase or decrease of speed. Two methods are used. The one is called the *positive* and the other the *non-positive* motion. One is direct and the other indirect. In the latter a lever with a pawl, and weighted, is driven forward with the motion of the slay, so that the pawl, or catch, pushes round the toothed wheel on the end of the cloth beam. According as the weight is light or heavy, the cloth beam yields less or more to the action of the slay. Here the thickness of the thread will have a strong influence on the movement of the cloth beam, because, the thicker the thread the harder the drive. In weaving woollens, or cloths in which the thickness of the weft threads vary, the non-positive motion is distinctly advantageous. For cloths in which the yarns are regular, the positive motion is to be preferred. The non-positive motion is merely a matter of adjusting the weight of the lever by a rough guess or the skill born of experience; the positive motion can be regulated according to scientific calculation. As we have said, the positive motion is carried through a train of wheels. The first of the train takes its motion from the loom, and the others are moved by it. If we vary the number of teeth on the wheels which are driven, we obtain a difference in the rate of speed. The value of each wheel is measured by the number of teeth to the circumference; by combining these values we get the speed at which the last wheel or the cloth beam is being driven.

FITTING, ERECTING, & ASSEMBLING

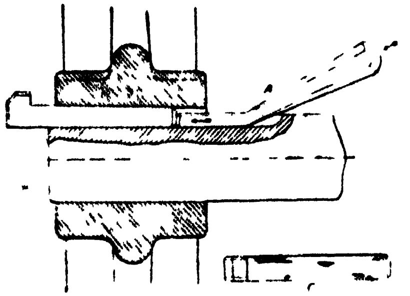
Approved Practice in Modern Fitting and Erecting Shops. Chipping and Filing, Erecting, Levelling, Hoisting, and Assembling

WORKSHOP PRACTICE
continued from page [illegible]

By JOSEPH G. HORNER

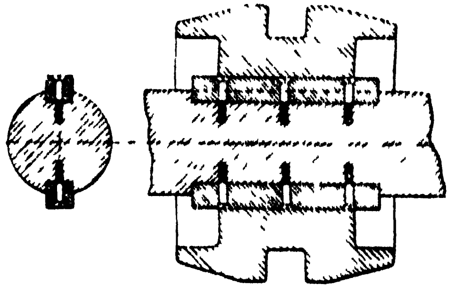
THE terms *fitting*, *erecting*, and *assembling* denote distinct departments of shop practice which follow the operations of the turnery and machine shop. In each the individual parts are built up into the relations which they have to occupy permanently. Fitting signifies the bringing together of certain sections only, as the parts of a cylinder, or the link motions, or the connecting rod ends, or a set of gears, etc., which have afterwards to be built into the complete engine or machine. Erecting and assembling both denote the latter operations—the final completion of a piece of mechanism all ready for service. But there is a most important distinction between the two. Erecting signifies the building up by means of mutual adjustments of connections by filing, scraping, reamering, by methods of trial and tentative settings. Assembling denotes the bringing together of parts without any corrections or adjustments, similar machined pieces being taken at random, and fitting at once into their place in any similar machine, being characteristic of the interchangeable system already alluded to in our study of the turnery and machine shop. These two methods have little in common Erecting is the older system, still unavoidable in massive constructions; assembling is the modern. The tendency is to the substitution of this latter system for the older in the manufacture of articles of small and medium dimensions. The economies secured thereby are enormous The system is indissolubly associated with that of gauging, and, therefore, methods of measurement are an essential feature of it—gauging involving absolute dimensions as distinguished from measurements involving mutual fitting and correction.

Fitting. Narrowed down to its strict meaning, this signifies the making of mutual contact between parts the nature of which contact varies. It may be that of plane or of curved surfaces. Fitting also may be tight or free. It may, further, be something very exact to dimensions or approximate only, fine fitting or coarse, and that of soft or of hardened surfaces. In the construction of mechanisms there is a wide field for all grades of workmanship.

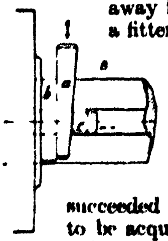


309. REMOVING A KEY

Chipping and Filing. In the older practice, chipping occupied a much larger place than it does in the present. It is a roughing down operation preliminary to filing, and is accomplished by cutting small chips by hammer blows directed on the head of the *cold* chisel. The chisel is doubly bevelled, and is made in different widths, ranging from ¼ in. in the *cross cut*, to ¾ in., or 1 in., in the *surfacing* chisel. The cuts are generally made to cross each other at various angles. If a large surface has to be done, the cross cut is used to form a series of grooves, leaving intermediate spaces to be dealt with more easily by the broad chisel than if the whole of the work were done by this tool. Chipping must never be done closely towards an edge, as it might cause the metal to break out, but away from it, or in a diagonal direction The portable machine tools have taken much of this work, because, when pieces are too massive to be taken to a machine, the portable tools are fixed to the work. This does not cover the case of repairs, jobs done away from the workshop, and therefore a fitter must be able to chip when the necessity arises.

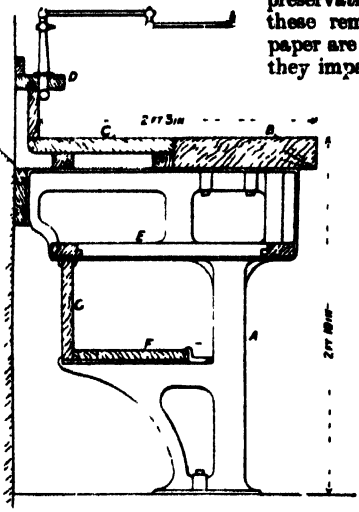


310. SUNK, OR FEATHER, KEYS



Rough filing follows chipping. Either the coarse, rough cut, or the bastard files are used first, followed by the fine or smooth grade files; and when great accuracy is required, these are succeeded by the scrape. Filing is an art to be acquired only by practice. The difficulty is to file *flat*. Only dead parallel files are perfectly straight; all others are more or less bellied, which shape is favourable to the production of flat faces. The right elbow is kept quite close to the workman's body, the body moves in unison with the file, and its weight is thrown into the forward stroke and relieved during the return stroke, though the file is not actually lifted off the work. Economy is sought by crossing the direction of the strokes at intervals. Frequently time may be saved in heavy filing by using the backs of half-round files before the flat files. The fine files should not be employed until the surface has been brought nearly level, and nearly to a finish.

Testing. The testing of plane surfaces is done with straightedges, winding strips, and surface-plates. Red lead paste, made with red lead and oil, is rubbed on the edge of the straightedge or on the surface of the plate, and indicates by its transference to the high parts of the filed surface the localities from which material has to be removed. As the correction approaches completion, the action of the file has to be localised by shorter strokes, or by operating with an inch or two only next the point. The red lead must then be applied more thinly. When the surface shows contact nearly all over nothing more can be effected with the file, but the scrape will be brought into service. This is held at an angle of from 30° to 40° with the surface of the work, and it removes the merest trace of metal from the high localities. The surface plate is still used to check results, but the film of red lead must be very thin, or else it is not used at all; but the mere contact of the work with the clean surface of the plate, or a thin film of clear oil suffices to indicate the points of contact. The surface of the work must be wiped clean every time of making contact.

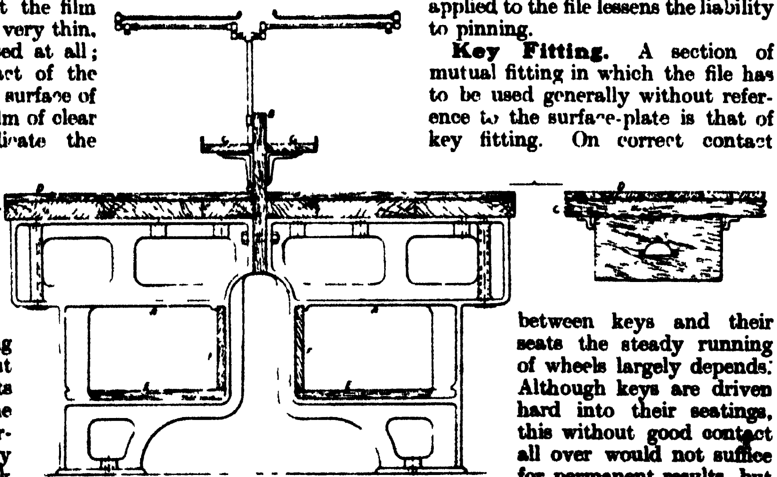


311. CAST-IRON BENCH

Mutual Fitting. It will be noticed that nothing has been said about making mutual fits between parts. The reason is that the surface-plate is the only test, and the work goes together for bolting or sliding fits as it leaves the test of the plate. If parts were fitted mutually, inaccuracy in one would produce similar inaccuracy in the other, but of opposite kind, as concave and convex, etc.

But there are many cases of mutual fitting of one part to another when one is known to be true. Thus bearings are generally fitted to their shafts in good work by scraping. The shaft is true, but for various reasons bearings are scraped to make easy fits with the shafts. The scrape is then worked edgewise in the brass, and red lead is smeared on the shaft journal.

Cautions. The practice of filing is of extensive application; but with some remarks on the preservation of the file, we must close these remarks. Though emery-cloth or paper are often used subsequently to files, they impart only a smooth finish. They do not effect accurate results, which can be produced only by scraping. The same remark applies to finish imparted by draw filing. A good file must never be used on the outer, hard skin of a casting or forging. If this has to be removed by filing, an old, practically worn-out instrument must be used. Or the skin can be removed by grinding if the allowance left is small, or by chipping if sufficient in amount. Or the work may be pickled as for machining in dilute sulphuric acid. A new file should not be used on wrought iron and steel, but on brass and gun-metal first, because partly worn files will not cut these alloys well, but will slip over them while they are yet capable of working on wrought iron and steel. Files that become clogged or *pinned* with particles of steel can be cleaned with card-wire; or chalk, or a little oil applied to the file lessens the liability to pinning.



312. DOUBLE CAST-IRON BENCH

Key Fitting. A section of mutual fitting in which the file has to be used generally without reference to the surface-plate is that of key fitting. On correct contact between keys and their seats the steady running of wheels largely depends. Although keys are driven hard into their seatings, this without good contact all over would not suffice for permanent results, but they would work loose in time. Either the key may be fitted to its seating or vice versâ. A key should be planed or ground truly, and it may be tested on the surface-plate. If the groove has not been slotted truly, then it, rather than the key, should be corrected by filing. But it is usually more convenient to ease the key to fit its seating, and the slot is usually assumed to be true. To effect this it is driven in with moderate force and then removed, the bright marks caused by friction with the key-bed indicating where to file off metal. Red lead or chalk is rubbed on the key before driving in, to help to show the high spots and prevent seizing. After filing, the key is again driven in and removed, the process being repeated until good contact is obtained and the key is sufficiently let in.

The removal of keys during fitting is done by the key drift [309 A], driven with the hammer when it is possible to get through the back of the keyway; or as 309 B, with a wedge (*a*) and packing (*b*), which is advisable only when the key (*c*) is supported by the key-bed in the shaft. Often, however, when the drift (A) cannot be got in, a wedge is used, and the head of the key is supported by holding a heavy sledge hammer to prevent bending down, which would involve subsequent straightening. Fig. 309 C shows the appearance of the key top when the contact is only partial; the aim of the fitter is to make the friction marks appear all over.

Sunk, or feather keys [310] are let in the shaft, and the wheel, etc., driven over them, removal and filing being done several times as necessary. When the clutch has to slide as in 310, the feathers are secured by countersunk screws, or sometimes rivets, to prevent their working loose. Fitting is a question of filing the tops and sides of the feathers until the clutch slides freely, but without shake, special care being taken that good contact is made along the sides, otherwise loose working will soon ensue.

Cottared Joints. A special type of fitting allied to the keys is that of cottared joints, with or without gibs. Though the parts are machined, some adjustments are usually necessary in the cottar holes and in the cottars and gibs. The same methods of filing and checking with red lead are adopted, but as the number of pieces involved is greater,

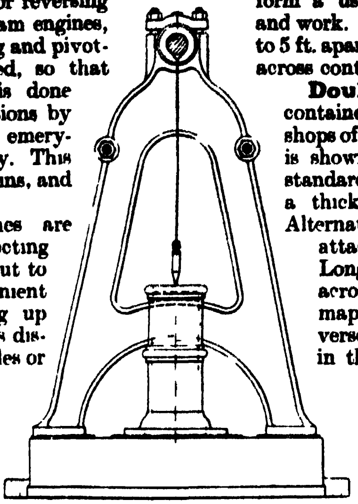
FITTING-SHOP APPLIANCES

313. Parkinson vice 314 and 315. Vice clams 316. Trestle 317. V block 318. Testing foundation with straightedge and spirit level 319. Testing bearings by plumb line

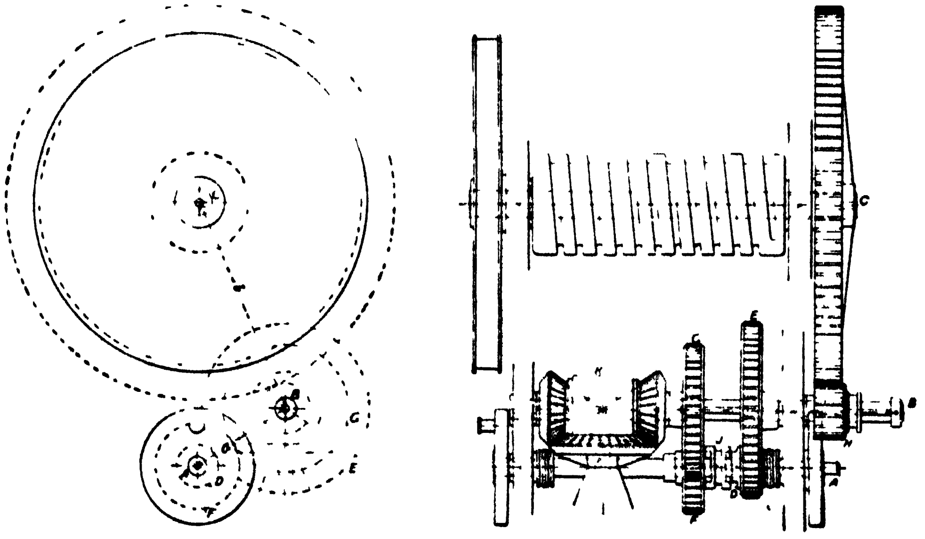
considerable care has to be exercised. A complete joint of this kind will include the stub end of a rod, the brasses and strap, the cottar, and one or two gibs, with or without set screws. Link motion, or motion work for reversing and operating the valves of steam engines, is high-class fitting. The sliding and pivoting surfaces are case hardened, so that though the principal fitting is done before hardening, some corrections by scraping or grinding, or with emery-cloth, are necessary subsequently. This includes the links, die blocks, pins, and pin holes.



320 TESTING CYLINDER CENTRE BY PLUMB LINE

Benches. Fitters' benches are necessary in all fitting and erecting work, not only to carry vices, but to afford a surface at a convenient height for laying and building up the small parts of mechanism, as distinct from those erected on trestles or on blocking on the shop floor. The bench also carries small tools and various appliances, some in drawers.

The common timber benches built up something like that of a carpenter, but carried along for a considerable length, have given place in many shops to those of cast iron, which are more rigid, durable, and cleanly. An example to go against a wall is shown in 811. The cast iron portion consists of the leg or standard (A) fastened to the floor with a coach screw, and to the wall with a couple of countersunk screws entering a wood packing. The thick piece of timber (B) forms the front of the bench top, and stands the heavy work, as well as carrying the vice which is held by a bolt passing down through the boss seen near the front of the casting. At C a thinner timber is used, packed up on strips; a narrow shelf (D) is supported above C to carry small tools and the gas or electric light fittings. The frame for the drawer is mounted inside the casting at E, and a lower shelf (F) and back (G) form a useful addition for holding tools and work. These legs are placed from 4 ft. to 5 ft. apart, the timbers, of course, running across continuously.

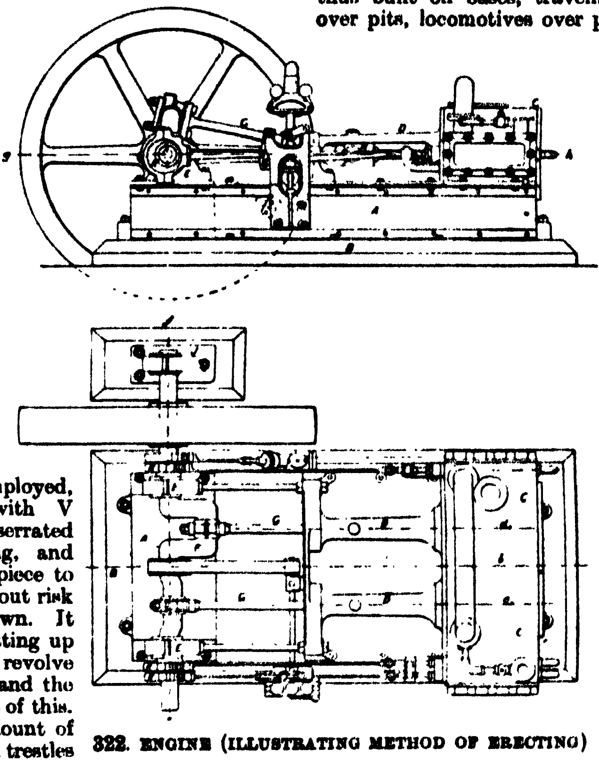


321. MARKING BEARING CENTRES FROM GEAR WHEELS

Double Bench. A double and self-contained design, such as is used in the shops of John Lang & Sons, of Johnstone, is shown in 812. Here two cast-iron standards (AA) are bolted together, with a thick piece of timber (B) between. Alternatively, one leg alone may be attached against a wall, as in 811. Longitudinal timbers (C) are laid across, and then faced with hard maple 1⅛ in. thick, placed transversely and tongued together as seen in the front view, showing also the drawer hung on bearers screwed to the underside of the planks (C). A deep boss is provided, as in the previous example, for attachment of the vice. E and F are shelf and back boards to carry work in progress clear of the floor. Small shelves (G) are attached to the upright (B), and a gas-pipe is also supported thereby. The height of such benches averages 2 ft. 10 in. to the top of the board.

Vices. Fitters use both the ordinary screw and the instantaneous action vices, the advantage of the latter being that the jaws may be opened and closed instantly to any size without the tedium of turning the screw many times. The Parkinson vice, a combination type, is seen in 813. It has a fixed jaw (A) bolted down to a base (B), and embracing the sliding jaw (C). The latter carries a buttress thread screw (D), fitting a half nut (E) lying in a recess in B. The screw, or the instantaneous action, is alternatively brought into operation as desired, according to whether nut E is lowered out of mesh with D (as seen), or whether it is raised up to engage. In the first case the jaw (C) may be slid freely to and fro; in the second it can be moved only by turning the screw by the long handle, acting then as an ordinary screw vice. The movement of E is produced by the lever F, which, when clasped by the hand to the knob of the screw (D), turns the flat strip (G) lying in a groove in E, and lowers the latter. When F is released the spring (H) draws it outwards, pressing E upwards, so that in the normal state the vice remains a screw one.

Clams. Clams are necessary for much vice work on finished surfaces, the hard steel serrated jaws being only suitable for black or rough work. Sheet iron or copper clams [314] are suitable for ordinary use, but for brass or other soft work thick lead clams are desirable. Various special forms are also employed, such as those with V grooves for rods, serrated grooves for piping, and those made in one piece to support shafts without risk of their slipping down. It is very handy in fitting up shafts to be able to revolve them at intervals, and the clams in 315 permit of this. A considerable amount of fitting up is done on trestles [316]. two or more being used for a piece of work. Shafts are supported thus for key and other fitting, resting in V blocks [317], often in preference to using the bench vice, because the latter is not so convenient, and does not allow the workman to walk all round the job.



322. ENGINE (ILLUSTRATING METHOD OF ERECTING)

Erecting. Erections are assumed to deal only with rather heavy work which cannot be done on the bench. Work completed on the bench is properly fitting, so that a pump or small motor, if bench work, would be classed as fitting; but a large pump or engine put together on the floor would be erecting.

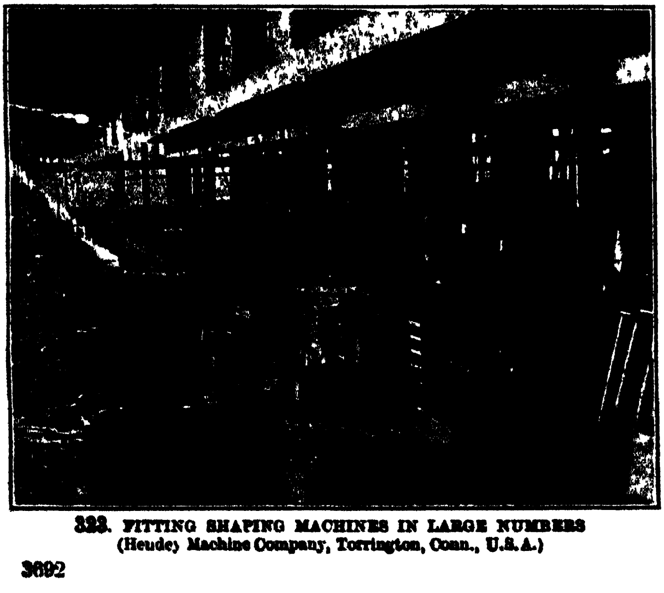
Levelling. Erecting generally involves dimensions or relations too large for the employment of rules and small instruments of measurement. Hence, the spirit level and the plumb line are of regular utility. Hence, too, most work is built up from a truly horizontal foundation of some kind or another, which may be either a part of the machine itself or an artificial and temporary basis. Most engines and machines have some kind of solid foundation in the form of bed, bed-plate, base-plate, or base in one continuous length, or in two or more disconnected parts. In erection, these are levelled up truly horizontal by means of a spirit level laid on a straightedge [318]. Usually they are levelled and wedged up on heavy timber blocks cut from balk [318]. When there is much work of the same kind, a permanent foundation is laid in the shop, on which to bolt the actual foundation of the engine or machine. Some cranes are thus built on bases, travelling cranes on rails over pits, locomotives over pits, marine engines down in pits, and so on. In each case before any superstructural work is done the actual foundation is fixed and levelled, and any necessary fine adjustments are made by wedges. Once levelled it remains permanently fixed until the superstructure is completed over it.

Reasons for Levelling. The necessity for levelling is to have a basis from which to erect perpendicular faces and centres, and also to ensure parallelism of all parts that lie in horizontal planes. If the base is levelled, all other horizontal faces are fixed by the employment of the spirit level. If perpendiculars are erected, all perpendiculars and horizontals must obviously be at right angles with each other without any need to set by squares, though this would still be done in the case of short or low faces and centres. But the use of a square is obviously impracticable when heights of many feet are concerned. Neither can a square be applied in many cases where a plumb line can be, as through the centre or axis of a bearing for example. The practice of levelling can be extended to include bearings for shafts which may have no other bases for adjustment, and for bearings standing at right or other angles with each other. The bottom of the bore is then used for the working base, parallel straightedges being laid therein and receiving the spirit level on the top edge. Another way is to lay the actual shaft in its bearings, and level the top edge of the shaft.

Straightedges are necessary in all levelling where the length or area to be checked exceeds two or three feet, and they must, of course, be parallel, the bottom edge coming on the work, and the level resting on the top edge. It is necessary also to turn the level about end for end in case the instrument should be out of truth. Or levels with an adjusting screw may be used.

The value of a truly horizontal base is seen at every stage of subsequent erection. If measurement be taken from that base to any centre above, the spirit level ensures parallelism. If shafts or faces are not situated perpendicularly over one another, so that direct measurement cannot be taken, each one can be measured directly from the base. Parallel parts in the horizontal plane can be measured off at any height from the base by dropping a plumb line and by taking horizontal dimensions therefrom. Bearings in the same perpendicular axis are centred by dropping a plumb line through the centre of the upper one [319], the bob coming over the centre of the lower one, both bearings being bridged with wood on which to get the centres. A bearing above can be centred by a plumb bob over a centre on the base plate below, or to one side of such a centre to any dimension. The centre of a cylinder can be located plumb with a shaft bearing similarly [320].

Centres and Edges. The measurement of distances between shafts or faces is variously done, sometimes by centres, sometimes by edges. The latter is, as a rule, the more convenient method, though centres are the dimensions laid down on drawings, and when lining out work. In erecting it would often be difficult to employ centres. Having shafts or faces in the same plane, calipers or a rod gauge are generally employed in preference to the rule, measurement being taken between the adjacent shafts or faces. If they are not in the same plane then a parallel straightedge may generally be carried along and set horizontally by means of a level, and measurement taken from that to the second shaft or face.



322. FITTING SHAPING MACHINES IN LARGE NUMBERS
(Hendey Machine Company, Torrington, Conn., U.S.A.)

Straining Line. In some cases a straight cord or fine wire is employed as a centre from which to take measurements. This is most convenient in engine erecting. The wire is strained taut down the centre of the cylinder bore, retained centrally by strips in the ends, and being carried beyond to the guides and crank shaft bearings, measurement is taken therefrom. The same device is employed in testing shaft bearings arranged in line along a shop wall, or along the girder of an overhead travelling crane. It is also used in order to observe the amount of set, or deflection, which a beam or girder undergoes when loaded. An alternative to the strained cord in the adjustment of bearings in a horizontal plane is to lay the shafting in, in successive lengths, levelling each length in turn with the spirit level, and coupling up as the work proceeds. The strained cord would still be employed for checking dimensions laterally. In a long length of shaft involving numerous bearings, a wire would sag or drop slightly, hence the preference given to the spirit level, but it would not sag laterally.

When pieces of work have angular relations in plan, and dimensions are large, the plumb line is usually preferred to the square or bevel. The relations of right or other angles are marked on the base, or bed plate, by geometrical methods preferably, but never by small instruments, the errors in which would be magnified, and the plumb line is dropped to these lines. In small work, of course, squares and bevels are employed

In setting and checking dimensions it is necessary to be careful to avoid errors, which are less likely to arise in working by centres than by edges. Addition or subtraction for thicknesses and semi-diameters have to be made, and allowances for any inaccuracies in rough work. A safe course to adopt when there are a number of dimensions in one plane is to add them all, and see if they total to the correct overall dimensions. This serves to check both the drawing and the workman's reckonings out.

Gear Wheel Centres. A part of the erectors' work is often that of lining out. Thus it may happen that certain centres cannot be obtained until the centres of gear wheels have been determined. When there are trains of iron and steel wheels with cast teeth, shrinkages and exact centres cannot be determined beforehand. Hence, the centres of bearings are often marked out from the wheels themselves. Fig. 321 illustrates a typical set of gearing. The shafts A B C have to be connected at centres which are fixed by the gears, and A and B have two sets of gears of different sizes, so that, if any inaccuracy occur in these, it has to be averaged between the two in setting the centres of the shafts. D E are for slow lifts, and F G for quick. The centres are *a* and *b*, and generally the locations of one or of two are fixed by other fittings or movements. Cast steel gears often give much trouble in centres—more than those of iron do, because of their greater and uncertain shrinkage; hence, one reason for the growing popularity of cut gears, the diameters of which are exact. The shaft fittings include the keying up of fixed gears, and the fitting of the sliding or feather keys and pinions. The latter are slid with a clutch motion, H, or a sliding clutch engages with the gears as at J and K.

324. ERECTING PLANING MACHINES (C. Redman & Sons, Halifax)

Erecting an Engine. Fig. 322 illustrates a compound horizontal engine which will serve as an object lesson on erecting of the class of which it is typical. In any work of this kind there are, of course, alternative methods, into which we cannot enter. But, broadly, there are two ways in which such an engine could be erected, one being by taking section by section, and measuring and checking each; the other by doing all the machining by templets and gauges made from a first engine completely fitted up, and then taken apart and each part being used as a templet, or gauge, or employed to make these from. This method is suitable when a considerable number, say above ten or a dozen engines, are wanted all alike. This is a half-way device between erecting and assembling; for slight adjustments would have to be made, as reamering of bolt holes through parts in place, and easings with file and scrape. Yet for a class of work of medium size these slight corrections would not invalidate the term "interchangeable" applied to such a class of work, though not in the stricter sense in which it is applied to the smaller mechanisms.

Engine Bed. In 322 the engine bed is shown at A as built up of plate and angle, alternatively to a casting. The top face, *a*, is levelled first, irrespective of the truth of the bottom face which goes on the foundation, B, of masonry and concrete. The top, *a*, is planed level, and the bottom might be also, or be left rough. But *a* is the face to be levelled, both before erection of the engine in the shop, and at the time of its erection on its foundation, B. A centre line, *b*, is run along the bed, and to right and left of this the centre lines, *c*, *d*, of the cylinders are marked, and at right angles with these the line, *e-f*, for the crank shaft, and by these the principal work is done. In the other direction the important centre is *g-h*, corresponding with the axis of the cylinder, cross head, and crank shaft in the horizontal plane.

Details of Erection. In the figures the cylinder lagging conceals the joints, but the two cylinders are cast separately, and bolted together. In some cases they are cast as one. But in either case the machining is finished—boring, facing, etc.—before they are put on the bed plate, and if cast separately, they are bolted together before being attached to the bed plate. They are then clamped to the bed plate, and bolt holes drilled and reamered, after due checking of the longitudinal accuracy of the cylinder axis. Being set over their centres, a straightedge is passed down the bores to the crank shaft, provided the guides, D D, are not cast with the cylinders, and lateral measurements taken there. Or a cord or wire is strained down the centres through wood strips bridging the ends, and measurement taken from that before the final reamering is done. The cross-head guides, D D, are shown as cast with the cylinders. Often they are cast separately and bolted on. If so, they are attached to the cylinders before the latter are bolted to the bed plate. The piston and piston rods, together with the glands and covers, will have been fitted to the cylinders at the bench, and these will be removed during the setting of the cylinders by the straining line. By the same line the positions of the crank shaft bearings, E E, will be adjusted laterally, before their bolt holes are drilled and reamered. The bearing centres will be squared up from the centre line *e-f*, scribed on the bed. The crank shaft, F, is now dropped in, and the connecting rods, G G, fitted to the shaft at one end, and the cross heads, H, at the other. If, however, these parts had all been made by templet from a sample engine, then the cylinders, guides, and rods would be set bodily at once, and connection made to the crank shaft with no settings and adjustments, except, perhaps, a slight amount of reamering of bolt holes. The

Notice how the expression $-ap+bq+cr$ is formed from the denominators of the given fractions, by taking $-a$ times the first denominator, b times the second, and c times the third. By the result just proved, we know that the given fractions are each equal to a fraction with denominator $-ap+bq+cr$ and whose numerator is formed in the same way as the denominator, *viz.*, by taking $-a$ times the first numerator, b times the second, and c times the third.

Hence the given fractions are each equal to

$$\frac{-a\,(cy+bz)+b\,(az+cx)+c\,(bx+ay)}{-ap+bq+cr}=\frac{2bcx}{-ap+bq+cr},$$

by collecting terms in the numerator.

In exactly the same way we can show that each of the given fractions is equal to

$$\frac{2cay}{ap-bq+cr}, \text{ and also to } \frac{2abz}{ap+bq-cr}.$$

Therefore these three expressions must be equal to one another. On dividing each of them by $2abc$ we obtain the required result, *viz.*,

$$\frac{x}{a\,(-ap+bq+cr)}=\frac{y}{b\,(ap-bq+cr)}=\frac{z}{c\,(ap+bq-cr)}.$$

140. The method used in Art. **139** of putting each of a number of equal ratios equal to a single letter, k, can always be followed in such cases as the following.

Example. If $a:b::c:d$, prove that

$$a:a+c::a+b:a+b+c+d.$$

Let $\dfrac{a}{b}=\dfrac{c}{d}=k.$

Then, $a=bk$ and $c=dk$.

$$\therefore\ \frac{a}{a+c}=\frac{bk}{bk+dk}=\frac{b}{b+d},$$

and

$$\frac{a+b}{a+b+c+d}=\frac{bk+b}{b\,(k+1)+d\,(k+1)}=\frac{b\,(k+1)}{(b+d)\,(k+1)}=\frac{b}{b+d}.$$

Thus,

$$\frac{a}{a+c} \text{ and } \frac{a+b}{a+b+c+d}$$

are each equal to $\dfrac{b}{b+d}$.

Therefore,

$$a:a+c::a+b:a+b+c+d.$$

VARIATION

141. Consider an article sold at a fixed price, say, 6d. per yard. It is evident that if we double the number of yards we double the total cost; if we take half the number of yards we make the cost amount to half its former value, and so on. When two quantities are related in the way that the number of yards and the cost are here related, so that any two values of the one quantity are in the same ratio to one another as the corresponding values of the other quantity, then the one quantity is said to *vary as* the other quantity.

The words "varies as" are denoted by the symbol $\propto$, so that "a varies as b" is written "$a \propto b$", and means that the ratio $a:b$ has always the same value.

Denoting this constant value by k, we have $\dfrac{a}{b}=k$, and therefore the value of k can be found when we know one set of corresponding values of a and b.

Example. If a varies as b, and a is 2 when b is 15, what is a when b is 9 ?

Since $a \propto b$, we have $a=kb$, k being constant. Therefore, since $a=2$ when $b=15$, it follows that $2=15k$, or $k=\dfrac{2}{15}$.

Hence, when $b=9$ we have

$$a=9\times\frac{2}{15}=1\tfrac{1}{5}\ \underline{\textit{Ans.}}$$

142. One quantity is said to *vary inversely* as another when the first varies as the reciprocal [Examples **30**, No. **2**] of the other.

Thus, a varies inversely as b, when $a \propto \dfrac{1}{b}$, so that $a=\dfrac{k}{b}$, where k is constant.

One quantity is said to vary as two others *jointly* when it varies as their product.

Thus, a varies as b and c jointly when $a \propto bc$.

One quantity is said to vary *directly as second and inversely as a third* when its ratio to the product of the second and the reciprocal of the third is constant.

Thus, a varies directly as b and inversely as c if $a:b\times\dfrac{1}{c}$ is constant, *i.e.*, if $a=\dfrac{kb}{c}$, where k is constant.

As in Article **141**, the constant can always be found when one set of corresponding values of the quantities is known.

Example. The volume of a right circular cone varies jointly as the height and the square of the radius of the base. The volume of a cone 14 in. high and having a base of 3 in. radius is 132 cubic in. What is the volume of a cone 9 in. high with a base of $3\frac{1}{2}$ in. radius?

If $V=$ the volume, $r=$ radius of base, and $h=$ height, then $V \propto r^2h$, so that $V=kr^2h$.

Hence, when $V=132$, $r=3$, and $h=14$, we have $132=k\times9\times14$. Therefore, $k=\dfrac{22}{21}$, and when $h=9$ and $r=3\frac{1}{2}$,

$$V=\frac{22}{21}\times\left(\frac{7}{2}\right)^2\times 9 \text{ cubic in.}$$

$$=115\tfrac{1}{2} \text{ cubic in. } \underline{\textit{Ans.}}$$

Group 13

GEOGRAPHY

26

Continued from page 3587

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

New Guinea. New Guinea (nearly 300,000 sq. miles) stretches between the islands of the Malay archipelago and Australia. Much of it is mountainous, peaks in the Owen Stanley and Bismarck ranges rising to at least 13,000 ft. or 14,000 ft. There are many large rivers, of which the Kaiserin Augusta in the north, and the Fly in the south, are the largest. The northern part of New Guinea has rain at all seasons, but most in northern winter months with the northern monsoon, and is covered with dense tropical forests. Little of the interior, however, has yet been explored. The south has less rain, and this falls chiefly during the northern summer months, when the southern monsoon blows. The vegetation here is open forest, with many eucalyptus and mimosa trees.

Politically, the island is divided between Britain, Germany and Holland. Port Moresby is the chief place in British New Guinea.

AUSTRALIA

The Australian Commonwealth (3,000,000 sq. miles), consists of the continent-island of Australia, with the neighbouring island of Tasmania (26,000 sq. miles). It includes the States of Queensland, New South Wales, Victoria and Tasmania in the east, South Australia in the centre, and West Australia in the west.

Seas, Gulfs and Islands. Australia lies to the south of the islands of the Malay Archipelago, from which it is separated by the Timor and Arafura Seas, and to the south of New Guinea, from which it is separated by Torres Strait. Its western shores are washed by the Indian Ocean, its eastern by the Pacific. The shape of Australia is compact, with few peninsulas and gulfs. Let us look out in a map Cambridge Gulf in the north-west, the great Gulf of Carpentaria, enclosed by the peninsulas of Arnhem Land and Cape York in the north, and on the south coast Encounter Bay, Spencer Gulf, and the Great Australian Bight. Notice how few islands lie off the coast, the only considerable one being Tasmania, a detached fragment of the continent, separated from the mainland by Bass Strait, above whose waters rise small islands. Though lacking in gulfs, Australia has many inlets, which form excellent harbours. Among them are Port Jackson, which forms Sydney Harbour, one of the finest in the world, and Port Philip, the harbour of Melbourne.

Mountains and Rivers. The highest land in Australia forms the eastern highlands, which, under various names, stretch along the east coast of the continent, and are continued in Tasmania. These highlands, generally called the Great Dividing Range, are highest in the south-east, where the Kosciusko group reaches 7,350 ft. To the west of this the highlands are known as the Australian Alps, and north they are known as the Blue Mountains, the Liverpool Range, etc. These long formed a barrier to expansion from the coast to the interior.

The most formidable barrier to exploration was the Blue Mountains behind Sydney. Expedition after expedition was unsuccessful in attempting to find a route across them. "Between the ranges lie yawning chasms, deep-winding gorges, and frightful precipices. Narrow, gloomy, and profound, these stupendous rifts are enclosed between gigantic walls of sandstone rock, sometimes receding from, sometimes frightfully overhanging, the dark bed of the ravine, and its black, silent eddies or foaming torrents. Everywhere the descent into the deep abyss is full of danger, and the issue almost impracticable." At last routes were found, and the railway is now carried across this formidable barrier.

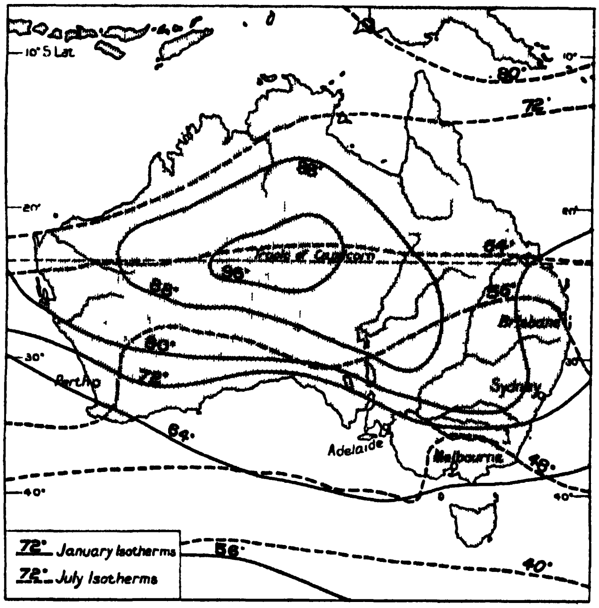
Rivers of the Eastern Highlands. The eastern highlands lie near the coast, and descend more or less steeply to it. Under such conditions, no long east-flowing rivers can be formed. Look out the Burdekin, Fitzroy, Brisbane and Hunter.

The rivers from the western slopes of the northern part of these highlands carry little water, and lose themselves in the dry interior, except after rains, when they flow to Lake Eyre. The largest is Cooper's Creek. The higher, better-watered, southern part gives rise to the only considerable river of the continent, the Murray-Darling. The more northerly waters are gathered up by the Darling, which flows south-west to its confluence with the Murray, which has gathered up the rivers of the southern highlands, the most considerable being the Lachlan and the Murrumbidgee. The main stream of the Murray comes from the Australian Alps, issuing from the mountains, like all the rivers of this part of the system, in a profound gorge, which is known as the Gate of the Murray. The plains surrounding the Murray and its tributaries form the Riverina district, which affords excellent pasture.

The Central Depression and Western Plateau. West of the Murray, which widens at its mouth to Lake Alexandrina, rises the Flinders Range. West of this is a depression which extends across the continent from the Gulf of Carpentaria, the submerged northern part of it, to Spencer Gulf in the south. The rest of the continent is a low plateau, highest round the margin. The rivers shown in maps are, for the most part, dry channels, except after rains. The Swan River in the south-west should be noticed.

Climate. If we look at any map of the world, we see that the greater part of Australia is in the same latitudes as South Africa. We also notice that Australia is extremely broad from west to east, and that its general elevation is low and uniform, both favouring a dry climate.

Australia is almost bisected by the Tropic of Capricorn, which crosses it at its broadest part. A very large part of the continent, therefore, has the hot summers and warm winters of tropical lands. The summer solstice coincides with the earth's position in perihelion, when the sun is 1,500,000 miles nearer the earth than at the summer solstice of the Northern Hemisphere. For this reason, and also as a consequence of the absence of a protective covering of vegetation, very high temperatures are recorded in the interior of the continent, where the ground is sometimes so heated, that a match falling on it ignites. Only in the extreme south is the climate temperate, but with warmer summers and winters than our own.



134. ISOTHERMS OF AUSTRALIA

The north and north-west coasts are in the monsoon region of wet summers and dry winters. The eastern highlands condense the winds from the sea and provide a fairly abundant rainfall for the east coast at all seasons, but most in summer. Parts of the south-east and south-west have a moderate rainfall, which is of the Mediterranean type, and falls in winter. The interior of the continent is for the most part an almost rainless desert. Tasmania has rain at all seasons, and differs little in climate from the Channel Islands.

Vegetation. Australia seems to have been cut off from the rest of the Old World very early, and its plants and animals are in many ways exceptional. The trees are evergreen, and suit the hot, dry climate. The tough, leathery leaves are set sideways, presenting their edges and not their surfaces to the sun's rays, thus greatly reducing evaporation. This makes them very shadeless, but as a compensation allows grass to grow where it would otherwise be impossible. The trees grow tall and straight, and stand well apart. The commonest is the eucalyptus, or gum tree, the species of which are very numerous. Many shed their bark annually, and the long, dead strips fluttering in the wind give a weird appearance to the landscape. In the drier regions many trees possess water-storing properties, as in the other arid regions of the world.

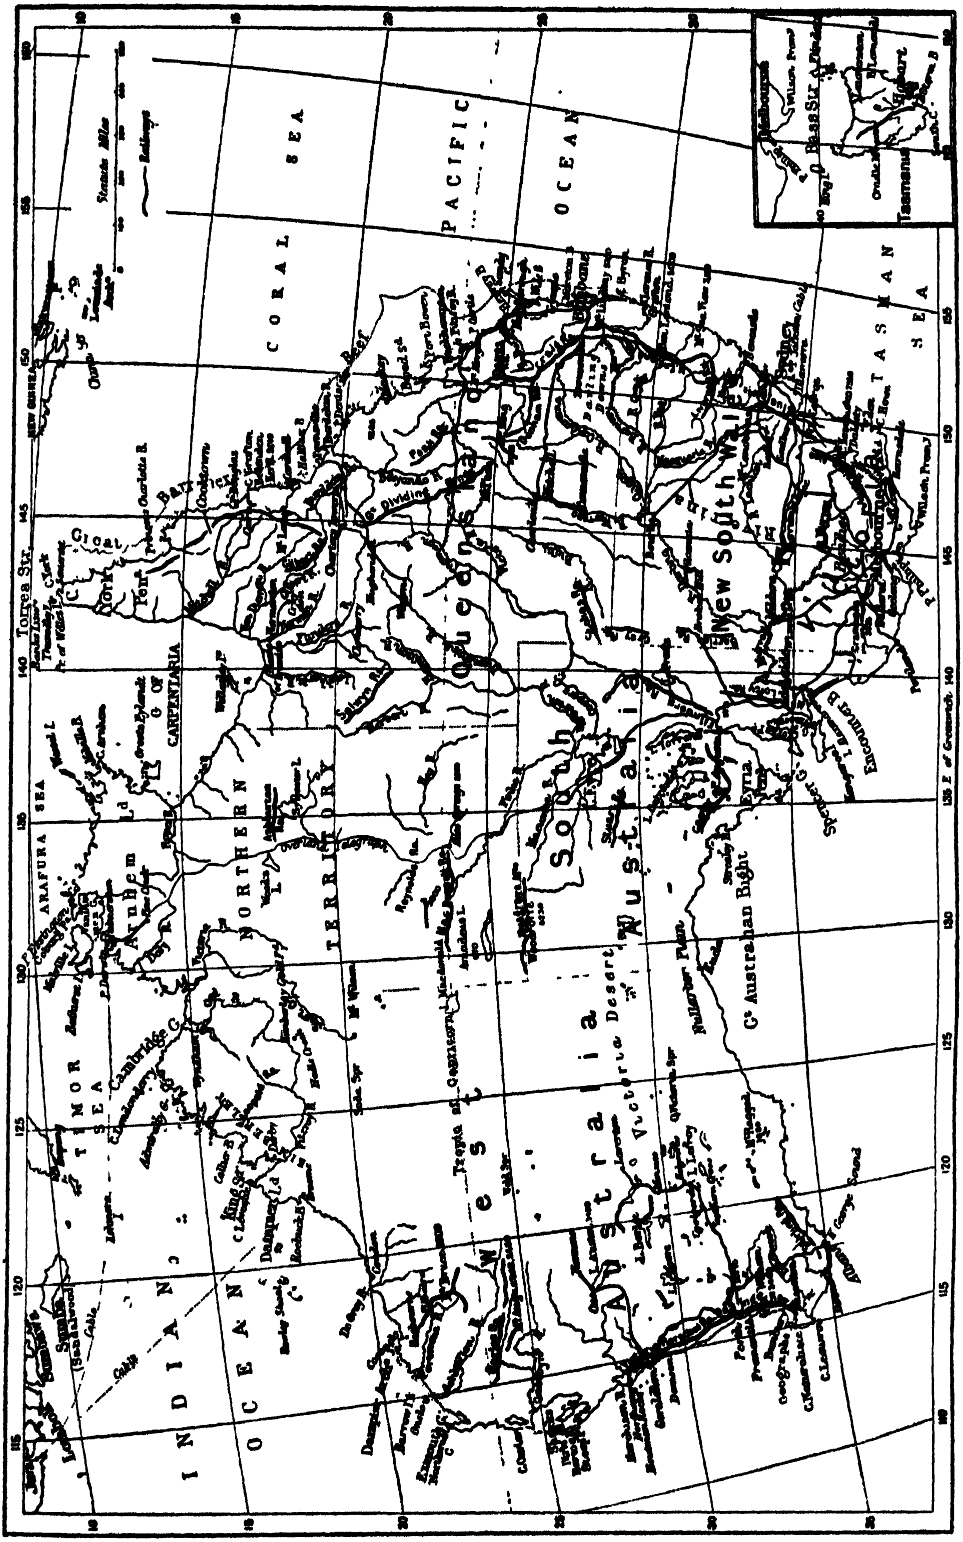
Drought-resisting Plants. The hot, wet, northern tropical regions are covered with tropical forests, with such trees as screw pines, palms, bamboos and mangroves along the coasts. On the drier western margin the forests open out and pass into savanas. The trees diminish in height, and grass or dwarf bushes known as scrub predominate. Of these the commonest are the dense brigalow scrub, the mulga scrub—a sharp, spiny plant very difficult to penetrate, the dreaded spinifex or porcupine grass—whose hard, sharp-pointed leaves, resembling groups of bayonets, inflict cruel wounds, and the salt bush, which covers vast areas of Eastern Australia. All these are drought-resisting plants. Towards the interior even this hardy vegetation disappears and the country becomes a desert.

The east coast is well wooded in the wetter part, various species of eucalyptus predominating. Beyond the Divide the woods pass into grassy downs, scrub and desert. Hardier even than the eucalyptus are the acacias, or wattles, of which numerous species occur.

In the regions of winter rains in Victoria and Western Australia are found two valuable species of eucalyptus, the jarrah and the karri, both hard, durable woods in great demand.

Animal Life. Some curious types of animals are found in Australia. Many are marsupials, which bring forth their young prematurely, to complete their development in the mother's pouch. The kangaroo and the opossum are the most familiar. Other creatures combine the characteristics of reptiles and mammals. The numerous species of birds include the emu, cassowary, lyre-bird, etc. The domesticated animals of Europe have been introduced, and sheep are extremely numerous. The rabbit has become a pest, and starves out sheep by eating up the grass.

Occupations and Population. Australia suffers from two drawbacks—drought and scanty population. The population is



185. MAP OF AUSTRALIA

mainly confined to the coast, and chiefly to the State capitals, especially Sydney and Melbourne.

The exploitation of tropical Australia is rendered difficult by the question of labour. It is not a white man's country, but the introduction of indentured coloured labour is open to grave objections. In Victoria and South Australia wheat is cultivated; and many fruits, especially the vine in the regions of winter rain, come to perfection. As a permanent occupation sheep and cattle breeding will probably always be more profitable than agriculture. Gold mining is extremely important. Enormous sums have been spent in Queensland and other parts of Australia in sinking deep artesian wells to the water-bearing strata, in order to render irrigation possible. Manufacturers are protected by a heavy tariff, but the great stimulus to development, a large home market, is yet wanting.

Races. The aboriginal inhabitants are dying out, and the bulk of the population is of British descent. The aborigines were at a low level of culture, subsisting on the produce of the forests and grass lands, and practising hardly any arts. There is a strong Australian opposition to the immigration of the yellow races, who have secured a precarious footing along the northern coasts. Here, again, an ample population would be a better safeguard than legislative enactments.

QUEENSLAND

Queensland (668,000 sq. miles), is a distinctively tropical colony. The Dividing Range recedes from the coast, giving Queensland navigable east-flowing rivers, whose alluvial lands receive abundant rains from the Pacific. The lands round the Gulf of Carpentaria receive less rain, while the interior is dry.

The Forests of Queensland. The coastal lands of Eastern Queensland were originally densely forested; but with the advance of settlement forests are rapidly disappearing. Sawmills have sprung up in all directions, and in the forest clearings maize, tobacco, sugar and cotton are planted. Coffee has been introduced into the scrub lands of Northern Queensland. An immense variety of fruits can be grown, including the coconut and date palm, the banana, which grows wild, the pineapple, orange, lemon, mango, and many others.

In the Dividing Range the forests remain in their original magnificence. "Centuries old, and towering 200 ft. above you, their topmost branches massed with orchids and lichens, rise the huge, russet-brown columns of the bunyas, the ringed, majestic heights of the pine, and the smooth white pillars of the beech, 100 ft. without a limb. Festoons of brilliant creepers and the thick cordage of the scrub vine swing overhead. At times you pass down avenues of white and yellow orchids, past beds of arum lilies, and between dark-green walls of scrub myrtle, or through a miniature forest of tree ferns. Here the moss-covered trunk of some fallen cedar giant shows amidst a rambling mass of wild raspberry bushes; there a huge Moreton Bay fig-tree spreads a leafy shade, its hollow trunk a network of grey cables, inside which a man can climb for 40 ft."

The Darling Downs West of the Divide lie the grasslands of Queensland. The richest portion is known as the Darling Downs. This is a fertile and well-watered plain, some 70 miles by 30, surrounded by mountains whose streams have covered the Downs with fertile alluvial black soil. At present it is mainly a pastoral and fruit-growing region, but mixed farming and co-operative dairy industries are developing. Large areas are being sown with wheat, maize, and lucerne, and as settlement advances the Darling Downs will supply wheat, cereals, potatoes, and malting barley, as well as butter, cheese, bacon and fruit. The pastoral products of these and the other grasslands—wool, hides, meat, tallow—are of great value. There is a large export trade in frozen meat, and along the east coast are many freezing works, boiling down works, preserving works, and chilled meat stores.

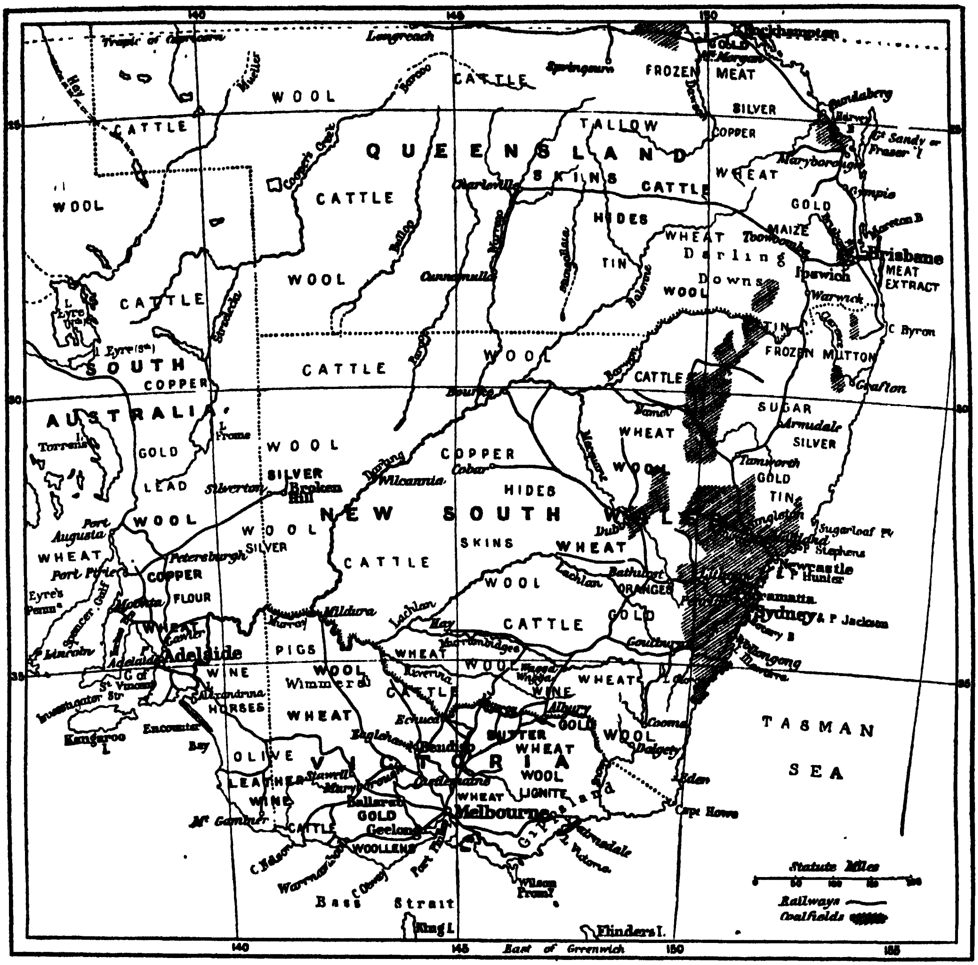
Mining Industries of Queensland. The mineral wealth of Queensland consists of gold, silver, copper, tin and, in fact, most metals, and many precious stones, such as sapphires. Among many famous gold mines Mount Morgan may be mentioned. Originally bought for £1 an acre, it has paid nearly £5,000,000 in dividends. Charters Towers has yielded over £14,000,000 since 1872.

Artesian Wells. The western part of Queensland is dry, but in recent years it has been found possible to obtain water by sinking deep artesian wells. Up to June, 1902, nearly 950 such wells had been sunk, the deepest of which was over 5,000 ft. while several others exceeded 4,000 ft. Many hundreds of millions of gallons are thus obtained daily, so that a country which a few years ago could not be settled is "now traversed for miles by the lines of rushes which follow the overflowing waters as they meander for miles over the downs, led in channels formed by huge ploughs made for the purpose"

Towns of Queensland. The towns are chiefly along the coast, opposite breaks in the Great Barrier Reef, which skirts the coast. Brisbane, in South Queensland, the capital, is the outlet for the rich Darling Downs region, in which are situated Toowomba and Warwick. Other busy towns are Maryborough, near a sugar, gold, and fruit-producing region; Rockhampton, the chief place in Central Queensland, the outlet for wool and other pastoral produce, and for the gold of Mount Morgan; Mackay, a sugar town; Townsville, the principal port of North Queensland, connected by rail with Charters Towers and other goldfields; and Cairns, in a district growing rice, sugar, coffee, cacao and other tropical produce.

NEW SOUTH WALES

New South Wales (310,000 sq. miles) is the oldest Australian colony. The climate is sub-tropical in the north, while the difference between winter and summer temperatures is not great in the east. The south is temperate.



136. SOUTH-EAST AUSTRALIA, SHOWING PRODUCTS

In the interior, where the heat of summer is intense, the range of temperature is much greater. The rainfall of the east coast is generally sufficient, but west of the Dividing Range it becomes very scanty, and long periods of drought are common.

The Dividing Range. This is from 3,000 ft. to 7,000 ft. high, and fronts the coast steeply at a distance of from 30 to 120 miles. It culminates in Mount Townsend, in the Kosciusko group, which just rises above the snow line, and secures to the Murray a permanent flow. The coastal belt is fertile and crossed by many small rivers, all liable to flood after rain. West of the Dividing Range lie pastoral regions drained by the fan-like tributaries of the Murray and Darling, many of which are empty in the dry season, and flood the country after heavy rains. This region passes gradually into the desert, on the margin of which the camel has been introduced for transport purposes.

Resources of the Colony. About one-fourth of the colony is wooded, and the forests, which are mainly composed of various species of eucalyptus, produce some beautiful cabinet woods. There are many sawmills in the forest area.

Agriculture is carried on in the better watered east, and is growing in the Riverina district. Wheat and maize are the chief cereals, the former producing flour of superfine quality. The brewing industry is developing. Sugar is cultivated in the hotter northern part of the colony. The orange is the chief fruit grown. In the drier west, agriculture is difficult, but in the irrigated districts various fodder crops are raised.

The minerals of New South Wales are valuable. Gold is widely distributed. Silver and silver-lead are abundant round Broken Hill in the west. Coal is mined round Newcastle, Illawarra, and Lithgow, where iron is smelted. Opals are found in some districts, though they are not of the finest quality.

The great resource of New South Wales is the pastoral industry. In 1901 the colony contained 21,000,000 sheep, the merino breed predominating. Where herbage is poor the runs have to be very large, but the productive power is enormously increased when irrigation from rivers or artesian wells can be carried out. Rabbits are a great scourge, and rabbit-proof fences are erected at great expense in the pastoral lands. The products of the pastoral industry are wool, hides, leather and meat. Meat preserving, boiling down, and wool-washing establishments are numerous. Bourke and Wilcannia are important pastoral centres.

Drought in Australia. A vivid account has lately been written of the horrors of an Australian drought. "Sunrise comes with a fiery red glow, and a scorching wind. After a hasty breakfast washed down by milkless tea, the pastoralist throws himself into the saddle and rides to the big station tanks to superintend the work. Round the shrunken pool of yellow water stands a row of sheep, unable from sheer weariness to extricate themselves from the mud into which they have rushed in their eagerness to drink. The owner looks at the bleating animals, mere skeletons covered by wool and hide, with a dull wonder that they have lived so long. He rides on. On all sides are skeletons and decaying carcasses. Not a blade of grass is to be seen anywhere, nothing but the scanty black-green foliage of the gums, and in the distance the grey, dusty mulga-scrub. He heads for the scrub, crossing the creek bed, now dry and choked with dust. Men are cutting down the mulga, the only food the station affords to the starving sheep. The animals eat it, but not eagerly, even though they are starving, for it is tough and uninviting. The next visit is to the stud flock, once the pride of the station. From a deep water-hole a man is pumping water into troughs, while another is opening bags of chaff. This is hand feeding and an expensive business. Every sheep costs 6d. a day to feed, for the chaff has to be brought hundreds of miles by boat and train, and last of all by team or camel train. The sun climbs higher, and the feeble sheep creep into the shade of the gum trees. Men set about removing the hides and wool of those that have recently died. The choking wind sweeps across the sun-baked land."

Towns of New South Wales. Sydney, the capital, has now eclipsed its former rival Melbourne. It is the terminus of many important steamer routes both from east and west. Its harbour on Port Jackson is one of the finest in the world. "One might live in Sydney a lifetime and then not know every arm and nook of Port Jackson. Each of its inlets is, in a way, a reproduction of the main harbour." The city is built in red and yellow sandstone on the heights round the bay, and presents a fine appearance from the sea. Newcastle is the second town and the principal seaport north of Sydney. Goulburn is an important centre in the south. Bathurst, 150 miles west of Sydney, is the centre of an agricultural, pastoral, and gold-mining district. Many other towns are on the road to prosperity, but at present population is too much concentrated in the capital, Sydney.

VICTORIA

Victoria (88,000 sq. miles), though the smallest, is the most densely populated of the Australian Colonies. It occupies the extreme south-east of the Continent, and has many good harbours, of which the finest is Port Phillip, which forms Melbourne harbour.

Victoria is crossed from east to west by the Australian Alps, rising to over 6,000 ft., a continuation of the Dividing Range. The mountains are forested, and contain many giant eucalyptus trees, some of which exceed 400 ft. in height. Fan palms, tree ferns, and acacias are also common. The southern slopes are drained by short rivers, which cross the fertile Gippsland district to the sea. The northern slopes are drained to the Murray. West of about 145° E. the rivers do not reach the Murray, but dry up or end in salt lakes or swamps. This forms the Wimmera-Mildura district, the poorest part of the colony. Much of this region is covered with mallee scrub, interspersed with the salt bush, and occasionally with good pasture grass.

The climate of Victoria is temperate, with hotter summers than our own, and winters cool enough for an occasional touch of frost, which disappears as soon as the sun is up. The rainfall of the coast is about the same as in Kent, but in the Wimmera district it becomes very scanty. It is everywhere irregular, and seasons of drought alternate with disastrous floods.

Products of Victoria. The leading occupation of Victoria is sheep farming, the wool produced being the finest in the world. The merino sheep has been introduced from Spain, where the climate is not dissimilar. The wool is longer, softer, and more lustrous than any other. Other pastoral products are hides, meat and dairy produce. The dairy industries are now adopting co-operative methods, as in Denmark and Switzerland, and large quantities of butter are consigned to the European market.

Next to wool ranks gold, most of which is minted at Melbourne. Bendigo and Ballarat are famous centres. At Bendigo is the deepest gold mine in the world (3,350 ft.), and several others are carried down to 3,000 ft.

The agriculture of Victoria is rapidly developing. The dry, warm climate suits wheat, which is increasingly grown. The yield is small, but the flour milled from it is of exceptionally fine quality. Fruit growing is important, and apple orchards are numerous. The warm climate, with winter rains, resembles that of the Mediterranean, and the vine is grown with great success. Some wine and light grape brandies are now made.

Towns of Victoria. Melbourne, the capital, on Port Phillip, is the rival of Sydney, and the seventh city in size in the British Empire. With its suburbs, of which Williamstown is the most important, it covers an area of 200 sq. miles. The fine harbour of Port Phillip is entered between the Heads, beyond which the Bay opens out like a great inland sea. Geelong, on the western shore, 45 miles from Melbourne, has woollen manufactures. The gold town of Ballarat is the second city in the colony.

ACIDS, SUGARS & BENZENE

Cyanides. Oxalic, Tartaric, Citric, and Uric Acids. The Carbohydrates: Sugars and Starches. Acetylene and Benzene. Coal-tar Colours

Group 5
CHEMISTRY
26

Continued from page 3538

By Dr. C. W. SALEEBY

WE must now consider the classical discovery of Wöhler, made in 1828. This chemist was the discoverer of the cyanates, and this discovery was the starting point of his artificial preparation of *urea*. Wöhler found that when cyanate of potash reacts with sulphate of ammonia there is produced, as might be expected, cyanate of ammonia, having the formula NH_4CNO. (The reader will not be puzzled by this formula. He will recognise in it the ammonia and the oxidised product of prussic acid which we have already called *cyanic acid.*)

But this cyanate of ammonia is not stable as such. The atoms of its molecules undergo almost immediately a re-arrangement within the molecules, producing an isomeric substance none other than urea—which is a characteristic end product of the breaking down of proteids in the living body, and the constitution of which is best represented by the formula $CO\begin{cases}NH_2\\NH_2\end{cases}$.

Urea, or Carbamide. The strict chemical name for urea is *carbamide*, a name which suggests its constitution. Two other processes of its artificial manufacture must be noted besides the process which will have a permanent place in chemical history. There is closely allied to carbonic acid—which is really carbonyl hydroxide $CO(OH)_2$—a gas known as *phosgene* or *carbonyl chloride* $COCl_2$. If this gas interacts with ammonia, urea and hydrochloric acid are produced, $COCl_2 + 2HNH_2 = CO(NH_2)_2 + 2HCl$.

Again, if ammonium carbonate be heated to about 130° C. it loses two molecules of water and yields urea.

But there is a method by which urea is produced naturally and this is of the utmost importance and interest. It is the most characteristic constituent of the secretion of the kidneys in man and the lower animals in general. It is derived from the breaking down of proteids in the body. These may be either proteids of the body or proteids of the food, which have served various purposes, and the last stage of the chemical degradation or simplification of which is represented by urea. About 500 grains of urea leave the body every day when a mixed diet is taken. The quantity falls to about 300 on a vegetable diet and rises to about 800 on an animal diet. If the subject goes without all nitrogenous food—which he can do for only a short time—he still produces about 200 grains of urea in consequence of the breaking down of his proteid or nitrogenous tissues. Urea leaves the body by the agency of the kidneys, but is not produced in those organs. Their function is merely to select it from the blood, and in this respect it may be noted that a certain amount of help is given them by the sweat glands of the skin, which are capable of excreting no negligible proportion of urea when the kidneys are out of order. It is known that the organ which produces urea in the body is the liver, and of the many substances from which the liver forms urea, three may be quoted—ammonium carbonate, ammonium lactate, and ammonium carbamate. These three substances are the chief immediate antecedents of urea.

Relations of Urea. The process by which urea is formed from ammonium carbonate outside of the body suffices to explain the manner in which the liver effects a similar change within the body. We must also note the fashion in which urea is produced from ammonium carbamate. The relations of the body known as *carbamic acid* will be readily seen from the accompanying formulæ:

$$\text{Carbonic Acid .. } CO\begin{cases}OH\\OH\end{cases}$$

$$\text{Carbamic Acid .. } CO\begin{cases}OH\\NH_2\end{cases}$$

$$\text{Carbamide (Urea) } CO\begin{cases}NH_2\\NH_2\end{cases}$$

It is, in short, a half-way house between carbonic acid and urea, or carbamide. The carbamate of ammonia has the formula of carbamic acid plus the formula of ammonia. The reader will see, if he writes this formula out, that the abstraction of one molecule of water from it will leave a molecule having the formula of urea. Thus, in both these cases the action of the liver is one of dehydration; and both of these actions can be produced outside the body by heat, since ammonium carbamate, like the carbonate, yields urea and water when heated. Ordinary smelling salts, by the way, consists more of ammonium carbamate than of its nominal constituent ammonium carbonate.

Urea is a Base. Its reactions with acids prove that urea is a base, for it readily forms a number of salts. One of these, the nitrate of urea, is utilised on account of its relative insolubility. If the secretion of the kidney be evaporated to a syrupy consistence, and then nitric acid added, the nitrate of urea is formed. This can be decomposed by barium carbonate, yielding barium nitrate, carbonic acid and urea, which is separated from the barium salt by means of alcohol. Urea forms white prismatic crystals which are very readily soluble in alcohol and in water. It is so soluble and diffusible that its removal from the body is an extremely easy matter. In these physical characters urea markedly differs from another substance which we are shortly to study, *uric acid*, which is the characteristic end product of the chemical degradation within the body of a particular kind of proteids which are known as the *nucleo-proteids*.

Other Reactions of Urea. Just as urea and water are produced by the decomposition of ammonium carbonate, so, under other conditions, urea and water can be made to form ammonium carbonate. This synthesis is also effected by the vital activity of an omnipresent microbe which is known as the *bacillus ureæ*.

The estimation of the quantity of urea produced by the body every day is a matter of the first importance in a very large number of diseases, and is usually accomplished by the estimation of the volume of nitrogen given off from a given quantity of urine when the urea in it is decomposed by the addition of a solution of hypobromite of sodium. This salt has the formula NaOBr, and is a powerful oxidising agent. Carbonic acid is formed, but is absorbed by the free alkali in the hypobromite solution, nitrogen alone being evolved and measured as soon as it has cooled.

Some New Organic Acids. There remain a few important organic acids derived from the hydrocarbons that we must briefly discuss. They have varying claims to attention, the first being of great importance as a poison, while others are very valuable constituents of various fruits, and help to account for their dietetic value. Tartaric acid, which belongs to this group, has already been discussed in part.

Oxalic Acid. We have already seen that all the carbon acids contain the group carboxyl, COOH. The formula of oxalic acid is simply twice that of carboxyl. It may be prepared, for commercial purposes, in many ways, and occurs naturally in certain plants in the form of its salts. Thus, the oxalate of lime is contained in rhubarb, while the hydrogen potassium salt occurs in sorrel, and is thus known as *salts of sorrel*. Oxalic acid is largely used for cleaning straw hats, so that in some parts of the country it is known as *bonnet acid*. We have already referred to it as an acid which exercises poisonous actions independently of the actions common to all the strong acids. Thus, a soluble salt of the acid is almost as dangerous as the acid itself. It acts upon the central nervous system, causing drowsiness and stupor. The essential part of the treatment in cases of oxalic acid poisoning, which is lamentably common, is not merely to neutralise it, but to form *an insoluble salt*, and this can be done by the administration of any preparation of lime. Clever and well-trained policemen have not infrequently saved life in these cases by scraping whitewash from a wall and administering it to the patient. Salts of sorrel is often used for the purposes of a poison, and is practically equivalent in its action to oxalic acid itself. Broken-down crystals of oxalic acid are sometimes sold by mistake as Epsom salts or sulphate of magnesium.

Malic Acid. This is another form of organic acid which naturally occurs in various forms of vegetable life, and especially in apples, from the Latin name of which (*Malum*) its name is derived. Like lactic acid, malic acid contains an asymmetrical carbon atom—an important term already defined—and therefore rotates the plane of a ray of polarised light.

The natural acid is left-handed, and an artificial acid can be prepared which is optically inactive, consisting of a mixture of right and left-handed acids.

Tartrates. When discussing the work of Pasteur we said all that need be said about tartaric acid, but some of its salts are worthy of mention. The hydrogen potassium salt is known as *cream of tartar*. A double salt of potassium and sodium is known as *Rochelle salt*. Cream of tartar is deposited on the sides of wine casks in the crude form known as *argol*. It is used in medicine, having the characteristic properties of salts. Rochelle salt is produced by the addition of cream of tartar to a hot solution of sodium carbonate, and is similarly employed in medicine. It is one of the chief ingredients of a seidlitz powder. (The reader must not confuse *argol*, the salt, *argon*, the gaseous element, and *Algol*, the famous double star.)

Tartar Emetic. Much more important in some ways is the salt known as *tartar emetic*, or *tartarated antimony*, which may be somewhat loosely described as a tartrate of potassium and antimony. It is prepared by the interaction of cream of tartar and antimonious oxide. In former days tartar emetic was very largely used in medicine, but we recognise nowadays that, since it contains antimony, it is a protoplasmic poison. Its administration causes extreme depression, and, despite its name, it should never on any account be used as an emetic. Indeed, it should be abolished altogether from the Pharmacopœia. In cases of acute poisoning by this dangerous salt, the symptoms of which are very similar to those of arsenical poisoning, the patient's strength must be conserved in every possible way, and tannic acid, or strong tea containing tannic acid, forms one of the best antidotes.

Citric Acid. Citric acid has already been mentioned as a typical organic acid which, for reasons we have explained, actually increases the alkalinity of the blood. Some of its many sources have already been named. It crystallises in rhombic prisms, is readily soluble in water, is the most pleasant to the taste of the organic acids, and has a calcium salt which is noteworthy in that it is less soluble in hot water than in cold. Citric acid may be taken freely in beverages without any fear that it will attack the enamel of the teeth. Citric acid is also deservedly famous as the specific preventative of the disease called *scurvy* or *scorbutus*, which was once the sailor's curse. At times this disease has threatened the safety of the British navy, but forty years ago the carriage of lime-juice—containing citric acid—on board ship was made compulsory, and now the disease has become extremely rare. It is interesting to note that doctors are quite at a loss to explain the disease, though there is none more easily cured.

Nowadays they are much more familiar with infantile scurvy. This disease very commonly occurs among children fed exclusively upon sterilised milk. Indeed, a baby fed on nothing but sterilised milk will develop scurvy. The mere addition of a teaspoonful of orange-juice—containing citric acid—to the daily diet of such a baby will cure or prevent the disease. Probably the most important factor in the relative success of Arctic exploration in more recent years has been the prevention of scurvy among the crews by the simple expedient of carrying lime-juice, the essential constituent of which is citric acid.

Uric Acid. The last acid of this group that we need consider is known as *uric acid*, and has the empirical formula $C_5H_4N_4O_3$. It is a subsidiary constituent of the secretion of the kidney in mammals, including man. In birds and reptiles, however, the kidney secretion of which is solid, urea scarcely occurs at all, and is replaced by urates. About ten grains of uric acid are daily secreted by man, not in the form of acid, but as its sodium salt. It is exclusively derived from the class of proteids known as *nucleo-proteids*, which have this name because they are characteristic constituents of the nuclei of living cells. No quantity of a simple proteid, such as white of egg, in the diet will increase the secretion of uric acid. On the other hand, the characteristic proteid of milk is a nucleo-proteid, and allied bodies are contained in meat in general. Furthermore, tea and coffee are capable of yielding uric acid. Now, there is a modern and popular doctrine that most human ills are due to the occurrence of uric acid in excessive quantity in the blood, and there is some small percentage of truth, at any rate, in this. Organic chemistry has so far advanced, however, that in cases where "uric-acidæmia" is really to blame, the diet can be so modified that scarcely any uric acid is derivable from it. Such a diet will be vegetable, and will include eggs and milk, which are of no practical importance as yielders of uric acid. The point to recognise is that uric acid is produced only by a certain group of proteids—besides malt liquors—and that if these be omitted, any quantity of other proteids may be taken. It is safe to say that, on the ground of excessive production of uric acid, and on other grounds, we must judge as very excessive the amount of meat consumed by the overwhelming majority of prosperous people in this country. Among the most characteristic constituents of meat, found most abundantly in meat extracts, is sarcin. This, when oxidised, yields another body called *xanthin*. The characteristic alkaloids of tea, coffee and cocoa are derived from xanthin. Extracts of meat, tea and coffee have their use—and unfortunately their abuse—as stimulants. They are destitute of any food value, and are therefore worse than useless where stimulation is not required, since the first, at least, leads to the formation of uric acid.

The Carbohydrates. We must now consider the last group of paraffin derivatives—the *carbohydrates*. The term has already been defined, and when we discussed formaldehyde reference was made to the theoretical fashion in which we may imagine the carbohydrates to be synthesised in plants—which, until recently, were their sole source. Lately, however, the artificial synthesis of certain carbohydrates has been added to the achievements of synthetic chemistry, and the noteworthy fact is, that it is formaldehyde from which the chemist starts. When a solution of formaldehyde in water is shaken with milk of lime and filtered, there is produced a substance called *formose*, which is itself none other than a carbohydrate or mixture of carbohydrates, and has the same empirical formula as the typical sugar, $C_6H_{12}O_6$.

We cannot here discuss the remarkable work which has been done upon the constitution and chemical relations of the sugars and their derivatives. Chemists have found, however, that these carbohydrates must really be looked upon as complex examples of other paraffin derivatives, which we have already studied. Some of them are really alcohols, some are aldehydes, some are ketones, and so on.

Dextrose or Glucose. This very important and typical sugar has the empirical formula $C_6H_{12}O_6$. It occurs in many fruits, and is produced in the blood in large quantities in the disease known as *diabetes*. In these cases it is derived from various carbohydrates of the diet, or, failing them, even from proteids, well proving the extreme complexity of the molecular constitution of these last. Glucose is also produced outside the body from other carbohydrates, such as starch, which has the formula $C_6H_{10}O_5$. If this be boiled with a dilute acid, each molecule of starch takes up one molecule of water, yielding dextrose. Cane sugar also yields dextrose if it be boiled with a dilute acid. Its formula is $C_{12}H_{22}O_{11}$, and this, plus a molecule of water, yields two molecules of $C_6H_{12}O_6$. As we shall see, however, they are not both molecules of dextrose, though they have the same formula, for the product is found to consist of two sugars, one dextro-rotatory—*dextrose*—and the other lævo-rotatory—*lævulose*. The net action of the mixture, however, is lævo-rotatory, whereas the original cane sugar was dextro-rotatory, and thus the cane sugar is said to have undergone the process of *inversion*.

Lævulose is found to accompany dextrose in fruit and in honey. Both of these sugars are readily decomposed by yeast, yielding alcohol and carbonic acid, as we have seen.

Tests for Glucose. The presence of glucose in the secretion of the kidney indicates its excessive presence in the blood, and is a matter of extreme importance. Thus chemical tests for glucose have been very carefully investigated. The most familiar of these consists in the employment of what is called "Fehling's solution." This consists essentially of cupric oxide, CuO, which is reduced, under the influence of glucose, into cuprous oxide, Cu_2O, forming a red precipitate. Various other bodies besides glucose, however, may effect this reduction, and, therefore, other tests are necessary. One of the best is the fermentation test, which is carried out by the use of yeast ferment.

Cane Sugar and Milk Sugar. We have already seen the formula of cane sugar or *saccharose*—the characteristic sugar of the sugar-cane, the beet, and other plants. This extremely valuable food is not utilised in the body as such, but as glucose—the final form in which the body utilises all its carbohydrates. Cane sugar is not capable of fermentation until it has been hydrolysed to form dextrose and lævulose. Reference has already been made to *lactose* or milk sugar, which has the same formula as cane sugar. Its sweetness is not very marked. It is less soluble in water than most sugars, and it is very resistent to fermentation, being thus specially fitted for milk.

Starch and Cellulose. If we examine a potato through the microscope, we find that it consists of a large number of granules of starch bounded by a tough wall. The contents of the granules are often known as *granulose,* while their walls consist of *cellulose.* Both have the empirical formula $(C_6H_{10}O_5)_n$. Cellulose is entirely indigestible by any ferment in the body, and thus the value of boiling a potato consists in the splitting of the starch granules so that the digestive juices can act upon the starch which they contain. Starch is the pre-eminent form in which vegetable life stores its energy. The "n" in its empirical formula doubtless corresponds to a very high number, and there are very many substances which have similar formulæ and may be regarded as modifications of starch. Among these is *dextrin* or British gum, a yellow powder which can be produced by heating starch to 200° C. It is soluble in water, and can be chemically distinguished from starch by the fact that it does not yield, with tincture of iodine, that intense blue colour which anyone can see for himself who drops the minutest trace of the tincture on his collar. The animal body also contains a substance called *glycogen,* which has the same empirical formula as starch, and is sometimes called *animal starch.* It is produced from glucose, and stored up in very large quantities in the liver, which can hydrolyse it again into glucose and serve it out in the latter form to the blood as a source of energy, according to need.

Digestion of Starch by Hydrolysis. Starch itself is readily converted into sugar outside the body by boiling with dilute acids, and also by the action of a ferment called *diastase* which, as we have seen, is found in the barley grain and in other germinating seeds. The starch first changes into dextrin and then into dextrose. A similar ferment occurs in the saliva, where it is known as *ptyalin.* An essential part of proper treatment of the food consists in due mastication, which means due admixture of the food with the saliva. Thus swallowed, the starch of the food undergoes change by hydrolysis into sugar in the stomach for twenty minutes or half an hour, before the process is arrested by secretion of hydrochloric acid by the stomach wall. The pancreas or sweetbread also produces a very much more powerful ferment, called *amylopsin,* which is poured into the bowel and converts all the starch hitherto undigested into dextrose, in which form it is absorbed.

We have here discussed only the most important of the large group of substances which may be classed as the carbohydrates and their derivatives. A point necessary to be emphasised is that we must not allow ourselves to be deceived by the name carbohydrate, nor by the apparent simplicity of the empirical formulæ of these bodies. Even if we consider formaldehyde itself, which has the ideal empirical formula of a carbohydrate, we find that its constitutional formula is $HCOH$, and that it is thus in no sense whatever a hydrate of carbon. Perhaps the best value that we can attach to this name to-day is the warrant which it appears to afford for the very probable theory that the beginning of the synthesis of the carbohydrates by the plant is to be found in the union in its leaf of the carbon which that leaf has dissociated from carbonic acid of the atmosphere with water which has been sucked up by its roots from the soil.

A New Group. We have now devoted all the available space to the paraffins and their countless derivatives. We now turn to another large group of bodies which are sharply distinguished from the paraffins by the condition of their carbon atoms. In the typical paraffin, which is methane, we find that, so to speak, all the four-handed carbon atoms are holding something. This is true of all the paraffins and their derivatives. But we must now describe a number of paraffins which are described as *unsaturated,* in order to indicate the fact that all the hands of their carbon atoms are *not entirely* occupied. If, for instance, we take the second paraffin, *ethane,* we see that the two atoms of carbon are united to one another by means of a single hand on the part of each, the other three hands of each being occupied with a hydrogen atom. But there is another substance called *ethylene,* which also contains two carbon atoms, but which has the graphic formula $H_2C=CH_2$. Here we find that the carbon atoms are *doubly linked* to one another, but, as ethane has proved for us, the second link is superfluous; one would suffice, and thus it is that these bodies are capable of combining with other atoms directly, thus becoming saturated, as the phrase goes; they are therefore known as *unsaturated compounds.*

The name applied to ethylene and the other members of its series is the *olefines,* and we can assign to them a general formula as we did in the case of paraffins. It is C_nH_{2n}. If the reader does not remember the general formula of the paraffins, so that he can mentally compare it with this, he should look it up.

Various Olefines. The first of the olefines should have the formula CH_2, but does not exist by itself. It is called *methylene.* We have already stated the formula of the second, *ethylene,* often known as *olefiant gas.* If we adopt measures which seem likely to result in the formation of methylene, we always find that its molecules pair up, so to speak, so that we get ethylene instead. This body may be prepared in many ways, as, for instance, the interaction of ethyl iodide and caustic soda. This results in the formation of ethylene, sodium iodide, and water. The reader should write the equation. It is also produced by the distillation of ordinary alcohol with excess of sulphuric acid. Hydrogen ethyl sulphate, as we have already seen, is formed, and if this undergoes decomposition, sulphuric acid and ethylene result, thus:

$$HC_2H_5SO_4 = H_2SO_4 + C_2H_4.$$

Olefiant gas is also produced in the destructive distillation of wood, coal, resins and fats, its production being due to the decomposition of the methane evolved from these bodies. It is one of the most important constituents of coal gas, being very inflammable, and burning with a luminous flame. (It is worth noting, however, that recent study of the luminosity of flames shows that this depends, much more largely than used to be supposed, upon the incandescence of solid particles within them.)

Characters of Olefiant Gas. Ethylene is a colourless, pleasant-smelling gas, very slightly soluble in water, but somewhat more so in alcohol and ether. Under the influence of cold and pressure it becomes liquefied, and its subsequent evaporation from this state is largely used for the production of extreme degrees of cold. The words *olefine* and *olefiant* mean oil-making, and ethylene was called olefiant gas because, when it becomes saturated by the addition of two atoms of chlorine, yielding $C_2H_4Cl_2$, or ethylene chloride, the product is an oily liquid; but our previous study of the oils will have shown the reader that, despite their names, the olefines have nothing to do with them. The other olefines, such as propylene and butylene, need not here be discussed. In general, the olefines may be converted into paraffins by the action of nascent hydrogen, as we should expect. This soon catches on, so to speak, to the scarcely occupied hands of the doubly linked carbon atoms. As in the case of the paraffins, we find that as we pass up the series of olefines successive members are found to be liquid, and, later, solid.

Oleic Acid. On account of its relation to the olefines, we may here mention oleic acid, $C_{17}H_{33}COOH$, which has already been referred to, in our discussion of the fats, but which, as we saw, is not a fatty acid, being related rather to the olefines than to the paraffins. This acid exists, in combination with glycerine, in most fats and oils, especially the non-drying oils. The acid itself is a soft solid below the temperature of 14° C. We have already seen that its sodium and potassium salts are the chief constituents of soaps. The oleate of lead used to be used in surgery as *lead plaster*—sometimes called *lead soap.* It can readily be produced by rubbing litharge or PbO and olive oil together in a mortar, or by boiling the oxide with water and olive oil. Olive oil is an impure oleate of glyceryl, and the products of the reaction are lead oleate and glycerine.

Acetylene. There remains only one other gas which we need study before we pass on to an entirely new series of organic compounds; this is the gas known as *acetylene* or *ethine.* It has the formula C_2H_2, and may be prepared in various ways. The elements unite directly if carbon be raised to a very high temperature in the presence of hydrogen. This discovery was made by Berthelot, in the year 1859, and is of historic interest since it formed the first stage in his artificial synthesis of alcohol. Acetylene is also produced by an incomplete combustion of hydrocarbons, as, for instance, methane. Part of the hydrogen of the methane is oxidised to water, and acetylene results. In practice, the acetylene is absorbed by an ammoniacal solution of cuprous chloride, forming a somewhat remarkable explosive compound of a red colour known as *copper acetylene.*

The gas may also be produced by the interaction of chloroform and metallic sodium. The reader should write out the equation showing how two molecules of chloroform and six atoms of sodium yield common salt and acetylene. The empirical formula of this substance throws no light upon its extremely interesting constitution. Its two carbon atoms must be regarded as united with one another by means of not one hand apiece, as in the case of ethane, nor two hands apiece, as in the case of ethylene, but three hands apiece. This triple bond is the characteristic of acetylene and its allies.

Characters of Acetylene. Ethine is an evil-smelling, colourless gas, and is a normal constituent, in varying degrees, of coal gas. It burns with an extremely luminous flame, which endows it with great value as an illuminant. Unfortunately it cannot be stored with safety in its liquid form, which is obtained by cold, or pressure, or both, since it is extremely liable to explode.

The various means of making acetylene which we have quoted have all been superseded in commerce by another process, which was first discovered by Wöhler. This chemist was the first maker of the compound known as the *carbide of calcium*, and he found that this compound was decomposed by water with the formation of lime and acetylene. Carbide of calcium is nowadays formed in the electric furnace by the direct union of the purest possible lime and coke. It is a crystalline solid, stable in dry air, but decomposed by the smallest quantities of moisture. The equation for the decomposition is simplicity itself:

$$CaC_2 + H_2O = C_2H_2 + CaO.$$

Needless to say, the lime unites with more water to form calcium hydrate.

Acetylene itself has definite poisonous properties, but some of the impurities which constantly occur in it, such as carbon monoxide and phosphoretted hydrogen, are worse. Great improvements have lately been made in the process of purifying acetylene before its consumption. Great improvement has also been made in the manner of its combustion. When the right kind of burner is employed, this gas yields a flame which, for brilliance and beauty, is equalled by none of its competitors. Every reader is familiar with it as an illuminant for the head-lights of motor-cars.

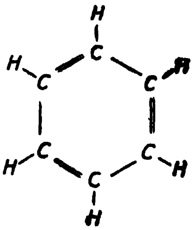
The Aromatic Group. We now turn from the paraffins, the olefines, and their derivatives, to an entirely new series of hydrocarbons, the typical representative of which is *benzene*. Adopting the widest possible classification, we may say that the bodies we have hitherto been discussing are of the fatty group, but that benzene and its allies belong to the *aromatic* group. The empirical formula of benzene is C_6H_6, and we may write this in a more generalised form, C_nH_{2n-6}. Hydrocarbons of this series, with their derivatives, belong to the aromatic group, a large number of them being obtained from aromatic substances, such as balsams and resins. The leading characteristic of this group, as a whole, is the relative stability of its compounds as compared with those of the fatty group. Here, however, we may quote Professor Meldola, regarding the relation that exists between these two groups, and the quotation will show us the propriety of concluding our study of the fatty group with acetylene:

> “The division here made between fatty and aromatic substances must not be regarded as one having a sharply defined boundary line. In point of fact, the two series merge into one another, and compounds belonging to one group can be transformed into compounds of the other. Thus, benzene, the typical hydrocarbon of the aromatic group, can be formed directly from ethine or acetylene, a hydrocarbon of the fatty group, by the polymerisation effected by heat:
>
> $$\underset{\text{Ethine}}{3C_2H_2} = \underset{\text{Benzene.”}}{C_6H_6.}$$

The Characters of Benzene. Let us first consider the sources and characters of benzene, and then let us see whether its chemical reactions will enable us to write its graphic formula. It is often known as *benzol*, and the name is derived from the gum resin known as *benzoin*, derived from a tropical tree, and the source of the famous antiseptic medicament known as Friar's Balsam. Commercial benzoin, however, is obtained from coal-tar, which is, indeed, the principal source of most of the members of this series. Coal-tar is the product left behind when coal is distilled so as to produce coal-gas. This coal-tar or coal-tar oil is of a very complex composition. It is first of all neutralised with soda and with a weak acid, so that any acids or bases present in it may be removed. The oil is then distilled, or fractionally distilled, certain portions of it coming over at low temperatures and others at higher temperatures. The “light oil” which distils over first consists mainly of benzene. This is a mobile, colourless liquid with a characteristic but not offensive odour, lighter than water, boiling at about 80° C. and freezing at 5° C. It is very nearly insoluble in water. In accordance with the generalisation already laid down, it is extremely stable, and can scarcely be oxidised. It burns with a fairly brilliant flame. Under certain conditions it can be made to take up six atoms of hydrogen, yielding a body the formula of which is C_6H_{12}. Or it may take up six atoms of chlorine, under the influence of light, giving a body with the formula $C_6H_6Cl_6$, or certain of its hydrogen atoms may be replaced by halogen atoms, as, for instance, in di-chloro benzene, $C_6H_4Cl_2$.

Graphic Formula of Benzene. All these reactions, and a host besides, including the formation of benzene from acetylene—as we have seen—by a sort of condensation in its molecules when they pass through a red-hot tube, led the chemist Kekulé to construct a graphic formula of benzene, the truth of which is now generally accepted by chemists, and the evidence in support of which might be extended over many pages. This celebrated formula is known as the *benzene ring*, the theory being that the six carbon atoms are united with one another in a closed ring or chain, on the outside of which, so to speak, are attached the six hydrogen atoms, one to each atom of carbon. If the reader draws such a formula for himself without any further hints from us, he will detect a flaw in it, and he will do us a favour if he tries to find out this flaw for himself before reading any further. Let him remember the valency of carbon—and consider.

The Necessary Correction. Plainly, it will be necessary for us to suppose that each carbon atom is in a different relation to its two carbon neighbours. To its neighbour on the one side it is united by only one hand, but to its neighbour on the other side by two hands, while the fourth hand is occupied, obviously, with an atom of hydrogen. Thus, the formula, as the reader originally wrote it out, can be corrected by simply doubling every other line between the carbon atoms, thus:



This discovery of the constitution of the benzene molecule occupies an important place in the history of organic chemistry. We may here quote, in conclusion, one simple illustration of the applicability of this formula to the facts. Let us take, for instance, benzene hexa-chloride, $C_6H_6Cl_6$, and see how its formula must be written. Plainly, all we need to do is to suppress the double bonds in the carbon ring, leaving each of the six atoms united to its fellows on each side by one hand only, and thus we shall see that hands are available for the addition of a chlorine atom beside the hydrogen atom all the way round. We may note the parallelism between this and ethylene chloride. Our graphic formula answers other requirements with equal satisfaction, and in all subsequent study of the aromatic compounds we shall take its truth for granted.

Practical Uses of Benzene. We have outlined very briefly the pure chemistry of benzene, and have seen how great its interest is. We must now consider its practical uses, which we can divide under three headings. In the first place, it is a very valuable solvent for a large number of organic compounds; secondly, it is the starting-point of the great industry concerned with the manufacture of dyes from coal tar; thirdly, it is the source of a host of derivatives which we may call the *benzene derivatives* or *aromatic compounds*, and which are of great practical utility. As may readily be imagined, the number of different kinds of molecules that may be derived from one so complex as that of benzene is illimitable. We may choose two of the simplest possible examples, and then consider the product. Just as in the case of methane we find it possible to replace a hydrogen atom by hydroxyl, so we find it possible in the case of benzene. The molecule is a symmetrical one, so that it matters not which hydrogen atom we require it to replace. The formula of the body just produced will, of course, be C_6H_5OH. Its technical name is *phenol*, the group C_6H_5 being known as *phenyl*, while its common name is *carbolic acid*. To take another instance, let us substitute the now familiar group carboxyl for a hydrogen atom, giving us the formula C_6H_5COOH. The body thus obtained is known as *benzoic acid*. Lastly, let us replace one of the hydrogen atoms with the group NH_2. We shall then have a body with the formula $C_6H_5NH_2$, chemically known as *phenylamine*, and commonly as *aniline*.

Carbolic Acid. Of these bodies, perhaps the most important and interesting is carbolic acid or phenol. In practice it is obtained by the treatment of heavy coal-tar oil with soda or potash. If an acid be then added, the carbolate of soda is decomposed and the carbolic acid comes over. We call this body an acid, but the reader will understand that it may also be regarded as an alcohol. It certainly is an acid in that it forms salts, but it does not redden litmus paper. We have just as good a title to call it *phenyl alcohol* as carbolic acid. The commercial product is extremely liable to impurities which commonly give it a reddish colour, and many of these are more poisonous and more irritant than carbolic acid itself—the use of cheap carbolic acid in hospitals being thus an unsatisfactory kind of economy. Pure carbolic acid crystallises in fine colourless needles ; it melts at 35° C., and boils at 187° C. It is highly soluble in alcohol, ether, and oils, but is only very slightly soluble in water. The solution commonly known as " one in twenty," is almost the strongest that can be obtained. On the other hand, one part of water with ten of carbolic acid produces what is practically a pure liquid carbolic acid. Even in its aqueous solution this substance coagulates albumin, and it exercises a very powerful caustic action when concentrated, even though it is not acid enough to redden litmus paper.

Uses of Carbolic Acid. We owe to the late Professor Calvert, whose name survives in the famous firm of that name, the possibility of the manufacture of carbolic acid in a pure form fit for use in medicine and surgery. A crude carbolic acid is also largely used for preserving railway sleepers, its value depending upon its antiseptic properties. Carbolic acid is also used as a source of dyes, though it is of less importance in this respect than aniline. Picric acid, for instance, is a brilliant yellow body produced by the addition of small quantities of nitric acid to carbolic acid. Lately, dilute solutions of picric acid have been found very valuable in the treatment of burns.

Among the convenient tests for carbolic acid may be named the violet colour, gradually turning brown, which it yields on the addition of the minutest quantity of a dilute solution of ferric chloride ; and the white precipitate, soluble in excess of phenol, which it yields with bromine water.

Carbolic acid is a protoplasmic poison, directly interfering with all life. It probably acts in virtue of its coagulation of albumin. It will always be the classical antiseptic, since it was employed by Lord Lister in the beginning ; but though it is still used in enormous quantities, it is very far from ideal. It is relatively weak, a solution of at least 2 per cent. in strength being necessary to kill the average microbe. Dissolved in oil, this acid entirely loses its antiseptic properties ; carbolic oil should therefore be dismissed from surgical service. The drug is very readily absorbed by the skin—even the unbroken skin—provided, of course, that it be applied in a very dilute solution. This property makes it very valuable in the treatment of such disorders as a whitlow, since we can imagine the carbolic acid, so to speak, chasing the microbes under the skin and killing them.

Toxicology of Carbolic Acid. It has already been noted that this acid acts as a poison independently of its local caustic properties, thus resembling oxalic acid. Certainly the acid may kill, in consequence of its action upon the stomach, and in cases of poisoning it is desirable to neutralise it with chalk on the spot, or to dilute it with white of egg, so as to avert its local action ; but it has to be remembered that any soluble carbolate circulating in the blood will surely kill in consequence of its action upon the nervous system. It is necessary, therefore, to consider further the history of carbolic acid after absorption, and to see whether there are any chemical means by which the consequences of its absorption may be neutralised. The question is a very important one to the surgeon, because he uses carbolic acid so extensively, and because it is necessary for him to be able to control immediately any undue consequences of its absorption. But it is also of great importance to the public in general, because the modern and wide employment of carbolic acid as an antiseptic and disinfectant has lately made it an extremely frequent cause of death by poisoning. Indeed, this dangerous acid is so easily obtained, on any of a hundred pretexts, that it has lately come to rank third among the poisons that most frequently cause death in this country.

The True Antidote. On close study it is found, then, that carbolic acid entering the blood undergoes oxidation in part into various innocent substances. The whole of the rest of it is converted into sulpho-carbolates, sulpho-carbolic acid being obtainable outside the body by the addition of sulphuric acid to carbolic acid. These sulpho-carbolates are quite innocent, and, therefore, so long as there remains any free sulphate in the blood, the absorption of carbolic acid is free from any danger. The dose of carbolic acid which causes death by its action after absorption is one which is so great that all the sulphates in the blood are used up, with the consequence that carbolates themselves are allowed to circulate.

This discovery is of the greatest practical importance. In the first place, it provides us with a test of safety. It is a simple matter to ascertain whether a patient who has been treated with carbolic acid externally or internally is excreting free sulphates by his kidneys. If free sulphates are absent, then danger is at hand. If they are present, the treatment may be continued. Secondly, we are now provided with a true chemical antidote to carbolic acid even after absorption into the blood. The whole danger lies in the using up of the available sulphates. We must therefore provide more sulphates. Any reader of this paragraph may have the opportunity of saving a life thus threatened—suicidally or otherwise—by the administration of, say, an ounce of magnesium sulphate—the Epsom salts which can be bought at any chemist's shop—dissolved in a tumblerful of water. The most rapid means of treatment consists in the injection into a vein of a sterile solution of half an ounce or more of sodium sulphate.

Nitro-substitution Compounds. The action of nitric acid, or a mixture of nitric and sulphuric acids, upon benzene and its allies is to form nitro-substitution compounds, of which the simplest is known as *nitro-benzene*, and has the formula $C_6H_5NO_2$. This is a yellow liquid with a pleasant smell closely resembling that of oil of bitter almonds which has the formula C_6H_5COH. Nitro-benzene is sometimes substituted for oil of bitter almonds in the manufacture of confectionery, and has thus caused death. There is no objection, however, to its use in perfumery. Di-nitro-benzenes are known in which two hydrogen atoms have been replaced by the nitro-group.

Picric acid, to which we have already referred, is a nitro-substitution compound of carbolic acid, its technical name being *tri-nitro-phenol*, three nitro groups having been substituted for three hydrogen atoms of the phenol. Its salts are called *picrates*.

Aniline. The body which has the formula $C_6H_5NH_2$—much better written thus than as C_6H_7N—is often known as *phenylamine* or *amido-benzene*. The name is derived from *anil*, the Portuguese word for indigo, since, in 1840, it was shown that this body could be produced by the action of caustic potash on indigo. It is a heavy, oily liquid, colourless, and has an unpleasant smell. It produces a greasy stain upon paper, but the oil is so volatile that this soon disappears. It burns readily and is oxidised on exposure to the atmosphere, turning a deep brown. It is a poison, and it has been shown that the poisonous action of nitro-benzene also is due to its reduction in the stomach with the formation of aniline.

As long ago as 1835 it was known that aniline produced a fine blue colour when treated with calcium chloride. But it was not until considerably later that this property of the body was turned to practical use. We shall shortly discuss the subject, because it affords an extremely significant lesson of national importance.

The Manufacture of Aniline. A substance of such great commercial importance has to be manufactured as cheaply as possible on the large scale, and the method employed depends upon the production of nitro-benzene, a body which we have already studied. This, having been produced from coal-tar, is reduced by nascent hydrogen which is evolved by the interaction of iron filings and dilute acetic acid. This is one of those processes in which certain of the reagents can be used over and over again. In this case ferrous acetate is produced, and then ferric acetate, nascent hydrogen being meanwhile evolved, and then the ferric salt is converted into hydroxide and free acetic acid again. From this last the aniline is distilled over. The equation representing its formation is

$$C_6H_5NO_2 + 6H = C_6H_5NH_2 + 2H_2O.$$

The commercial product, however, is not pure aniline, but a mixture of aniline with an allied body called *toluidine*, which is closely allied to it. The presence of the toluidine or toluidines is necessary for the production of colours from the aniline.

The Work of Perkin. The famous name in the history of this subject is that of Sir W. H. Perkin, F.R.S., the jubilee of whose great discovery has recently been celebrated in this country. It was in 1856 that Sir William was led to study the effect of mixing the sulphate of aniline with bichromate of potash in equivalent proportions. After some hours, when the reaction is complete, the black precipitate which is formed is washed and purified, and is found to consist essentially of the dye best known as *mauve*. Sir William Perkin patented this process at the age of 18, and it was in commercial employment in 1857. From that year dates the foundation of the coal-tar colour industry. Sir William met with many difficulties, but conquered them all. He discovered later a method by which he could synthesise the red dye known as *alizarin* in a fashion commercially practicable. This country long benefited by his work on this subject. In 1862 it was prophesied by Professor Hofmann, Perkin's first teacher, that "instead of disbursing her annual millions for these substances, England will, beyond question, at no distant day become herself the greatest colour-producing country in the world; nay, by the very strangest of revolutions, she may ere long send her coal-derived blues to indigo-growing India, her distilled crimson to cochineal-producing Mexico, and her fossil substitutes for quercitron and safflower to China, Japan, and the other countries whence these articles are now derived."

A Lost Industry. Thirty years ago it could be said that Hofmann's predictions were realised, but they are not true to-day. The practical extinction of the coal-tar colour industry in the land of its birth is the best-known example of an industry lost to a country by sheer carelessness and laziness. Year by year the industry has become more and more important, more and more competent and profitable. Since Perkin turned his attention to pure chemistry, having given this country a start which should have been worth millions of pounds, new coal-tar colours have been discovered with increasing frequency. At the present moment the industry founded by this Englishman is a German industry, and a source of enormous and ever-increasing profit to the enterprising people who believe in science. Incidentally, their vigour has destroyed, or is on the way towards the complete destruction of, certain industries of great importance to our Indian Empire, such as the cultivation of the indigo plant. In this country, the record of which in science is unparalleled in ancient or modern times, and is probably equal on the whole to the entire scientific record of the rest of the world put together, science and commerce are hardly on speaking terms. The manufacturer has a process which yields him profit. If he be a German he is not content therewith—some of the large German firms employing more young trained chemists apiece than are similarly employed in the whole of this country. Thus the German goes on while the Englishman stands still. Sir William had done far more than his share, but since the date—1874—when he turned to other subjects, those who are so deeply indebted to him have done practically nothing. The inevitable consequence followed. The industry went where its profits were earned. It is now a German industry, and Sir William's reflections on this subject in the year 1906, which still finds him hale and vigorous, would probably make remarkably interesting reading.

The Warning of Sir William Huggins. Having drawn the reader's attention to what must surely long remain a classic instance of a national loss thoroughly well deserved, we make no apology for quoting a paragraph, which cannot be too widely read, from a recent presidential address delivered before the Royal Society by one of the greatest men of science now living, Sir William Huggins. Referring to the testimony given by thirteen Fellows of the Royal Society before a recent Committee of the London Technical Board, Sir William says:

"The testimony of these expert witnesses was all but unanimous in showing that one of the most obvious shortcomings affecting our national industries—namely, the relatively small number of suitably trained men possessing the technical knowledge and creative skill needful for the improvement of our chemical, electrical, and engineering industries, must be regarded as a secondary symptom, following upon the smallness of the demand for such men. Further, that this smallness of demand is itself the necessary consequence of a wider and more serious state of things, which is affecting injuriously all our national activities—namely, the absence, speaking generally, of a sufficiently intelligent appreciation on the part of the leaders of the nation, whether as legislators, capitalists, manufacturers, or merchants, of the supreme importance of scientific knowledge and scientific methods, not only for the successful carrying on and improvement of all industrial enterprises, but also, and not less so, for the working out of all national problems whatever, whether of education, of economics, of hygiene, or especially of national defence in the construction of our armaments by sea and by land, and the training of our soldiers and sailors."

A Parallel Case. The text upon which we are now preaching may be illustrated in many ways—one of the most striking being the recent demonstration that an essential factor in the triumph of Japan in the late war was her adherence to the principles of hygiene, prevention of infectious disease, and antiseptic surgery, which the world owes mainly to this country, and which were so scandalously neglected, to the loss of thousands of lives and millions of pounds, in our own late war. But even this example is not quite equal in irony to that afforded by the recent celebration of Perkin's discoveries, while the people among whom the discovery was made and to whom he belongs yearly pay enormous sums to Germany for what are really the products of his brain. It is our earnest hope that the readers of the SELF-EDUCATOR may have cause to regard themselves as fortunate exceptions in respect of that system of education in which the thoughtful mind of Sir William Huggins has discerned the true underlying cause of the nation's failure to appreciate and to profit by the achievements of the individuals whom it is foremost in producing

Advance in Coal-tar Dyes. And now let us briefly consider the progress of the study of aniline during the last 30 years. An important step in this industry was taken when Hofmann discovered the nature of the coal-tar dye known as aniline red or magenta, which he found to be a salt of the base now known as *rosaniline*, and manufactured from aniline containing certain proportions of toluidine. Hence, there are now obtained rosaniline blues and violets, aniline green, and a certain proportion of what is called *aniline yellow*. These dyes are now used for many other purposes besides dyeing, and their use will steadily extend, for they are, in general, superior on every ground to their natural rivals. Their discovery should be a source of congratulation to the artist and to those who are sensitive to visual beauty, and should give such persons a friendly feeling for chemistry. It is not our business to discuss here the technology of the subject, which is of very great complexity, and which, under the conditions habitual in Germany, undergoes improvement and advance every day.

BELTING MANUFACTURE

Leathers Suitable for Belting. Cutting, Trimming, Shaving, Building, Splicing, and Joining Belts. Link Belting

By W. S. MURPHY

MANY beltmakers tan and curry the hides for their own use; but their processes differ in no way from ordinary tanning. In general, it may be said that the raw material of the beltmaker is the finished product of the tanner and currier.

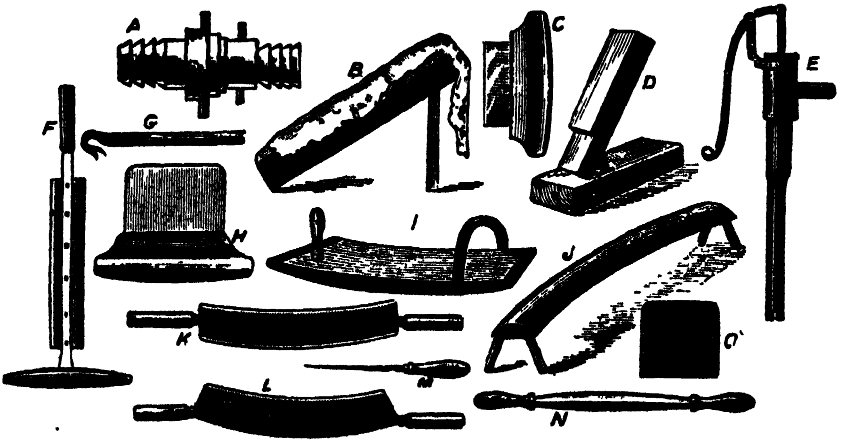
Belt Leather. For the finer and heavier classes of belts, however, special hides are required. Perhaps the best hides for heavy belts are those of Highland cattle, and next come the Shorthorns. From the carcase of a stout Highland bull you can get a hide giving about 1 in. of leather thickness—that is, after epidermis and flesh layer have come off.

Giraffe Hides. Among the hides of wild animals useful for belting are the pelts of the giraffe, the gnu, and the quagga—all abounding in British South Africa. Giraffe leather has great density of fibre, and stands the wear and tear of shifting, twisting, and sudden pulling in a remarkable way.

Rawhide Belts. As shown in the table of tensile strengths [page 3532], the best tannages are chrome, alum, and "rawhide." The last is simply the method of the backwoodsman made into a factory system. After being thoroughly dried by exposure to the air, the hide is soaked in pure water for fifteen days. The hair now comes readily off on the unhairing knife. Next the hide is stretched on frames, and piled one above the other, in a dark, well ventilated shed to dry again. Shaving the flesh side, the curriers break-over and stuff with oil. When seasoned, the hide is ready for being made into belting. We have heard, with some surprise, many tanners praise that method of preparing leather, though, if it were adopted universally, their occupation would be gone. One thing is certain—"rawhide" leather retains all its fibres and gelatinous substance unimpaired, and has all the natural strength and tenacity of the hide.

Beltmakers as Tanners. One reason for so many beltmakers undertaking tanning and currying as well is that overtanned hides are almost useless for belts, and the fault is not easily detected if the tanner chooses to do a little doctoring. The beltmaker's tools [25] for currying are similar to the tools used for tanning leather for other purposes. Overtanning reduces the tensile strength of leather by about one half. It is the interest of the tanner to win the favour of a customer as important as the beltmaker, and he will no doubt do his best; but the beltmaker naturally knows the need of his trade better than the tanner, and can seek out new kinds of hides and methods of tanning with greater probability of hitting the mark.

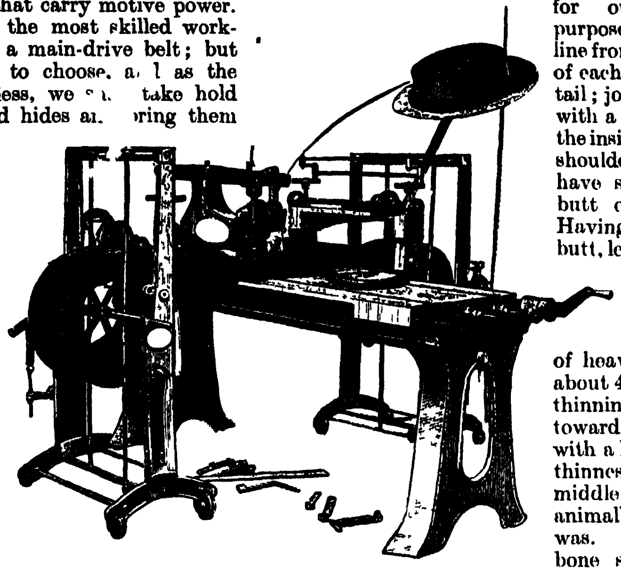
Complete Belt Factory. Looking at it from the outside, people think of the beltmaking trade as a very small one of limited range; but we have quite a different opinion. On the one hand, the trade extends into the tanning, and on the other it touches on cotton manufacture, indiarubber, and rope-making. We sometimes come upon contracts which cannot be filled by leather belts alone. Cotton belts, or belts of rubber-filled canvas, may be absolutely essential, and must be procured. If the profits of contract are not to be frittered away in paying high prices to other manufacturers for special work—prices to which they are perfectly entitled—the beltmaker must do his own weaving. A complete belt factory, therefore, is not a small undertaking.



25. TOOLS FOR TANNERS AND CURRIERS
a. Gun-metal union for base pipe *b*. Fleshing, scudding, or unhairing beam *c* Setting slicker *d* Shaving beam *e*. Tanners' hand pump *f*. Shaving knife *g*. Pit hook *h* Whitening or buffing slicker *i* Graining board *j* Pinning beam *k*. Fleshing knife *l* Fleshing-knife for cleaning *m*. Steel for sharpening *h* *n*. Striking pin *o*. Loose whitening or buffing blade for *h*

On the one side, you have the hide sheds, lime pits, tan pits, and currying shops; on the other are the cotton canvas looms, and in the midst are belt-making shops, where these materials are formed into the bands that carry motive power.

Stretching. Only the most skilled workmen are entrusted with a main-drive belt; but as we are at liberty to choose, and as the greater includes the less, we shall take hold of a batch of Highland hides and bring them through to the finished belt. The curriers have brought them to the drying-room, and hung them up; but we must not allow the hides to dry completely. As soon as the wetness has gone, the heavy sheets of leather must be stretched. If the hides are taken in from an outside tan works, they are dry, of course, and must be softened and damped. Take one of the stretching frames and lay it on the bench. In structure the frame is very simple. The sides are strong wooden battens; at top and bottom a pair of screw clamps cross the frame and hold on to the sides by slide joints. In the centre a thick worm-screw runs through holes in the under bars of the clamps. Lay the hide, evenly damped throughout, in the frame, neck to the head and tail to the bottom; screw the clamps firmly down; turn the centre screw till the hide is drawn tight as the head of a drum and tighter. All the hides of the batch must be treated in this way, and then left to dry. Leather shrinks in the drying, and the already stretched hide is drawn still tighter.



26. WIRE SEWING MACHINE FOR BELTING

Rules to be Noted. If the stretching is done properly, very little trouble will arise on that account during the working life of the belt. We need hardly point to the importance of this. Young workers, however, sometimes require the caution that "strength and ignorance" are not the equipment of a beltmaker. You may be gifted with the strength of a young bull, but it is not necessary to exert the whole of it in stretching leather. Some judgment is needed as well. With such an instrument as the stretching frame, a strong man could rack the hide, but that is not the purpose of it. The long lever has been devised to make hard work a little easier. So, too, with the damping and drying; the natural force of shrinkage is called in, not to break the frames, but to lighten the stretcher's labour. Muscles are spared in order to afford brain a chance. Accidents will happen, of course, and even the most careful workman will occasionally hear the rending crash of a drying frame breaking under the strain; but experience quickly enables the worker to understand the stretch required by the average hide.

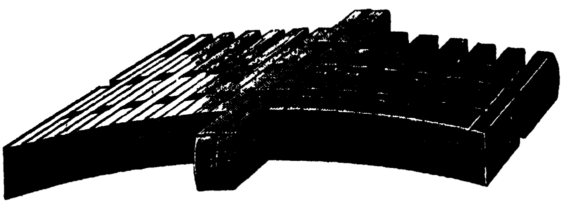
Cutting the Hide. The sole-leather manufacturer rejects a considerable portion of the hide, but we reject a good deal more. In fact, only about one-third of the hide is useful for our present purpose. Draw a line from the middle of each flank at the tail; join these lines with a third across the inside of the fore shoulder, and you have sketched the butt of the belt. Having cut out the butt, let us see what we have got. It is an almost square piece of heavy leather—about 4 ft. square—thinning slightly toward the sides, with a hard bank of thinness along the middle where the animal's backbone was. This backbone strip should be made the centre of a broad belt if possible, because it is strong and gives the belt a gentle, natural curve inward, hardly perceptible in the finished article, yet secretly effective in aiding the belt to cling to the pulley when working.

Trimming. In the trimming-room all kinds of cutters are provided. Our tool, however, is a huge guillotine cutting machine. The blade, 5 ft. long, is hung in the cross-beam above the table and between the supporting pillars. By means of a gauge at the side we can measure the breadth of the cut to the thousandth part of an inch. The exact size got, and the clamp screwed down, we set the terrible blade going, and it shears down through the leather with irresistible force. One side trimmed, the other is put in and cut to the size.

Shaving. In spite of every care, the flesh side of the leather is rough, and, of course, the hide varies a good deal in thickness all over. We can get rid of the roughness and inequality at one time. Cylinder shaving machines have been provided for the purpose. Section after section of our belt, showing every possible variation in relative thickness and roughness, is run into the machine after it has been properly adjusted, and all come out from under the cylinder as alike as so many bullets. Anyone can learn to work the shaving machine. It is a cylinder covered with knives geared above an adjustable roller. Having been set to the proper thickness, the machine carries the leather against the revolving knives, and a surface as smooth as glass is the result. We often hear of the superiority of machine over hand production, and this is certainly a finished piece of work; but we have seen hand shaving quite as good. A first-class workman will shave a hide as smoothly as any machine yet invented, and his hand is gentler on the leather. The machine is quicker and more reliable; let the mechanic be content with that.

Hand shaving is an accomplishment that never comes amiss to a beltmaker; indeed, a good hand shaver is frequently needed in shops where machinery runs from basement to top flat. Perhaps the best place to learn how to handle the shaving knife is at the whitener's bench in the currying shop. Take the broad-bladed knife, hold the handle with both hands, letting the thumbs grip on the back and the four fingers of each hand rest lightly on the blade. Setting the edge at the proper plane, you curve round with a sweep, reversing the curve at the next stroke. With careful practice a man can learn to shave a dry hide so smoothly that no line of the knife is visible. It is good training for the hand and eye.

Building the Belt. Now we go into the machine shop, and here the practice of beltmakers differs to such a degree that what is right in one shop may be held to be altogether wrong in another. The merest outlines, therefore, are all that can be given. Some beltmakers pride themselves on having invented the machines they use, and the new man in the shop has to learn a part of his trade over again. However, it is all in the way of making belts, and the building up of a belt is the same, whatever may be the way of doing it.



27. TULLIS' PATENT FLEXIBLE CENTRE LINK BELT

First, then, having gathered our pieces from the cutters and trimmers, we begin to build up our big belt.

Splicing. The great belts that fly round on the drive of a dynamo of 500 h.p. appear to be one single piece, but we know that is impossible. We have to build those long things up piece by piece, not one piece more than 4 ft. long. The homogeneity of the belt is accomplished by splicing. For instance, take two pieces of leather, pare the ends of both to a thin edge in a slice of about 4 in., put them together, and you will find, if you have done the paring evenly and equally, that the two make no more than the thickness of the rest of the leather. That is splicing or *skiving*. We have a few skiving machines, all of them quite effective. One, the best we have seen, has a slanting table adjustable to any angle, and driven under a fixed blade. On the table the belt-piece is laid, and the blade shaves off a graduated strip, beginning at a thin edge, and rising to the thickness of the belt. To balance the belt, and make all the pieces lie on a level plane, the skiving is cut alternately on flesh and grain side. The two ends of each piece are exactly half the thickness of the belt, extended over a graded surface, and when the two are put together they make exactly the same bulk as the rest of the belt.

Joining. We have many methods of joining the splices together, those most common being thread sewing, wire sewing, lacing, riveting, and cementing. For single belts, the breadth of which is one piece, we prefer cementing. It makes the neatest job, and lasts as well as any.

Many beltmakers have patent cements of their own, the composition of which they jealously keep secret, but many good recipes are the common property of the trade. The following are representative and reliable:

1. Soak in water just sufficient to cover them, for ten hours, equal parts of common glue and isinglass; gradually bring to the boil, adding tannin extract till the whole takes on a ropy consistency. Apply the cement to the freshly spliced surfaces, join, and clamp them firmly together.

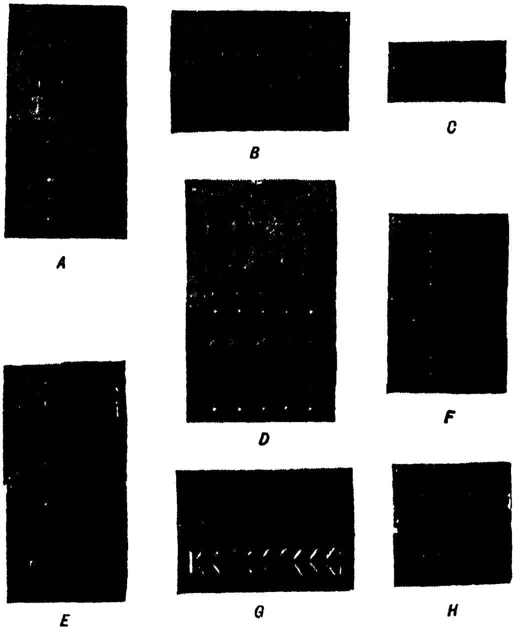
2. Gutta-percha dissolved to the consistency of syrup in bisulphide of carbon makes a strong cement. In applying, first fill up the pores of the leather with the mixture cold. Heat the cement, cover both surfaces, join together, and hammer the joint till it has become firm and cold.

3. Mix ten parts of bisulphide of carbon with one of oil and turpentine; put in as much gutta-percha as will make the liquid thick when it has dissolved. When ready, the cement is a slowly flowing mixture. Before applying this cement, however, it is necessary to clear the surface of the leather from grease. Steep a cloth in strong ammonia, lay it on the piece to be joined, and run it over with a hot iron. Coat the cement over both sides of the joint, join, and put under the press.

Stitching. All the other methods of joining splicings require that holes be bored in the leather. When sewn on the machine [26], the needle does the perforation in the fittest way. Up till very recently, the idea of applying a sewing machine to a belt wider than six inches was regarded as preposterous; but now we see machines joining belts nearly thirty inches broad. Before stitching, either by hand or machine, it is advisable to channel the course of the sewing, so as to protect the threads from friction

Lacing. If lacing be considered the best way of joining a belt, another point comes into prominence. We ought, rather, to say two points—namely, the piercing of the holes and the pattern thereof [28]. Punching holes is altogether discredited, because the force of the punch bruises the leather round the holes, and drilling is now generally adopted. The holes should be drilled perfectly round, and in a V shape, slightly angled. By adopting this shape, you never have more than one hole in the same line across the belt. This spreads the lacing over the belt and gives a firm grip.

Riveting. Extra broad belts require to be built together like the sides of a ship, and here, as there, the rivet is the only sure binder. Riveting calls for a system of splicing of its own. Instead of a broad, graduated band, you make a narrow flange, little broader than the rivet-hole. There are many riveting machines in use, and hundreds of different makes of rivets on the market. The ideal rivet is round, with a broad, thin washer. It must always be remembered that the pull of a belt is lengthwise, and corners or points on rivets will break into the leather in spite of the most ingenious safeguards.



28. BELT LACING

a. Four-inch belt. Double lacing. Stands highest test of tensile strength *b.* Lap belt lacing *c* One-inch diamond pattern lacing *d.* Six-inch double lace with full lace *e.* Four-inch belt with narrow lace *f.* Three-inch belt with narrow lace *g.* Herringbone pattern lap lacing *h.* Two-inch double lacing with narrow laces

Link Belts. Between the swiftly running pulley and the driving belt there is always a cushion of air. In narrow belts this mattered little, but when we began to put on belts six feet up to ten feet broad, the air-cushion became a decided nuisance under certain conditions, notably when swift drives were on. To make a perforated belt was to weaken it enormously. Nature seemed to have put a barrier across the beltmaker's path of progress, saying, "Thus far, and no further." But it occurred to one beltmaker and another—for no one has a monopoly of the idea—that a link or chain belt would solve the difficulty [27]. Moreover, the beltmaker has a lot of offal, that goes into the glue-pot. By adopting the link idea, we at once have a new form of belt and a means of using up our scraps. Scrap leather, it must be said, is good leather, but simply too small for forming a belt out of. The making of link belts is a new and important branch of the trade, and highly interesting.

Making Link Belts. First, the pieces of scrap, of a proper thickness, are put under the die-cutter and cut to size. Next, the pieces are soaked in warm water, and then put under the hydraulic press in a mould. When the pieces come out, they are as hard as iron. Now they are put under the drills, and two rivet-holes bored in each. It is obvious that we can build up any size of belt we like out of these pieces, just as you can make any breadth of chain by putting links together. The method of building up these belts is simple and ingenious. One piece forms the centre, and to each end of this two pieces are riveted. Each of those joined pieces has a rivet-hole free, into which another pair of links can be fixed. The end pieces are half-links, with only one hole, thus giving a flat surface at the finish, and a complete belt.

We have purposely left out of account the numerous kinds of small belts made, because the greater, in this case, includes the less. If you can make a belt for the main drive, the small machine belts will give you no trouble.

Loom Pickers. Before the link belts were thought of, the beltmaker had found a certain kind of outlet for his offal in making engine-washers, loom-pickers, and other wares of that kind. It was for these purposes, indeed, that the die-cutters and hydraulic presses were introduced to a large extent into the belt factory. Loom-pickers require to be light, hard, and of firm consistency. Carefully selected, the leather for the pickers is steeped in oil, cut to shape in the die-cutter, and pressed. The pieces are cemented or riveted together.

Washers. By a process similar, water-proof washers for water engineers of all grades are made, from the rings of the huge hydraulic ram to the washers of the domestic water-tap.

Standing, as the beltmaker does, as a helper of many industries, he sees opportunities of usefulness and profit hidden from other workers in leather. Most of us hold the faith that "There is nothing like leather," but we have not all an equal opportunity of making practical recommendation of our faith.

BAD FOOD AND GOOD AIR

Milk. Cream. Butter. Cheese. Flour. Bread. Meat. Poultry. Fish. Condiments. Jam. Beverages. Air and its Impurities

By Dr. A. T. SCHOFIELD

WE shall here only touch upon those adulterations connected with our food or drink, and that only with extreme brevity; for we regret to say that the subject is so large and complex that a whole book could be filled with it. The difficulty is to find a single article of commerce that is not liable to adulteration.

Milk. There are three principal ways in which this is adulterated—as a rule, by the milk retailer. Adulteration is not so much practised by the wholesale dealer, for according to the report of the Local Government Board, only 17 per 1,000 samples are condemned in the wholesale trade to 125 per 1,000 in the retail.

These three ways are by adding water, by removing cream, and by adding drugs.

WATER. When water is added, the specific gravity is lowered. That of milk is 1·029; as a rule, some cream is removed at the same time and the specific gravity is thus raised, so that milk can be made very poor, and yet the lactometer will show the right gravity. A further test is needed. The total, which must be found by evaporation, should then be 12 per cent. of milk, of which 3·5 should be fat, leaving 8·5 solids *not fat*. If, then, solids are less than 8·5, water is added. For instance, if there are only 7·0 per cent., then $\frac{100 \times 7}{8\cdot5}$ or 82·35 is really milk, showing 17 per cent. of water has been added, and the use of the lactometer and evaporation together will always detect the double fraud.

CHALK. This is not now added to milk, but carbonate of soda, salt, boracic acid, salicylic acid, annatto, glycerine, formaldehyde, naphthol, starch, germs and dirt are put in it.

Most of these drugs, some of which are powerful irritants, are added to prevent decomposition, and the worst is that each person through whose hands the milk passes may add a little, so that the total amount is serious. For instance, it is not uncommon to find a drachm of boric acid (60 grains) in a gallon of milk; the full medicinal dose of which is 5 to 15 grains.

ANNATTO. This is a yellow colouring matter which makes poor milk and cream look richer.

GLYCERINE. This is detected by the excessive sweetness of the solids.

Perhaps, as a whole, the most deleterious substances added are those which are the result of carelessness rather than intention—filth of every description. We are entering fully into this in dealing with food in infancy, and therefore shall only say that in nearly every case it consists of some form of excreta from farmyard sweepings, in addition to ordinary dirt. The one remedy is to purchase milk only from those dairies which are inspected, and which make a special point of delivering pure milk. We must not name them, and can only say that every householder should be sure that the milk that is used is pure.

Cream and Butter. Cream is often thickened with gelatine and starch, coloured and preserved with drugs. Taste and smell should be guides in testing butter. According to analysis, it is generally sold pure, for out of 4,329 samples examined in London, only 321 were found adulterated. But this report is not wholly reliable; for it is impossible to discriminate margarine adulteration by analysis. In Holland, a very special form of margarine is scientifically prepared, and 10 per cent. of it can be mixed with butter without any fear of evidence that could result in a conviction. *Room-butter* or cream-butter is as special an article in Holland as *biene-honig* (bee honey) is in Switzerland, adulteration being so common.

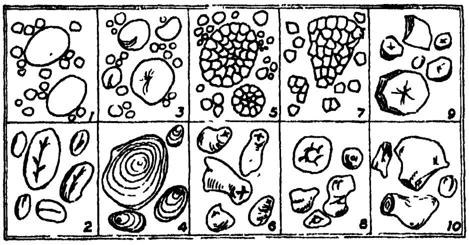
Besides margarine, water is added. Good butter has about 2 ounces of water in the pound; but bad butter, in 16 ounces, has often 6 oz. of water, 1½ oz. of margarine, and ½ oz. of suet and drugs—not a desirable compound. In one pound of butter, 94 grains of boric acid is sometimes used, equal to nearly 10 medicinal doses.

Cheese. Cheese should be moist, with a smooth rind. A rich cheese has bulging sides, a poor milk cheese has straight sides. Cheese is adulterated in many ways; starch is added to increase weight, and margarine may be added to milk cheeses to make them richer.

Flour. Flour is largely adulterated, besides being made from inferior and diseased grain.

Inferior kinds are generally of a bad colour, but by the addition of chlorine and ozonised air these can be made snow white, so that their imperfection is almost impossible of detection.

Fortunately, this diagram shows that each variety of starch has a different shaped grain, so that each one can readily be recognised with the microscope. The adulteration, therefore, of



STARCH GRAINS

1. Wheat Starch 2. Pea Flour 4. Potato Starch 5. Oat Starch 3. Arrowroot Starch 7. Rice Starch 8. Tapioca Starch 9. Maize Starch 10. Sago Starch

flour with inferior starches (rice, potatoes, etc.) is easily detected. Other flours are similarly adulterated besides wheat flour, such as sago, arrowroot. Arrowroot, being expensive, is extensively adulterated with potato starch; indeed, "English arrowroot" consists entirely of this.

Bread. Bread is adulterated with alum, but not so much so as formerly. If there be over 10 grains in a 4 lb. loaf, there is adulteration. This is readily detected by a solution of haemotoxylin and ammonia, which turns bread pink; but if there be alum, it turns blue.

Meat. Meat, fowl and fish are not, of course, adulterated; but much that is inferior, diseased or stale is still sold. We give, therefore, a few hints to help in securing wholesome food. [See also "A Marketing Guide," HOUSEKEEPING, page 1227.] It is not easy to distinguish the best foreign meat killed in England from home-grown and home-fed beef and mutton. Frozen meat, or, as it is sent now, refrigerated meat (that is, cooled, but not frozen) is quite good and wholesome. The principal difference between it and fresh meat is in the flavour, which is never so good in the case of meat which has been kept on ice. But the difference in price is so great that it is far better for those who are really poor to buy the best foreign meat than any other. To a certain extent, the following remarks apply to this sort of meat, though they are really descriptive of home-killed meat.

Stale or bad meat looks flabby, spongy, and whitish; the eyes of the animal are sunk and the kidneys are bad; the fat is yellow and there is very little of it.

In buying meat, always choose it yourself; see it weighed, and pay for it at the time, and thus save not less than 20 per cent. Deal, if possible, with one respectable butcher; or you may buy the home-killed beef from one, and frozen mutton from another, for frozen mutton is in better condition than frozen beef.

BEEF. Prime ox beef has an open grain, is of a carnation colour, and marbled with streaks of fat. The fat should be white. Cow beef looks paler and the grain is closer. If the meat is dark red and the fat skinny, it is too old. If it rises quickly upon pressure by the thumb, it is prime meat; if not, it is poor.

MUTTON. Prime mutton, if large, is probably Sussex or Scotch; if small, Dartmoor or Welsh. The latter is darker and leaner, the former paler and fatter. The meat should be firm and close-grained, and the more fat, the primer the meat. Good meat does not shrink much in cooking, and does not gape wide open when cut.

VEAL AND LAMB. Never buy very young veal or lamb. Veal should be two months old at least, and the flesh dry, not clammy. Lamb should be small, pale red and fat.

PORK. Pork is best with a thin rind. Buy only from a dealer you can trust, as it is often diseased. The meat should not be flabby or clammy, but the fat hard and the lean nearly white. The pressure of the thumb on the rind should leave a dent or mark.

BACON. Bacon should be fat, clear, and not streaked with yellow. The flesh should adhere closely to the bone.

Poultry. As a rule, fowls and turkeys are very digestible, but ducks and geese, which are fatty, do not suit everyone.

FOWLS. In buying fowls, choose male birds. If young, they have smooth legs and short, soft spurs; the feet bend, the eyes are full and bright. Never buy a fowl turning blue or with stiff feet, and a cock with a sharp spur is too old. Young birds have transparent, unwrinkled skins. Dorking fowls are considered the best.

YOUNG GEESE have yellow feet; old ones have red.

DUCKS should have the breast-bone soft and gristly, and the feathers unformed.

TURKEYS should have a smooth skin and no spur.

Fish. When buying a fish, see that it is short, thick, well made, with bright scales, and stiff and springy to the touch. The gills should be fresh and red, and the belly firm. If the gills are not bright and of a fresh red, the fish is uneatable. Be sure and clean fish as soon as ever you can, and especially remove the livers, as if they are left in, the oil from the liver will soak into the flesh and make the fish taste very rancid.

COD is in best condition from November to March. The flesh should rise again when pressed by the finger, and not leave a dent.

EELS should, if possible, be bought alive and killed by dividing the spine just behind the head. Fresh water eels are the best, and silver eels better than dark ones.

FLOUNDERS are rather watery, but very cheap. The best are the plain dark grey ones, without red spots. They should be firm and stiff.

HADDOCKS are very good, nutritious and cheap, and when bought fresh are most delicious.

HERRINGS and MACKEREL should be bought very fresh, not the least faded or wrinkled, or pliable in the tail, but stiff and springy.

SALMON, like all other fish, may be judged by the gills, eyes, scales and general stiffness. When fresh, it has a curd between the flakes. After a day or two, this melts, and the fish becomes richer and more indigestible.

In buying SOLE, choose small ones for frying, and large ones for boiling.

TURBOT are best when of moderate or small size; large ones are more watery. The flesh should be firm, white, plump and creamy. This fish will, if bought fresh, keep two or three days

PLAICE are very similar to turbot, only not so firm.

WHITING should be cleaned all over. They are the lightest fish to eat when fresh, and very wholesome.

CODLING are often sold for whiting, but they are not nearly as good. They can be distinguished from whiting by their beards.

LOBSTERS and CRABS should be chosen by their weight in proportion to their size. The heavier they are the better.

Fish kept on ice loses its flavour, though it may be quite fresh. It is worth while finding out when the fishmonger receives his fish, and making the purchase then. Be very careful in buying dried fish. If it be not properly cured, parts soon become bad, and may cause serious disease.

Condiments. To return now to definite adulteration of food.

PEPPER is adulterated with husks, ground olive stones, rice, rape seed, bone dust, etc. Olive oil is sometimes half cotton-seed oil.

MUSTARD is often largely wheat and pea flour, cayenne, plaster of Paris and clay.

PICKLES are coloured with chlorophyll (harmless).

VINEGAR is adulterated with dilute sulphuric acid (vitriol), acetic acid, and caramel. Lemon juice has added to it sulphuric acid, tartaric acid and water.

SWEETS have various substances added. If the colour is soluble it is probably harmless.

Jam. The adulteration of jam is still extensive, and consists largely of carrots, turnips, vegetable marrow refuse, apples, and glucose, which we must always remember is liable to contain arsenic (as seen some years ago in the epidemic poisoning in Manchester from beer so adulterated).

Jams are also adulterated in other ways. Seeds to imitate raspberry seeds are most ingeniously made by a special machine which turns them out in enormous quantities from pine wood. Most of these additions are, however, practically harmless.

HONEY is adulterated with glucose, and GOLDEN SYRUP with starch and glucose.

Beverages. Turning to beverages, we find these are frequently adulterated

TEA, though no longer faced in green tea with poisonous salts of copper, is still largely adulterated with tea sweepings, old used re-dried leaves, and sometimes clay, lime, or sand, to give weight. Other leaves, such as currant, are sometimes added. Formerly sloe and willow leaves were used.

COFFEE is much adulterated with chicory, sometimes up to 80 per cent., or even more. One-ninth of the coffee and one-sixth of the cocoa examined in London were found to be adulterated—coffee with chicory, roasted wheat, potato flour, acorns, date stones, beans and maize.

CHICORY is the dried and pounded root of a plant, and contains no caffeine. It is injurious in quantities, and has many bad after-effects; but the taste in England is so vitiated that coffee is often preferred with about 30 per cent. of chicory added, while "French Coffee" often has 75 per cent. of chicory, and is sold at about half the price of coffee; 5 per cent. of chicory is not injurious. Under the microscope, coffee has small angular cells, those of chicory being large and oval. In water, chicory sinks and colours it, while coffee floats and does not.

COCOA is adulterated with sugar, starch, brick dust, Venetian red, and peroxide of iron, etc. Sometimes half the fat is removed, which makes it easier of digestion.

Spirits. Alcoholic beverages are particularly open to adulteration.

BRANDY, when first distilled, is colourless, like gin, but darkens with age, and is often coloured with burnt sugar. Other adulterants are chiefly water, cayenne pepper and acetic ether. Much of the brandy sold, as we have pointed out, owes nothing to the grape at all. A recipe for artificial brandy is to add to every 100 pints of proof spirit ½ lb. of argol, some bruised French plums, and a quart of Cognac. The distilled mixture has the acetic ether, tannin and sugar added.

WHISKY is adulterated in the same way as brandy, but is also often prepared from potatoes mashed up with malted barley and roughly distilled and burnt to give it a smoky flavour.

RUM is often fraudulently made from malt or molasses spirit, with a flavouring made of butter, distilled with sulphuric acid and alcohol. This imitates the pineapple.

GIN in England, besides juniper berries, has often oil of turpentine added to it. It is largely adulterated with water, which makes it cloudy; it is cleared with alum and sugar of lead; sugar and cayenne pepper are then added. It is the most adulterated spirit sold.

WINES offer an extensive field to the adulterator. They are generally adulterated by added spirit, artificial colouring, plastering and fancy naming. "Plastering" is adding mineral acids or salts to the wine, and particularly gypsum or Spanish earth. This sulphate of lime clears the wine, makes it look brilliant, and changes the tartaric into sulphuric acid. The object is to make the wine dry.

In cheap wine, aniline dyes, logwood, cochineal, etc., are added for colour. Many imitation ports, sherries and other wines are made in England, sold for a few pence a bottle wholesale, and retailed as foreign wines. British wines are are not made from grape juice at all.

Many wines are also artificially made in Hamburg and elsewhere, ports and sherries from fusel oil, and champagne from rhubarb, apples, etc. German still wines are artificially aerated.

BEER being now legal if not made from malt and hops, cannot be said to be adulterated even when made from quassia, gentian, calumba, and other bitters. Formerly beer was much adulterated; now, except when the materials are themselves adulterated, as in glucose, containing arsenic, the chief adulterants are water, salt and alum. If the SALT amount to over 10 grains per gallon the beer is adulterated.

GOOD AIR

The atmosphere is the vapour or gaseous covering of the globe, on which life depends. It extends everywhere up to a height of 40 miles.

We, on the surface of the earth, are indeed moving about on the bed of a vast air ocean, 40 miles deep, and the pressure of this enormous mass is so great that it is equal to 15 lb. on every square inch of surface. Our bodies, therefore, and everything around us are naturally and instinctively constructed to stand this great pressure, which, being equal on all sides, is not perceived. The force of it is seen at once when it can only press on one side of a body, as, for instance, on the outside of a glass bell from which all the air inside has been removed. The bell is then pressed to the table by the weight of air, so that it cannot be moved. It is probable that the air ocean is even deeper than 40 miles, for there must be some oxygen at any rate much further than that distance, since meteors burst into combustion at 200 miles from the earth.

What Air Is. We will first of all consider what air is, and then examine the various impurities with which it is adulterated; they are so numerous that it is quite likely that many that have drunk pure water have never yet breathed pure air. The air we commonly meet with has as many ingredients as soup. If we want to breathe pure air such as we are going to describe, we must go to the top of some mountain over 10,000 ft. high, letting no one come with us to contaminate the air. We must face the wind, and then we can inspire pure air. In no part of this country is such air to be found.

Air is a mixture and not a compound like water. In the latter, two gases are chemically compounded and form a liquid. In air two gases are intermixed like sugar and sand, and merely form a mixture of gases without chemical change.

By volume air is one-fifth oxygen and four-fifths nitrogen; or per cent., oxygen 20·9, nitrogen 79·1, and carbonic acid gas (CO_2) ·04. By weight the percentage is oxygen 23, nitrogen 77, and carbonic acid gas ·06. There are also small amounts of other gases and water vapour in pure air.

Constituents of Air. The gases found in air are nitrogen, oxygen and carbonic acid gas (carbon dioxide).

NITROGEN. This is an inert gas used in air simply to dilute the too fiery oxygen. It cannot support combustion or life as a gas, and yet as a chemical element in combination it is an absolute essential of all life. It used to be called "azot"—*i.e.*, without life, and yet there is no organism on earth that can exist without it as an essential food. Nitrogen means the birth giver or the mother of nitre or saltpetre.

It is readily separated from the air by passing air over red hot copper, which absorbs all the oxygen and leaves the nitrogen.

OXYGEN. Oxygen in the air varies very slightly in amount. On the most breezy moor there is 20·98 per cent., or very nearly 21 per cent.; in the closest house there is 20·87 per cent. On a high mountain the oxygen is less than on a moor, because there is no vegetation.

OZONE. Oxygen, again, is of at least three qualities. There is the ordinary oxygen found everywhere; then there is a concentrated form called *ozone*, formed by electricity and the action of the sea water and seaweed round the coasts. This is extremely vitalising, and has a penetrating smell. One part of ozone in 2,500,000 parts of air can be detected by the smell. There is most ozone at night, in the winter, on high ground, round the coast, in the country, after thunderstorms, and with a west wind; there is none normally in towns or rooms. The most that ever occurs is one part to 700,000 of air. It is to this chiefly that the benefit of the sea air is due. Then there is *expired oxygen* that has been breathed and re-breathed, found in crowded resorts. Town air, though it contains the same proportion of oxygen as moor air, is devitalised, because the air is not of the same quality. Air is purified and ozonised by electricity, hence the literal truth of the expression that a thunder-storm "clears the air," and the peculiar fresh feeling of town air after one.

CARBONIC ACID GAS (carbon dioxide). If the amount of carbonic acid gas in air does not exceed 4 parts in every 10,000—that is, ·04 per cent.—the air is not accounted impure. It generally varies in pure air from ·02 to ·04 per cent.

Water Vapour. This is present in all but pure desert air in the dry season, and is necessary for life. The cooler the air the less water vapour will it hold. The greatest amount it can retain in proportion to the temperature is as follows in grains of water to cubic feet of air:

Air	Water	Air	Water
30 cub. ft.	2 gr.	70 cub. ft.	8 gr.
40 cub. ft.	3 gr.	80 cub. ft.	11 gr.
50 cub. ft.	4 gr.	90 cub. ft.	15 gr.
60 cub. ft.	6 gr.	100 cub. ft.	20 gr.

Air saturated with water vapour from 30° to 40° feels very chilly and raw; at 60° saturated air is comfortable; at 100°, as in hothouses, it is close and heavy. The most comfortable amount is from 1 to 1½ per cent. of water (in the form of vapour) in the air, or from 50° to 75° of saturation.

Properties of Air. The chief properties of air are three in number, *weight*, *expansion* and *diffusion*. To the first we have already alluded, and have shown that the pressure of 40 miles of air equals 15 lb. to the square inch on the earth's surface. This pressure is sufficient to support a column of mercury in a ¼ in. tube 30 in. high, forming a barometer, by which the varying pressure of the air is measured. Fifteen pounds to the square inch is one ton to the square foot; and as the surface of the body is 16 sq. ft., the pressure on each person amounts to 16 tons, and yet it is not felt.

The weight varies according to moisture and temperature. Air gets lighter as it gets warmer and wetter, and under these conditions the barometer falls.

If there were no *expansion* of air the separate gases, of which air is composed, would all lie in layers one above another, the lightest at the top. This would be the water vapour, then would come the nitrogen, then the oxygen, and at the bottom, next the earth, all the carbonic acid gas, CO_2. This would mean death. Again, if there were no diffusion, by which one gas rapidly changes place with another, there would be no uniformity in the composition of the air, as it is by this law that the carbonic acid gas in the blood rapidly changes place with the oxygen in the lungs, and the carbonic acid gas formed in a town is rapidly removed to the country to be absorbed by plants. On this property again life depends.

So far, then, we have given a brief sketch of air in its pure and normal state. We will now consider the numerous impurities with which all the air we use is really more or less mingled.

Need of Purity. There are two points to notice about air regarded as human food.

One is that, unlike all other food, which can be selected of the greatest purity and best quality from all parts of the world, we are compelled by an inexorable law of nature to use that air that is just in front of our mouths, however foul and poisonous it may be. The other is that where pure air is most wanted—that is, in cities—it is always most difficult to find, because the very men who need it themselves poison it. It is curious to think that seventeen times every minute pure air is a vital necessity, and yet that seventeen times a minute we are pouring poison into it. This is exactly similar to pouring our sewage into our well of drinking water. In air, however, impurity is unavoidable, and to mitigate the evil effects the science of ventilation has sprung up. With this we shall be concerned later. At present we will briefly consider what the impurities are, before seeing how best to remove them.

Impurities are of three classes: gases, organic particles, and inorganic particles.

Gaseous Impurities. These are ammonia, nitrous oxide, excess of CO_2, carbonic oxide, sulphuretted hydrogen, marsh gas and sulphuric acid.

AMMONIA. This arises from all decaying organic matter. The amount in the air is generally about 3 parts in 10,000,000. Rain washes it out of the air together with many other impurities.

NITROUS OXIDE. This is formed from electricity after thunder, and also from decomposing animal matter.

EXCESS OF CO_2. The excess occurs in all indoor air and in much town air. It has been found as follows:

Place	Excess
National School (Leicester)	·2 per cent.
Public Library	·2 per cent.
Assize Court (Manchester)	·19 per cent.
Strand Theatre	·1 per cent.
Bed-room at night	·19 per cent.
Barracks	·05 per cent.
Manchester Station	·04 per cent.
Mine in Cornwall	·78 per cent.
Convict Prison	1·0 per cent

It occurs in excess in mineral water factories. In London streets it seldom rises above normal—*viz.*, ·04 per cent. When pure, CO_2 is fatal if it amounts to 7·5 per cent., while 1·5 per cent. produces giddiness and fainting. Anything below 1·0 per cent. produces no immediate effect on health. CO_2 is a narcotic and produces deep sleep, hence one often sleeps better (if used to it) in a close unventilated room, through being half poisoned with CO_2.

It is well to remember that CO_2 is heavier than air, and therefore always tends to lie on the floor; hence, the advantage of a bedstead, and the danger of sleeping on the floor in a close room. Its weight can be shown by pouring some into a thin paper box balanced on a scale or on to a light paper overshot wheel, which it will cause to revolve. The reason one hears so much of it as an impurity is because air containing 4 per cent. breathed out 17 times a minute by every human being is laden with organic particles which are more injurious than the CO_2 itself. This poisonous organic vapour clings to walls and clothes, and leaves a room slowly. The CO_2 itself is easy to remove, for it diffuses rapidly; but the organic matter is difficult to remove, for it is not a gas. We may state here that the extreme limits of foul air found in frequented resorts have been as regards deficiency of oxygen 20·6 per cent. in an old courthouse, and, for excess of CO_2, ·7 per cent. in a crowded school-room. This amount is, however, very rare.

CARBONIC OXIDE (CO) This is a far more deadly product, but is fortunately much rarer. It arises generally from unburnt gas, red hot cast-iron stoves, and charcoal stoves. Even ·007 per cent. is quite unpleasant in the air, while ·05 per cent. (the common quantity of CO_2 in the air) is fatal. Even ·01 per cent. has caused death. At an old church at Ambleside, 800 persons were poisoned by it from a heated iron stove. It is formed wherever combustion goes on in close air, and is without smell or taste.

MARSH GAS. This is practically harmless.

SULPHURETTED HYDROGEN. This is a sewer gas.

SULPHUROUS ACID. We find this in the combustion of coal in close places such as underground railways. It is a powerful disinfectant.

Organic Particles. These include pollen from flowers, skin cells, pus cells, bits of insects, germs of all sorts, hair, wood, flax, wool, cotton, paper, silk, starch, manure, vegetable cells, seeds of all sorts, and other organic refuse. The skin cells are in innumerable millions, being cast off the body of each individual daily as dust, and then constantly inhaled. Pollen produces hay fever. Germs are very numerous, and are either harmful or harmless. In London air it is computed that some 14,000 are inhaled by each person every hour, and all are retained in the body, for the expired air contains none. When we consider this fact and think of all the filth with which the air is laden, there is surely a strong argument in favour of breathing through the nose. All inspiration should be so conducted, and then not a single germ enters the lung and no filthy impurities enter the mouth and defile it. No clean person who knows of what dust consists can breathe town air through the mouth on a windy day. The manure and dust in the streets and the disgusting germs connected with it are so common in London air, that during an investigation a short time ago there was not a single specimen of milk from the smaller dairies in London that was not swarming with them.

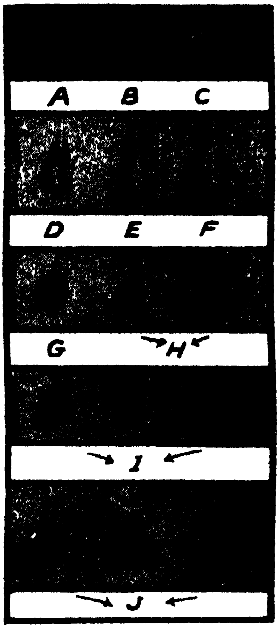
Insects—continued

8 **Flies and Fleas.** This enormous assemblage of insects, most of which are small or even minute, includes many species that have earned an undesirable reputation as blood-suckers and pests. Except in fleas and a few others, such as sheep-ticks, there are only two membranous wings, for the hinder pair of these organs have been reduced to vestiges (balancers), which serve as sensory structures. The mouth parts of the female are very often piercing and sucking organs of great efficiency, the first and second jaws being in the form of slender lancets protected above and below by the upper and under lip respectively [**461**]. But in other types, such as the house-fly (*Musca domestica*), the jaws are modified into a proboscis used for sucking juices, and devoid of powers of perforation [**460**].



459. LIFE HISTORY OF THE HOUSE-FLY
a. Eggs *b, c.* Young larvæ
d f. Older larvæ *g—i.* Pupæ
j Adults
(Photo by Prof. B. H. Bentley)

The life-history exhibits a well-marked metamorphosis, which may be illustrated by reference to the blow-flies (*Calliphora*) or the house-fly [**459**]. The elongated whitish eggs ("fly-blows") are laid in animal substances, such as meat, and hatch out into limbless maggots of extreme voracity. After growing to a certain size, these become quiescent ovoid pupæ enclosed in firm investments, from which the adult flies ultimately make their escape.

Hessian flies are minute forms, of which the larvæ greatly damage grain crops, while the fungus flies are also very small, and lay their eggs in fungi, as these constitute the food of the young. The little maggots which riddle mushrooms are of this nature The larvæ of some of these flies (*Sciara*) are known in the Northern Hemisphere as "army worms," because millions of them may sometimes be seen migrating from place to place, aggregated into writhing, snake-like masses by means of sticky threads.

Mosquitoes and Gnats. These [**464**] are particularly notable for the blood sucking propensities of the female. The larvæ are little worm-like creatures which may be seen wriggling about in stagnant water, and possess a breathing tube at the tip of the tail, that can be pushed above the surface to procure air. The pupa floats at the surface, with two breathing tubes projecting from its head. If alarmed, it is able to dive. After a time the pupal skin opens, and the perfect insect makes its way out.

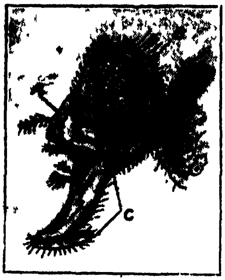
Agents of Disease. Some tropical mosquitoes disseminate the germs of such diseases as malarial fever and sleeping sickness. Wholesale destruction of the early stages, by pouring petroleum on the surface of the stagnant water in which they live, has been employed with great success at Havana as a preventive measure against yellow fever and malaria.

Midges are very minute gnats, of which the aquatic larvæ are known as blood-worms. Crane-flies are familiar to us in the persons of daddy longlegs (*Tipula*), well adapted for climbing among grass. The larvæ (leather-jackets) gnaw the roots of grasses, and become pupæ in the ground [see AGRICULTURE, page 1667]. Sand-flies are small gnats of unusually bloodthirsty disposition; their larvæ are aquatic.

Voracious Flies. In the flies so far described the antennæ are long, but in the others now to be mentioned they are short. Of these the breeze-flies or gad-flies possess powerful piercing mouth-parts, with which they torment both stock and human beings. A well-known species is the long brown clegg (*Hæmatopota pluvialis*), often met with in woods. In some tropical kinds the jaws are of enormous length [**462**]

Robber-flies are voracious and insatiable forms which prey upon other insects, even wasps, dragon-flies, and tiger-beetles being among their victims.

Hover-flies are swift and elegant insects which have already been mentioned in connection with flowers. Some of them closely resemble bees in appearance, and this has been described as a case of protective mimicry. The larvæ of some well-known species (*Eristalis*) are called "rat-tailed maggots," and live in liquid filth The "tail" is in reality a breathing tube. Other larvæ (*Volucella*) inhabit the nests of bees and wasps, and probably act as scavengers. House-flies, blow-flies, and many others make up yet another family. The dreaded tsetse-fly (*Glossina morsitans*), so fatal to horses in parts of South Africa, belongs here [see Plate facing page 3361]. Germs of the fly-sickness (*Nagana*) are introduced into the blood of the victims. The

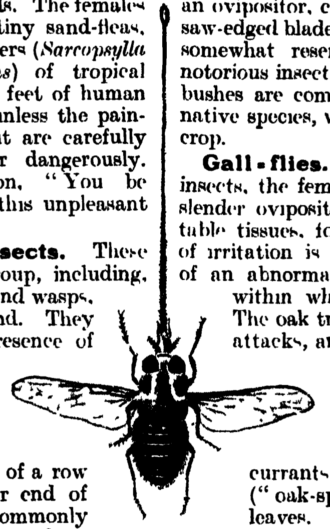


460. HEAD OF HOUSE-FLY
a. Antennæ *b.* Eye *c.* Proboscis

bot-flies have been described and illustrated on pages 2626 and 2627 in the course on Agriculture.

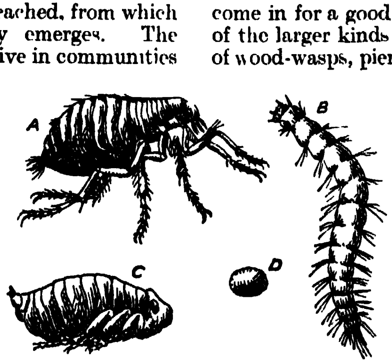
Fleas. Fleas [463] are wingless members of the order, and their agility fully compensates for the loss of the power of flight. There are many species infesting different mammals and birds. The females of the tiny sand-fleas, or chiggers (*Sarcopsylla penetrans*) of tropical America deposit their eggs in the feet of human beings (or other animals), and unless the painful swellings thus brought about are carefully treated they are apt to fester dangerously. Probably the slang expression, "You be jiggered!" is an invocation to this unpleasant insect.

9. **Membrane-winged Insects.** These constitute a vastly numerous group, including, among many others, ants, bees and wasps, the most intelligent of their kind. They are readily recognised by the presence of four transparent wings traversed by a comparatively small number of veins, the hinder ones being much smaller than the others, to which they are in many instances attached during flight by means of a row of minute hooks. The posterior end of the body in the female is commonly provided with a piercing apparatus, which may either serve for boring holes, in which eggs are laid, in which case it is called an "ovipositor," or may have been modified into a poisoned sting, useful for offence and defence. The conspicuous black and yellow, or black and red bands, of wasps and bees are "warning colours," indicating their stinging powers.



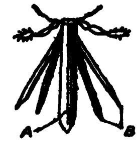
462. NEPAL LONG-BEAKED GAD-FLY

The larvæ either resemble caterpillars, or are pale, helpless maggots, devoid of limbs, for the welfare of which more or less elaborate provisions are made by the mother insect. Later on, a quiescent pupa stage is reached, from which the winged adult ultimately emerges. The highest members of the order live in communities comprising several castes, as in termites. These include males, perfect females (queens), and one or more kinds of imperfect female workers (soldiers).



463. LIFE HISTORY OF FLEA
a. Adult *b.* Larva *c.* Pupa *d.* Egg

Wood-wasps. These insects somewhat resemble wasps in appearance, except that they do not possess the characteristic "waist" and sting. The giant wood-wasp [see Plate facing page 3361] is a typical species, in which the female has a powerful boring apparatus, with two strong blades that serve as augers for perforating the trunks of sickly or felled pine-trees. The eggs laid in the holes thus made hatch out into wood-eating larvæ. The life-history is somewhat prolonged, and the perfect insects have been known to escape from wooden furniture after the lapse of several years.



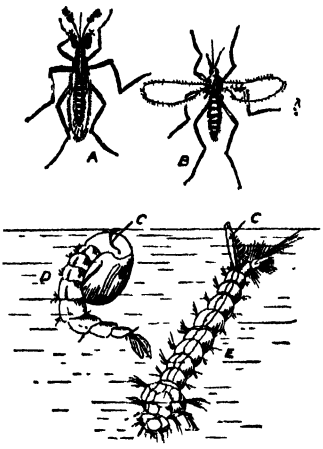
461. JAWS OF BLOODSUCKING FLY
(Spread out)
a. Upper lip
b. Lancets

Saw-flies. In these small insects [465] the female possesses an ovipositor, consisting of two elegant curved saw-edged blades, sliding on supports. The larvæ somewhat resemble little caterpillars, and are notorious insect-pests. Rose-trees and currant-bushes are commonly attacked by some of our native species, while others devastate the turnip crop.

Gall-flies. These are minute black insects, the females of which are provided with slender ovipositors, used in piercing soft vegetable tissues, for egg-laying purposes. A kind of irritation is set up, resulting in the growth of an abnormal swelling known as a "gall," within which the larva lives and feeds. The oak tree is particularly liable to such attacks, and is victimised by a large number of species. The most familiar case is afforded by the spherical brown bodies known as "oak-apples," while other common oak-galls look like currants, or circular brown scales ("oak-spangles") on the backs of the leaves. The curious tufted red swellings (bedeguars) often seen on wild rose-bushes, are of similar nature.

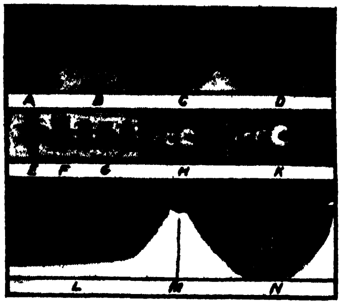
Ichneumon Flies. These flies [see Plate] make up a host of mostly inconspicuous little creatures, which go far to check the ravages of vegetarian insects, and are therefore among the most valuable friends of the farmer, market gardener, and forester. Their eggs are laid near, on, or in the immature stages of other insects, the juices of which are absorbed by the larvæ. The caterpillars and even eggs of butterflies and moths are favourite objects of attack, while the destructive plant lice (*aphides*) come in for a good deal of attention [467]. Some of the larger kinds check the ravages of the larvæ of wood-wasps, piercing infested timber with their powerful ovipositors [468]. In this way they are able to deposit their eggs in the galleries of the wood-wasp larvæ, to which their own larvæ attach themselves on hatching out. One of our native gall-flies actually makes its way under water for the purpose of attacking caddis worms.

Bees. These familiar insects construct cells of various materials in which they lay their eggs, and devote most of their time to feeding and caring for the helpless larvæ. Some are solitary forms, but between these and the complex communities of humble bees and honey bees there are various intermediate stages. Their dependence upon the pollen and nectar of flowers has been elsewhere considered, but it will be well to remember that their structure has been profoundly modified in relation to their peculiar diet.



464. LIFE HISTORY OF GNAT
a. Male *b.* Female *c.* Breathing tube *d.* Pupa *e.* Larva

Carpenter Bees. These are large and handsome insects which build their nests in dry wood. After biting out an entrance, the female constructs three or four parallel tunnels, each of which is divided into a number of cells separated by partitions constructed of sawdust cemented together with saliva. Each cell contains an egg, together with a store of food.



466. HONEY BEE

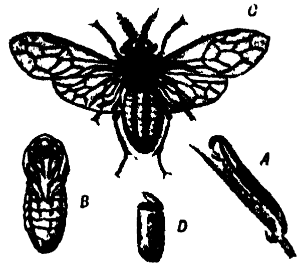
(Photograph by Prof. B. H. Bentley)

Carder Bees. These bees make their cells in ready-made hollows, sometimes using empty snail shells for the purpose. The material employed consists of down from the stems and leaves of various plants. This is skilfully woven into the cell walls, cement being added to prevent the stored honey leaking out.

Leaf - cutting Bees. These nest in various hollows, walling-in their cells with pieces of leaves glued together. One species native to this country employs the scarlet petals of the poppy in this sort of upholstery work.

Mason Bees. Mason bees have been studied with painstaking care in the South of France, and the following are a few of the details observed. A flat stone having been selected as a foundation, the first cell is made of earth worked into a kind of mortar with saliva. This is then stored with honey and pollen mixed together into a sort of sweet paste ; an egg is [illegible] Other cells are now added, to the number of eight or nine, and the whole is covered with mortar and small stones. The completed nest is convex in shape, and about half the size of an average orange.

467. ICHNEUMON FLY [illegible] LOUSE

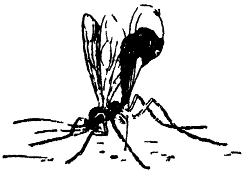


465. PINE SAW-FLY
a. Larva *b.* Pupa *c.* Adult *d.* Cocoon

Cuckoo Bees. Like their namesakes among the birds, cuckoo bees have acquired the vicious habit of taking advantage of the industry of some of their allies for the benefit of their progeny. One such form (*Stelis minuta*) victimises another bee (*Osmia leucomelana*), which constructs its cells in blackberry stems. The intruder lays an egg in the midst of the provisions stored in each such cell, and as the destitute alien is the first to hatch out, it grows more rapidly than the lawful owner. Ultimately the two larvæ meet, that of the cuckoo bee killing and devouring its opponent.

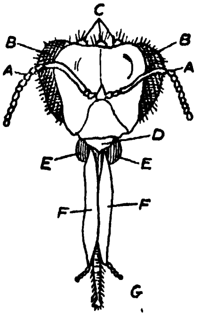
Gregarious Bees. Helping to explain the origin of communal life among bees are certain cases—*e.g.*, *Halictus*—where a number of females undertake a certain amount of work for the common good, excavating a branching tunnel in the ground, with an entrance and vestibule used by all. But each individual constructs, stores, and finally lays her eggs in cells as an entirely independent task. A comparison may almost be made with a series of flats opening upon a common staircase, and with one front door between them. And just as in such a congeries of human dwellings an individual employed by all may be responsible for front door and staircase, so among these particular bees a sentinel is set at the entrance to the burrow. In what manner this functionary is appointed remains to be shown.

Humble-bees. [See Plate facing page 3361.] These common bees are large, somewhat clumsy-looking insects which live in communities including workers or imperfect females as well as ordinary members of the two sexes. The nests are constructed in holes in the ground or other sheltered places, and the establishment of [illegible] the labours of a foundress queen in early summer. She makes a number of waxen cells, stores them with honey and pollen, and afterwards feeds the larvæ



BORING WOOD

when they have devoured these provisions. From the first (and several other) batches of larvæ workers are chiefly produced, which undertake the constructive and nursing work, until at last the queen has nothing to do but lay eggs. Males and other queens are reared from some of the eggs laid in late summer and early autumn.

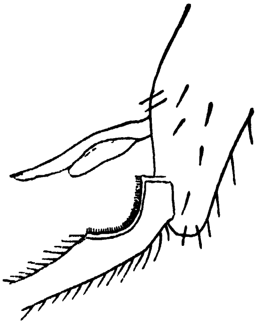


469. HEAD OF WORKER WITH PROBOSCIS EXTENDED (FRONT VIEW)

a. Feelers *b.* Compound eyes *c.* Simple eyes *d.* Upper lip *e.* First jaws *f.* Second jaws *g.* Tongue

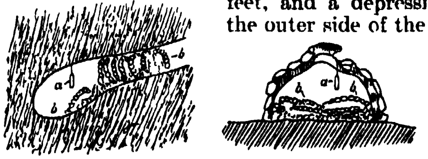
The brood-cells differ in size according to the destiny of their occupants, the smallest being designed for workers, and the largest for queens. Pollen and honey are stored in special receptacles known as pollen-tubs and honey-tubs. Living in the nest of a humble-bee (*Bombus*), and on good terms with the members of the community, are to be found individuals belonging to a related genus (*Psithyrus*). These construct their cells in association with those of their hosts, and steal the honey and pollen which these have stored up for their own benefit.

One species of humble-bee, at least (*Bombus ruderatus*), is known to appoint a "trumpeter," which wakes up the community at three or four o'clock in the morning.



471. FEELER-COMB

The Honey-bees. The honey-bees (*Apis*) are so well known that it will be unnecessary to say much about their habits, especially as details will be found in the course on Bee-Keeping. A community consists of a single queen, the mother of all the remaining individuals, a large number of workers, and numerous drones, or males [**466**]. The cells are of different sizes, as with humble-bees, and eggs that would otherwise give rise to workers may be made to produce queens by feeding the larvæ which hatch from them with more stimulating diet, and assigning them large "royal cells."



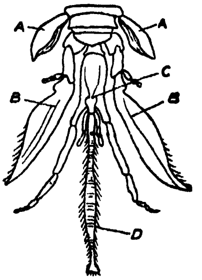
Odynerus reniformis

Eumenes

473. NESTS OF SOLITARY WASPS (IN SECTION)

a. Suspended eggs of wasp *b.* Stored caterpillars

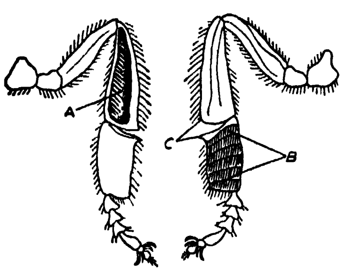
Structure of Honey-bees. Many of the points in the structure of the honey-bee fit it for the performance of its complex activities. Upon the head there are two large compound eyes, used for near vision, and three small simple eyes by which objects at a distance can be perceived [**469**]. There is a well-developed sense of colour, and flowers which specially lay themselves out to attract bees are mostly of blue or purple hue. Bees have also a keen sense of smell, which not only attracts them to fragrant flowers, but also helps them to detect the presence of nectar.



470. JAWS OF WORKER SPREAD OUT

a. First jaws *b.* Second jaws *c.* United third jaws *d.* Tongue

The mouth-parts of the bee are highly specialised [**470**]. The powerful first jaws (mandibles) are used in the construction of the comb, and for a great variety of other purposes, while the second and third jaws are drawn out into a long suctorial and licking apparatus. The basal part of this constitutes a tube through which nectar or other sweet fluids can be sucked up, while its terminal portion is a sort of tongue (*ligula*) that can be inserted into the recesses of flowers. This [**470**] is worked up and down so as to bring nectar within the tubular part of the apparatus. The end of the tongue is expanded into a sort of lappet for licking, and the sharp blades of the second jaws can be used for piercing certain flowers, such as orchids, which contain sweet sap. When not in action, the suctorial parts of the mouth are folded up on the under side of the head, enabling the first jaws to work freely.



Outer side Inner side

472. THIRD LEG OF WORKER

a. Pollen basket *b.* Pollen brush *c.* Wax pincers

There are marked differences between the three pairs of legs of a worker-bee. The first are provided with combs, by which the delicate antennæ are cleaned [**471**], while the third [**472**] are chiefly remarkable for peculiar pollen-brushes on the feet, and a depression or "pollen basket" on the outer side of the shin. The hairy feet brush pollen into the baskets, and when of dry nature, a little honey is ejected from the mouth on to the grains, so as to stick them together. Another peculiarity of the third legs is the nature of the joint between shin and foot, which constitutes a sort of pincers useful in manipulating wax. The wax used in constructing combs is secreted in the form of little plates by glands opening on the under-side of the abdomen.

Solitary Wasps. Wasps, like bees, are either *solitary* or *social*, and it is only in the latter that workers exist.

Solitary wasps construct small nests of clay and little stones, or else make burrows. They possess the curious habit of storing up immature—for example, caterpillars—or mature insects, or even spiders, for the benefit of their larvæ when these hatch out [473] The kind of victim depends upon the species of the wasp concerned, but in any case it is killed or paralysed by stinging.

474. HANGING NEST OF HERMIT WASP
a Roof *b*. Entrance

Social Wasps. Social wasps somewhat resemble social bees in their habits, but their building material instead of being wax is a kind of paper made of chewed wood mixed up with saliva. In some instances, the nest is suspended from a bush or tree, as in the example figured [474 and 475], and is provided with a kind of overhanging roof by which rain is drained off. In our commonest native species (*Vespa vulgaris*), an underground site is chosen, and a series of combs constructed from above downwards, the whole being enclosed in several layers of wasp-paper. Adjacent combs are held together by little pillars [476].

The young are at first fed upon fruit-juice, nectar, and other vegetable matter, for which a more stimulating diet of chewed insects is afterwards substituted.

The hornet (*Vespa crabro*) [see Plate facing page 3361] is a social wasp which commonly nests in hollow trees.

(Photographs by Prof. B. H. Bentley)

Ants. These familiar and intelligent diminutive creatures are perhaps the most interesting of all insects, owing to the extraordinary way in which they have become adapted to a great variety of modes of life. All are social, and a community typically consists of males, females, workers (of one or more kinds), and, it may be, soldiers. The two first are generally provided with wings, though those of the female are soon shed, but exceptions to this occur, and some species may have both winged and wingless individuals of one sex or the other. The first pair of jaws (mandibles) are well or even excessively developed, and possess unusually free powers of movement in accordance with the varied functions they have to perform. In many cases, the females (including the workers) are provided with a sting.

Ants hatch out as helpless limbless larvæ, which have to be fed and carefully attended, either by the fertile females or the workers, as the case may be. Feeding is rather a curious affair, for the nurse possesses a sort of pouch (crop) connected with her gullet, and this is used as a store from which nutriment can be squeezed up into the mouth. Adults can feed one another in the same way, as also the little beetles and other insects which are often found as guests in their communities.

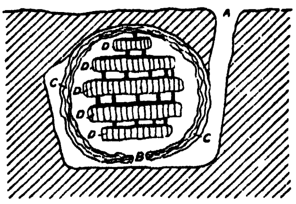
The *wandering* ants that are to be found in the tropics are of highly carnivorous habit, and move about in large armies, devouring everything of animal nature that comes in their way. The fact that they are blind, or practically so, does not seem to interfere with their devastations. Some of these forms (*Eciton*) are common in the hotter parts of South America, while others, the "driver" ants (*Anomma*), are well known in Africa, where criminals, it is said, are sometimes tied up in their path, to perish miserably, if speedily.

Robber Ants. Ants which steal the supplies of other species belonging to their own family are not infrequent. The brown meadow ant (*Formica fusca*), that occupies subterranean dwellings, is subjected to the unwelcome attentions of a smaller species (*Solenopsis fugax*) living in narrow galleries [484] communicating with the broader ones of its host, which is unable to follow the depredators into their fastnesses.

If the walls of our houses were riddled with galleries inhabited by a pigmy race of marauders the situation would be a similar one, supposing our intelligence were not sufficient to tackle effectively the problem of protection.

Slavers and Slaves. Some of the ants have anticipated human malpractices in the way of slaving by pressing weaker species of their kind into unmerited captivity. In one familiar instance the relatively large oppressor (*Polyergus rufescens*) is of reddish colour and well endowed in the matter of jaws [480], while the enslaved species (*Formica fusca*) is small and dark. Regular slave raids are made from time to time, when, after a stubborn resistance, the pupæ and older larvæ of the weaker form are carried away to lead a life of bondage, to which, indeed, they take very kindly. This kind of social economy has indeed become an absolute necessity to the slavers, which have quite lost the power of feeding their own young, while some such species cannot feed themselves.

A most extraordinary state of things occurs in the case of a small kind of ant (*Anergates*) which possesses no workers of its own, but lives within the communities of another species (*Tetramorium cæspitosum*) entirely made up of workers. What has become of the males and females of the host under such circumstances is not definitely known.



476. SECTION OF COMMON WASP'S NEST
a. Hole in ground *b.* Entrance *c.* Covering of wasp-paper *a.* Combs

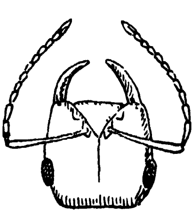
Cow-Keeping Ants. Some ants, such as the little black species (*Lasius niger*) common in gardens, use as part of their food a sweet fluid that exudes from plant lice (*aphides*), and keep these insects as we keep kine [477]. The captives are fed, sheltered, and jealously guarded. Fenced enclosures are constructed for them on plants in the vicinity of the nest, with which they are connected by covered roads. During winter, the fragile eggs of the plant lice are taken underground and sedulously cared for.

477. ANT MILKING A PLANT-LOUSE

Honey-pot Ants. There are certain ants (*Myrmecocystus*) native to the United States and Mexico, and others (*Plagiolepis*) found in South Africa, which have adopted a remarkable method of storing surplus honey that may have been collected. Certain individuals remain in the nest and play the part of living "honey-pots," swallowing the sweet fluid that is administered to them until their distended crops dilate the abdomen to an enormous size [485]. It is supposed that the members of the community are able to draw from this store when necessary.

479. HANGING NEST OF A SOUTH AMERICAN ANT

Harvesters. In Europe, North Africa and North America, a number of ants are known that construct extensive underground dwellings, in which they store seeds of various kinds. Some of the American species (*Pogonomyrmex*) may be even said to winnow their grain, for they carefully strip off the husks and deposit these on rubbish-heaps outside the nest.

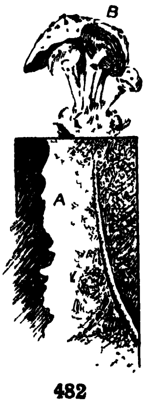


480. HEAD OF SLAVER ANT

Maltsters and Mushroom Growers. Some of the seed-storing ants almost deserve the name of maltsters on account of the way they deal with their harvest. The human method of making malt is to allow the barley grains to germinate to a certain extent until the contained starch is converted into malt-sugar, when the process is arrested by scalding. In similar fashion ants permit germination to go on to a certain point, and then kill the seedlings by biting away the little shoots and roots. In this way a supply of the sweet food they love is secured. Among the most interesting of ants are leaf-cutting forms (*Atta*) native to tropical America. They are associated in huge communities occupying complex underground dwellings, the sites of which are marked by mounds that may measure as much as 40 yards round. The chief food consists of a kind of fungus (*Rozites gongylophora*), cultivated on bits of leaf, and treated in such a way that little white swellings are produced [482]. It is these that the ants desire.

478. GUEST-BEETLE OF ANTS BEING FED AND CLEANED BY TWO WORKERS

The chief duty of one set of workers is to collect the pieces of leaf required. To facilitate their operations, roads, largely underground, are constructed, which lead to suitable trees, and may be as much as 20 yards long, or more. Curved pieces of leaf are bitten out and carried back to the nest, where they are handed over to another set of workers, by them to be reduced to smaller fragments and made into mushroom beds.



482
a. FUNGUS GARDEN OF ANTS
b. TOADSTOOLS PRODUCED NATURALLY BY FUNGUS

Something has been already said about plants which are in possession of body-guards of ants, for which both food and shelter are provided by the rest of the community. Such plants are often more or less modified as an adaptation to this curious kind of mutual benefit association. A well-known instance is afforded by the bull's horn acacia of Brazil, the large hollow thorns of this being inhabited by the guardian ants, for which a special kind of food is provided

481. HANGING GARDEN OF A SOUTH AMERICAN ANT

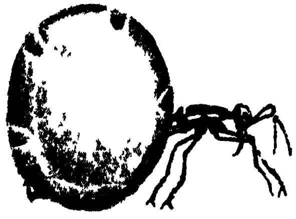
in the form of nutritious "food bodies"—namely, little swellings on the tips of the leaves. The acacia benefits by this arrangement, for the ants keep off leaf-cutting insects. Certain small birds have also learned to build in the branches of this acacia, the ant-guards of which prevent the visits of monkeys and other enemies.

Some South American trees (*Cecropia*) also maintain ant-guards (*Azteca*) that live within their hollow stems, in each joint of which there is a little round pit, serving as a ready-made front door to the dwelling provided. At the base of each leaf-stalk there is a swelling covered with brown hairs, between which grow little "food bodies" for the benefit of the ants.

In some of the East Indian ant plants there is a basal swelling [483], traversed by a labyrinth of passages in which the attendant insects find a commodious dwelling. These passages are formed naturally and not excavated by the ants themselves. Some such plants are flower-bearing species, while others are ferns.

Homes of Ants. It will already have been gathered that ants live in dwellings of the most varied kind, many being underground. In a large number of species ant-hills are constructed of various loose materials, our common native wood-ant (*Formica rufa*) being a good example of this. An Asiatic ant (*Oecophylla*) constructs a summer-house of leaves in a curious fashion. The larva possesses silk-glands from which a sticky fluid exudes, hardening quickly on exposure to the air. Advantage of this is taken by the workers, for they hold larvæ in their jaws, and employ them as living gum-bottles, while the leaf edges to be cemented are held in position by other workers.

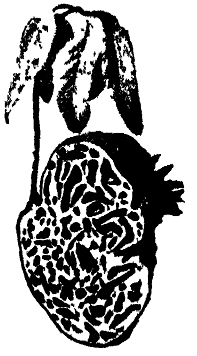
Hanging Nests and Gardens. Some of the South American ants construct hanging nests in trees [479], by which protection against floods is secured. Other ants in the same part of the world make curious homes which well deserve the name of "hanging gardens," for they are mainly constructed of living plants, some of which have never been found in any other situation [481]. The plants are cultivated and tended by the ants with which they are associated. The soldiers of certain ants (*Colobopsis*) which tunnel out homes in the wood of trees play the part of living front-doors. Every entrance to the nest is guarded by one of these hall-porters, its huge head not only exactly filling the aperture, but closely resembling the adjacent bark in appearance. If this curious door be touched by a bit of stick or a feather, it remains shut, but is immediately opened when stroked by the antennæ of a worker.



485. HONEY-POT ANT

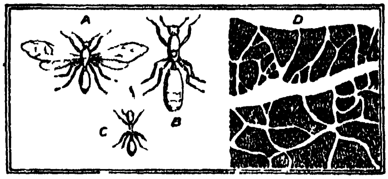
Ant Guests and Associates. Not only may ants of two or more kinds be associated together in the same dwelling, but a nest may also be tenanted by peculiar species of beetles (and other insects), spiders, mites, or other creatures. Many of these, especially the beetles, are fed [478] and cared for by the ants, some of them for the sake of a substance which exudes from their bodies, others, perhaps, to serve as pets.

The beetle-grubs are looked after as well as the adults, at least in the case of certain blind species. It is probable, too, that some of these guests perform the duties of scavengers.



483. ANT-PLANT, NATIVE TO JAVA
(In section)

Harboured Thieves. On the other hand, certain ant-beetles not only steal food from the ants, but also devour their young. There can be no doubt that these curious associations are very ancient ones, for many species of beetle are found nowhere else. A kind of bristle-tail that lives in ants' nests is a thief pure and simple. It has been seen to steal the drops of honey being passed from the mouth of one worker to another, afterwards retreating at full speed for fear of unpleasant consequences.



484. ROBBER ANT
a Male *b.* Female *c.* Worker *d* Part of nest (in section); the robbers live in the narrow passages

The common red ant (*Myrmica rubra*) shelters and feeds a curious kind of blind mite, which lives on the bodies of its hosts. By stroking its entertainers with its legs it makes known its need of nutriment, and such requests are never refused. Not impossibly some return may be made for these good offices, but, if so, their nature is so far entirely unknown.

One of the Indian ants (*Sima rufo-nigra*) lives on the bark of trees with a species of wasp (*Rhinopsis ruficornis*) and a kind of spider (*Salticus*), both of which closely resemble it in appearance. The three associates appear to be good friends, while wasp and ant sometimes engage in a friendly wrestle.

Means of Communication. The complex life of an ants' nest is a striking instance of order among apparent disorder. Each of the innumerable individuals discharges its special tasks without hesitation, unless unusual circumstances prove a hindrance. It would seem, therefore, that there must be some means by which one ant can convey information to others. When two meet they frequently stroke one another with their feelers, and this perhaps serves the purpose of language.

THE MYSTERY OF COLOUR

What Colour is. Why the Sky is Blue. The Dust and the Sunset. The Spectrum. The Mind and Colour. Vision. Colour-blindness

By Dr. C. W. SALEEBY

WE know what colour is essentially—that it is precisely comparable to pitch in sound, and that one pure colour differs from another, if the complications introduced by our seeing apparatus be ignored, neither more nor less than red differs from the infra-red heat rays, or F from G.

How Colour is Made. Colour is a matter of wave length and of frequency of vibration. The onward speed of all forms of light is the same. Indeed, we have seen that this speed is one and the same for ethereal vibrations in general, and not merely for the octave we call light; but the factor of time enters in an entirely different way into our study of light. For though red and violet light both pass onwards at the same speed, the vibrations constituting the first occur at the rate of four hundred billions (400 millions of millions) per second, while those constituting the latter are about twice as frequent. There is a due proportion between wave length and frequency, so that as the wave length becomes shorter the frequency of the vibrations increases. It is when we think in terms of frequency per second that we recognise, most completely, the precise parallelism between colour and pitch. We turn now to a further study of colour as dependent upon the relation between ethereal waves and material matter; and also as dependent upon the peculiarities of our retinæ. The analogy with sound will help us no longer, but we shall be helped, in some measure, by our previous study of *Radiant Heat.*

Why Red is Red. It was a saying of St. Augustine's that light is the queen of colours. We may read a modern meaning into this if we consider the reason why a piece of red glass appears red. So long as no light is allowed to fall upon or pass through the glass it has no colour, but is as black as everything else about it. Its redness, then, depends upon the manner in which it acts on the light which it receives. White light is the queen of colours because it contains all the colours, and a piece of red glass is red because it transmits the red elements in white light, but is opaque to all the others. Why it should be transparent to red, but opaque to everything else, is a further question which we can make no attempt whatever to answer. If the reader will consider it for a moment, he will see how difficult it is, and how entirely it depends upon an adequate knowledge of the nature of matter itself.

Meanwhile, we must content ourselves with the empirical unexplained fact that certain kinds of matter have certain relations to ethereal waves of certain lengths. The explanation of the redness of a red object is thus only partial, but it is unquestionably true as far as it goes; and it applies alike to bodies which are red by transmitted light and those which are red by reflected light. A piece of red paper is red because it absorbs all the constituents of the white light which falls upon it, except the red which it reflects.

These assertions can easily be proved by experiment upon the spectrum. We find that a piece of red glass reduces the spectrum of white light to its red elements, cutting off the others, while a piece of red paper appears red in the red part of the spectrum, but black everywhere else—because it is compelled to absorb all light except red.

What Makes the Sky Blue? It is this principle of selection which explains many of the most glorious colours of Nature. If we ignore, as we may, the stars, nebulæ and comets, and the moon and planets that gain their light from the sun, then all the colours of the sky and sea and land are to be referred to the white light of the sun. Why, then, should the sky be blue? This subject was very carefully studied by Professor Tyndall, who showed, now about forty years ago, that the explanation is to be found in the presence of excessively fine particles that float in the atmosphere and, because they are so fine, scatter light of very short wave lengths, while allowing light of longer wave lengths to pass through. Doubtless there is a certain amount of scattering of all the rays, but the short blue waves are much more scattered than the others, and thus endow the sky with its blue colour. It is a somewhat prosaic explanation of the spendid colour which we associate with the firmament, that it is due merely to minute particles of "dust" in our atmosphere—the total thickness of which, of course, as compared with celestial distances, is infinitesimal.

How the Dust Paints the Sunset. Reference has already been made to the peculiar shape presented by the sun when it is very near the horizon. It is now our business to explain the magnificent colouring which we see at sunrise and at sunset. The light leaving the sun is white at all times. What, then, is the reason of the apparent redness of the sun when it is near the horizon, and of the colouring that is produced around it? The answer is that when the sun is near the horizon, and the rays are piercing the atmosphere very obliquely in order to reach our eyes, its light is affected much more by the particles in our atmosphere than when the sun is overhead—since it encounters more on its way. As must be, the blue rays are especially scattered, and it is by the red rays especially that we see the sun at such times. Every Londoner is familiar with the fact that the presence of an exceptional amount of dust in the atmosphere on a foggy day similarly affects the appearance of the sun. Indeed, it may be said that the sun is never white in London, but is yellow even at noonday. It has recently been noted by M. Rodin, the great French sculptor, that Londoners are fortunate in the magnificent effects of colour which their sky often yields them. This is some compensation, but a very inadequate one, for the filthy and health-destroying fashion in which we burn our coal. Lastly, it may be noted that whenever a large amount of volcanic dust is thrown into the atmosphere exceptionally brilliant and magnificent sunsets are observed. This was the case after the eruption of Krakatoa, the eruption at Martinique, and the recent eruption of Vesuvius.

The Spectrum. We now turn to a subject which is on the borderland between physics and psychology, and which can never be properly understood unless we are careful constantly to distinguish between the phenomena which have a physical or objective explanation and those which have a psychological or subjective explanation. Let us begin, first of all, with the physical.

It is the physical fact that the light which we call white can be decomposed into a spectrum. It is also, as might be expected, the fact that the various colours thus decomposed can be re-composed or combined so as to form white light again. This can be done by throwing the spectrum on to a series of mirrors, so placed that they all throw the light falling upon them on the same spot on a dark screen. The spot reflecting to the eye simultaneously this mixture of rays will appear white. Various other means will produce the same result, provided that, as in this case, not only are all the necessary colours present, but they are present in the proportions in which they exist in white light. Now, if we manipulate our apparatus so as to prevent the green constituent of the light from falling upon the screen, we shall find that the illuminated part of the screen is no longer white, but red; or, if the yellow constituent of the light be interfered with, the spot will appear blue. The relation between such colours as blue and yellow which, taken together, form white light—so far as our eyes are concerned—is expressed by the word *complementary*. This means that if white light be taken as full light, blue fills up yellow to that fulness (Latin *pleo*, I fill).

The Absorption of Light. We must distinguish very carefully, however, between the behaviour of lights of complementary colours, such as blue and yellow, and pigments of corresponding colours. If blue and yellow lights are mixed together, the result is white light, but, as everyone knows, if blue and yellow paint are mixed together, the result is not white paint, but green paint. For the moment this may appear paradoxical, but it will seem so no longer if we think more carefully of the difference between the two cases. In the case of the paints, their colour depends solely, as we have already seen, upon the colour of the light which they are not able to absorb. The light which cannot be absorbed by blue paint, but is reflected by it, is green, blue, and violet. Similarly, yellow paint reflects merely red, yellow, and green. This is as much as to say that when the two paints are mixed, the only colour which they cannot absorb between them is green, and hence that is the colour of the mixture.

A simple device will show the difference between mixing blue and yellow paints and blue and yellow lights. The latter can easily be done by any of many methods, and the result is the production of a white or grey light.

Colour Impressions on the Eye. Newton began the study of this subject by a very simple and effective method, "the use of rotating discs which quickly superpose on the same area of retina different impressions of colour." Newton gave precise directions for the size of the seven sectors bearing the seven colours, from red to violet, which were to be painted on a disc of cardboard, so that, when the disc was rapidly rotated, it appeared to be of a uniform grey, approaching more and more to whiteness in proportion to the strength of the light by which it was illuminated. Clerk-Maxwell had the excellent idea of applying Newton's colour disc so as to make a colour-top. This is simply a flat top of a size suitable for holding a number of coloured discs, made with a hole at the centre so that they can slip over the handle of the top. Each disc has a slit in it, so that various pairs of discs may be fitted into one another, simultaneously exposing various pairs of colours in any proportions that may be desired. Then the desired result is obtained as soon as the top is rapidly spun. As the top rotates more slowly, the retina becomes unable to retain the successive impressions long enough for their combination, and thus successive flashes of colour are seen.

Deceiving the Eye. There are various ways in which the retina may be deceived so that the sensations of complementary colours are subjectively produced. Thus, after looking at a red spot very fixedly for a few seconds, one sees a green spot of similar size when one turns the eye to a white surface. The explanation of this extremely interesting though familiar fact is that the retina has refused to respond to the red constituent of the white light which is sent to it from a white surface, and so interprets the white light as green. We may possibly discern some further explanation of this when we turn to colour vision. Complementary colour sensations may also be produced subjectively by what are called *Gorham's discs*, and by various other methods. In all such cases the explanation is beyond the reach of pure physics, and must be sought in the facts of colour vision.

In another respect, also, the retina may be deceived. It interprets as simply yellow light two entirely distinct forms of external stimulus. The yellow light which, as we have seen, is given out by sodium, is a pure mono-chromatic yellow, all consisting of vibrations of one and the same length. But various other colours may be so artfully mixed that when their combination is submitted to the eye it interprets them also as yellow. In other words, the eye has no power whatever of distinguishing between a *pure colour* and a *mixed colour.*

The Brain and Colour Sensations. The explanation of these subjective colour sensations, as also the discussion of the circumstances in which they are aroused, is of the utmost interest in relation to painting and the kindred arts. There is some evidence to show that these complementary sensations are not due to anything that happens in the retina itself, but to the behaviour of the vision centre at the back of the brain. Thus, for instance, if one eye be closed and a brilliantly-coloured object be looked at with the open eye, the complementary colour sensation may be seen in the closed eye, which suggests that, in some mysterious way, the first colour appears in one part of the vision centre in the brain, and its complementary appears in the remainder. Then, again, if a colour and its complementary are seen at one and the same time, each appears richer and finer than it otherwise would—a fact which is apparently to be explained by the theory that each colour produces the other—or, rather, a sensation of the other—in that part of the vision centre which it is not itself affecting. This it is which explains the agreeable effect of contrast, provided that it be a harmonious and not a discordant contrast. What we call a harmony of colours probably depends on the process which we have just described—each component of the " chord " of colours producing its complement in the part of the vision centre which it is not itself stimulating.

Can Colour be Standardised ? There are certain elements or constants or physiological characters which are associated with every colour, and we must try to analyse these and to use, in this analysis, a series of definite terms. In point of fact, common language is never looser than when discussing colour. The language of art criticism is equally defective in this respect, words like *tone* and *shade* being used with extraordinary elasticity. It may also be noted—though we have no present remedy to offer for it—that the notation or terminology of colours in general is extremely defective. Such a term as *red*, of course, includes colours of very different wave lengths, and our attempts to define a particular kind of red are as often misleading as not. Very many students have attempted to devise some kind of notation for practical use, but none of these have hitherto been successful. Thus, when a lady wants to match a particular colour, she cannot write to the shop and say that she wants a red of 358 billions (358,000,000 millions) per second, but has to go and take a piece of the stuff with her. If we remember the analogy between colour and pitch, we shall see that there is no inherent reason why colours should not be standardised just as musical instruments are standardised to English or French pitch.

The Elements of Colour. The first character of any colour is its *hue* or *tone.* This depends absolutely and without qualification upon the wave length and frequency, and needs no further discussion.

In the second place, there is the character sometimes described as *purity* and sometimes as *saturation.* The word *tint* is sometimes employed to describe this character, but most unfortunately so. The saturation or purity of a colour depends upon the amount of white which is contained in the colour. A perfectly pure or saturated colour, such as any of the pure colours of the spectrum, contains no white whatever ; whereas the more the admixture of white with the colour, the less pure it is. Plainly there may be an infinite number of degrees of saturation from, for instance an absolutely pure red, on the one hand, to a colour, on the other hand, which one woul describe as a white having the faintest possibl tinge of red

The third character of any given colour i indicated by such words as *brightness, luminosity* and *shade.* The best word for its description however, is *intensity.* The intensity of a colour in any given case, may be determined by tw factors. In the case of a given eye at a give time, it depends upon only one factor—namely the extent or amplitude of the ethereal vibrations. It may range, of course, from the mos brilliant and luminous to the darkest and mos sombre shades.

A Red Rag to a Bull. Our use of th word *amplitude* will at once have shown th reader that intensity or brightness in the case c colour is absolutely parallel in every respec to loudness in the case of sound. But it mus also be remembered—and this is true of sound a well—that there is a subjective or physiologica factor which determines brightness or intensit for one and the same colour may appear intole ably bright to one eye, while it is almost somb to another. As an instance, we may take th colour red, often known as the *dynamogeno* colour—that is, the colour which *produces forc* We must believe that a red which has no mark effect upon ourselves has a far more inten influence upon the retina of a bull, which it m arouse to behaviour justifying the name dynamogenous. In certain morbid states of t brain, and in certain criminals and in lunatics, red colour may act similarly.

Perhaps the oldest and simplest theory colour vision was that the visual cells of t retina—the rods and cones—are thrown in vibration in unison with the ethereal vib tions that excite them. This theory has to dismissed if only because such rapidity of mov ment of ponderable matter, as distinguish from ether, is quite inconceivable. The lig energy cannot merely be transferred to t visual cells ; it must be transformed. We ha already noted certain consequences of this tra formation—electrical consequences, changes the pigment cells, and so on.

The Theory of Colour Vision. T most widely accepted theory of colour vision, *colour perception*, as it is somewhat undesira called, goes by the names of Young and Hel holtz. The theory appropriately comes fr these two great men, since they were b originally doctors, who, having received a physiological training, then turned their attention to physics. It was propounded by Young in 1807, being thus scarcely less than a century old, and was revised and elaborated by Helmholtz in 1852. This theory begins by taking into account the known fact that we are not capable of receiving simple colour sensations corresponding to every colour in the spectrum, but that if three primary colours are allowed us, their combinations will yield us impressions equivalent to all colours. The assumption, then, is that our vision is trichromic—that is to say, that it is based upon three primary colour sensations. The Young-Helmholtz theory assumes, then, that the retina must contain three kinds of photo-chemical substances—that is, substances which can be chemically influenced by light. These three substances are respectively sensitive to the three "primary" colours—*red, green, and blue* or *violet.* (Thus "primary" here has only a physiological meaning—not a physical.)

How Colour Strikes the Mind. These three substances are supposed to be connected with three corresponding sets of nerve fibres, and these fibres convey to the brain impulses in various proportions according to the wave length of the light with which the retina is stimulated. The following is the statement of Helmholtz as to what actually happens under stimulation by various colours, according to the trichromic theory of vision:

"1. Red excites strongly the fibres sensitive to red, and feebly the other two—sensation, Red.

"2. Yellow excites moderately the fibres sensitive to red and green, feebly the violet—sensation, Yellow.

"3. Green excites strongly the green, feebly the other two—sensation, Green.

"4. Blue excites moderately the fibres sensitive to green and violet, and feebly the red—sensation, Blue.

"5. Violet excites strongly the fibres sensitive to violet, and feebly the other two—sensation, Violet.

"6. When the excitation is nearly equal for the three kinds of fibres, then the sensation is White."

The arguments for and against this theory might be discussed at any length. Its most celebrated modification is known as *Hering's theory,* and is about a quarter of a century old. It is really a modification of Young's theory. Both of these theories, and also all other theories that have been put forward, find their most important illustrations and tests in the extremely interesting and important fact known as *colour-blindness.*

Colour-blindness. It is not our business here to discuss colour-blindness as a disease, nor its extraordinary transmission from grandfather to grandson by means of an intervening daughter and mother who does not herself suffer. We have to discuss the disease in relation to its physics, and as regards its practical consequences. It was first named by Sir David Brewster. The most famous case on record is that of the illustrious chemist John Dalton, who had "red-blindness," and studied his own condition in the year 1794, by the aid of the spectrum. Hence the disease is often known as *Daltonism.*

We may briefly note some forms of colour-blindness. In complete colour-blindness, "the spectrum appears in shades of grey throughout, being lightest in the position of the yellow-green, and darkest at each end. A coloured picture appears like a photograph or an engraving. According to the Young-Helmholtz theory, such cases are explicable on the assumption that all the three photo-chemical substances are alike," as is indeed believed to be normally the case in the outlying portions of the retina, which can readily be proved to be incapable of perceiving colour. In other cases the whole spectrum may appear in shades of one colour, suggesting that only one photo-chemical substance is present.

Partial Colour-blindness. But the common condition met is partial colour-blindness, which may be either green-blindness, blue-blindness, or red-blindness. Of these the most important are the first and last. In green-blindness the spectrum is not shortened, but contains no green. Furthermore, it is *di-chromic* —that is, consists of only two colours, with or without a neutral area of grey. The two colours composing the spectrum are a reddish-yellow and blue. Such patients confuse bright green with dark red, and cannot see at all a dark green letter on a black ground.

In *red-blindness,* or Daltonism proper, the spectrum is shortened, since the red end is absent, and it consists merely of two colours—yellow and blue. Such patients cannot distinguish between dark green and light red, nor can they see a dark red letter on a black ground.

Here we can merely allude to cases of incomplete colour-blindness, the range of which may be indefinitely extended. It is unquestionable that the eye of the painter sees very differently from the eye of the average person who, relatively to the painter, certainly suffers from incomplete colour-blindness. When a lady complained to Turner that she could not see all those colours in the sunset, he replied, "Ah! madam, don't you wish you could?"

The Consequences of Colour-blindness. Colour-blindness is mainly a disease of the male sex. In all nations, about 3½ per cent. of the men are colour-blind. Now, red, green, and white are universally adopted as signals to indicate danger and safety, and these are just the colours which the colour-blind men mistake. On the other hand, other colours cannot be substituted for them, since they do not transmit nearly so much of the light behind them. Thus, it is necessary to exclude colour-blind men from such work as that of signalmen; and this is done by causing them to match coloured worsteds. In order to study the colour sense most perfectly, one should employ the pure spectral colours, and Lord Rayleigh, among others, has constructed instruments for this purpose. The worsted test universally goes by the name of *Holmgren,* of Upsala, who was the first to employ it in a systematic way.

JEWELLERS

The business of a jeweller stands upon a different plane to most other shopkeeping departments. It possesses many technicalities, and demands the possession of a good practical knowledge of its rudiments and a theoretical knowledge of its many details. For instance, the successful jeweller must be familiar with the different qualities of gold peculiar to Britain, America, and the Continent, with rolled gold, and gold cased, also with the various precious stones, their degrees of colour, the various forms of cutting them, etc. We shall assume that our reader has the above knowledge, and a sum of £500, an amount by no means excessive. A smaller capital will curtail the ability to make an efficient display, except by getting into the hands of the wholesalers, which the beginner should avoid. If one were certain of doing a fair return from the commencement, it would be otherwise; but jewellery being one of the first trades to suffer in times of depression, reserve capital is essential.

Location. The first thing we have to consider is the site. The degree of ambition has an influence in determining that factor. A start may be made in city, town, or country, and the choice made from these three determine the rent and taxes to be paid, also the nature of the fittings, and the class and quality of stock required.

The city and town life are more strenuous than the country, the risks greater, but the success is also greater if attained. Nothing is gained without a certain amount of risk. But the timid, those who would be worried mentally over the thought of risks, are better to decide upon the easier and less expensive district. In any case, one must try and get a position or shop as close as possible to the centre or shopkeeping thoroughfares where the business is done, for few of the public go out of their way to purchase jewellery. The beginner in the city should not pay more than about £100 per annum rent, with the capital we mention, for rates and taxes will at the least be equal to one third additional. Six months' rent and taxes ought to be held in reserve, which, on the above basis, is approximately £65.

Fittings. One must study the district and see the class of goods that are more or less in demand, thereby forming an idea as to the necessary elaborations in fitting up the shop.
Try and work out a design of your own, even
it should be rough in its nature; strive to get in
it a distinctive feature; too much of the prese
mode of working and constructing is stereotype

60 days, 90 days net. A few give only 2½

cent. discount for 30 days, and after that net. One thing to be careful about is overbuying before you are sure of your district. Select articles that you believe to be in demand. In other words, simply form a nucleus upon which you can work. It is easier to get new stock in than to get rid of old and unsaleable goods. A nice selection, arranged so as to make your shop appear full, is all that you require to begin with. Let that nucleus be composed principally of the genuine material—gold and silver, etc.; then you have at least making-up price in the market value of the material, whereas rolled gold and imitation jewellery, once soiled, is difficult to renew or make fresh. Stock to the value of about £200 should be ample to begin with. That should include principally the everyday articles, such as rings, brooches, charms, necklets, lockets, pendants, with an assortment of gold, silver, and metal watches; muff chains are not in great demand at present. Of gents' gold alberts, stock a few only, as they are cut so much that they are practically not worth handling, but they cannot be entirely neglected.

Where to Buy. To those in the trade it is pretty well known that Hatton Garden and Charterhouse Street are the districts in London where the wholesale jewellers congregate. In Clerkenwell Road and the surrounding district there are several very good houses, where you can get everything and anything of good quality and at reasonable prices. For the country in general outside of London, Birmingham is the home of the jewellery manufacturing trade, and there all qualities of jewellery may be obtained—good, bad, and indifferent; even London cannot do without Birmingham. The names of many good houses will be found in the retailers' monthly, the "Watchmaker, Jeweller, and Silversmith," published at 150, Holborn, London, E.C. However, the individual firm need not trouble the beginner, for he will not be long open before he is found out by the army of travellers looking out for fresh business. Here we warn our novice not to believe all that is told him by the knights of the road. The retailer must set his mind firmly against being influenced to take what he is not certain will sell. One cannot avoid a little dead stock, but to keep it as little as possible constitutes the art of buying.

Stockkeeping. Having attained the necessary stock, the next duty is to take a record of it in what is called a *stock book*, noting the description of each article, the number attached to it, and its cost. See that the stock is kept clean, as well as the window and shop. Nothing deteriorates in appearance as the result of finger marks more than gold and silver surfaces when finished, and nothing looks more shabby. The salt that is in the perspiration has a chemical action, and if not wiped off at once it is almost impossible to get it off afterwards, as the surface is eaten into. Therefore, the few minutes spent with the chamois leather is both time and money saved.

We advise that very little rolled gold or gold-cased articles be stocked. There are, of course, certain districts where the bulk of the trade is done in that class of goods, but here we are dealing with jewellers as jewellers, not as fancy goods shops. Later on, the jeweller can judge if there is much demand for such goods in his district, and, if so, it is quite easy to procure stock. Better to work on the above principle than load oneself at the beginning with doubtful articles. In reference to profits in general, it is not wise to run under 33⅓ per cent., and get 50 per cent. if possible. One must bear in mind the nature of the trade. Jewellery is not a necessity of life where you are sure of a certain turnover day by day, and, as we have stated, it is the first trade that is subject to suffer from general or local depression. Meanwhile, the expenses are running on and have to be met, for the landlord and the tax-gatherer do not take the ups and downs of your business into consideration.

Repairing. There is one source of revenue to be made which is a great help in a small business—namely, the repairing department. Nearly all jewellers take in watch and jewellery repairs. If you are a watchmaker you can fill up your spare time at that branch, and if you have not enough work to employ a practical jeweller, you can always get such work done at a trade shop; in every town there are some, but one can find out only by experience the best and most reasonable. Avoid cutting a man down too much, for you will only get value accordingly. Although the finished article may look all right, in a very short time it will reveal its nature, and then you will have trouble with your customer, or lose him altogether. Most people are open to reason, and a little explanation before taking in hand a piece of work to be repaired or cleaned properly at a fair price, is understood. If customers attempt to beat you down, as some will, it is preferable to refuse to do the work rather than take it in and do it unsatisfactorily. Again, however, with a regular customer one has to come and go a little. There are many articles that will take up a man's time so long that the public eye cannot see where the value comes in; and it is then difficult to convince as to the reasonableness of the charge. But one's judgment and tact must be brought into play, and, as a rule, matters will right themselves.

We have not touched on silver plate because the sum on which we have been considering cannot well include this department. That can come later on if the business warrants it, and the subject is treated in another article in this course. But a few fancy ornaments, etc., with an assortment of clocks should be added, those being necessary to every household.

General Policy. It will be observed that we have absorbed £365 out of the £500, leaving £135 in hand. It is not to be expected that the beginner will pay his way from the day of opening. Jewellery is a business about which the public as a whole know little, and it takes time to gain confidence. But confidence once inspired, every effort should be made to retain it. At the opening there are incidental expenses that are not thought of at the moment, but which cannot be avoided, therefore the odd £35 can be looked upon as pretty well absorbed. So, with the £100 in hand, with care in management, and by sticking closely to business till it is established, one should be able to develop and command the wholesale market pretty well through being able to meet the accounts as they become due, thereby also saving the discount. It is these small items that help one in this world of competition.

One item to be remembered is the gold and silver licence issued by the Government in two forms. The retailer may sell articles up to two ounces of gold and 30 ounces of silver on the licence at £2 6s. per annum, and for all above that weight the sum is £5 15s. It is advisable to become a member of the National Association of Goldsmiths, which assists and protects retailers who are members.

LICENSED VICTUALLERS

The trade of the licensed victualler is not usually regarded as a branch of shopkeeping. Although there is no fundamental reason for this, the view is to some extent justified by the great differences which exist between the conditions of selling excisable liquors and those of all other branches of retailing. No other trade is so encompassed and hedged about with laws, so subject to legal regulation in all its details, or so great an object of the attentions of social reformers and zealots. From the time of Edward VI., when the first licensing Act was passed (1532), at least fifty principal Acts affecting "the trade" have become law, of which four-fifths have come into being in the last 170 years.

Working-up. There are very few proprietors of licensed houses who started life in "the trade," chiefly for the reason that the conditions of employment in beer and spirit selling have little or no attraction for smart businesslike young men, and do not foster those habits of industry and energy which go far to make the successful proprietor. Further, barmen, and even managers, have no great opportunity or incentive to save money. Another reason is that it is not a trade which requires the experience of a lifetime, for it is so bound and fettered by laws and by the system of "tieing" houses that there is little room for development by enterprise. Nevertheless, men have worked their way up. The lowest grade of employee in the trade is the potman. Formerly his office and pride was the keeping and polishing of the pewter pots. Now, however, he has degenerated into a general handy-man, his duties ranging from sweeping out the bar to "chucking" out its obstreperous occupants. The wages vary from 10s. to 16s. per week living in, or 20s to 27s. out. On Saturday nights or other busy times he may be called upon to help behind the bar, and thus get a footing therein and obtain an under barman's place. From under barman at 12s. to 17s. per week to head barman at 18s. to 26s. is a matter of personal progress.

A Managership. The ambitious man will combine the duties of cellarman with those of bar supervision and serving. He may not get extra pay for doing so, but he will accumulate valuable experience which will enable him to take advantage of a managership opportunity later on. The cellarman is responsible for fining the ale, for the condition of the beers, keeping the spirit vats and the earthenware supply casks for the bar stocked, and for keeping the bar supplied with the bottled goods as well as for the absolute cleanliness of the cellar and its utensils. By watching advertisements in the trade newspaper—the "Morning Advertiser"—or the trade journals, or by the help of convenient friends, he will achieve his next step—to manage a house either as working manager under the proprietor or as manager in sole charge. The character of the post naturally depends upon his experience. He should be married. With his wife to take charge of the housekeeping side (providing food for the bar and the staff and managing the household affairs) and to serve in the bar on occasion, he may obtain from £2 to £4 a week with board and lodging and will draw about 10s. a week extra per head for the board of the staff. If unmarried the manager is generally expected to provide a female assistant to undertake these duties.

"Tied" and "Free" Houses. Next must be considered the man with a limited capital which he desires to invest in a public house. He may be our manager who has saved a few hundred pounds. Public houses are divided into two definite classes—houses which are "free" and houses which are "tied," the latter far outnumbering the former. In 1893 only 12·8 per cent. of London houses were entirely free, and since then the number has been greatly reduced by brewers' purchases. In the provinces they are still fewer. Prices almost fabulous have been paid for free houses in the past. Their value lies in the fact that they are not burdened with loans, whereas the man who runs the "tied" house is either indebted to a brewer for part of his capital (lent on mortgage) or may be only the brewer's tenant. In both cases he must buy his beer from this one brewer at higher rates or smaller discounts than the "free" man, and if he has also received an advance from a distiller he is also bound in the purchase of spirits. Free houses are now so few in number and their prices so high that they do not come within the range of this article. They are objects of ambition for the man of considerable capital.

Capital. A man with a small capital may either start as a brewer's tenant or as landlord of a small tied house. The novice may be attracted by advertisements offering tenancies which can be entered upon with a very small inclusive capital, say, £150 to £200. But it is necessary to lay stress on the fact that it is practically useless to lay out money in taking over a house doing the very small trade which only can be expected for such a sum. A living trade is hardly possible where the takings of the house are less than £100 per month. For capitals of from £300 to £500 a man may reckon upon being able to obtain modest tenancies of houses turning over, according to locality (town, suburban, or country) and class of trade, from £100 to £250 per month. These capitals will be made up as follows: Deposit with brewers, £75 to £125; loose effects, £100 to £150; stock, £50 to £100; cash in hand, £40 to £75; legal and brokers', etc., charges and proportion of licence duty, compensation fund payment, rent, rates and taxes, £35 to £50. This may sometimes be reduced a little by arranging with the brewers and distillers to take over part of the stock, which is bought back as trade requires. The lower capitals will apply to the provinces where houses are more completely tied than in London and other large centres.

Similar houses on lease from brewers instead of on a tenancy agreement will need capitals of from £1,500 upwards. They possess the advantage that they can be sold by the landlord, at a profit perhaps, making speculation possible; and also that, in the event of extinction, the lessee gets a considerably larger proportion of the compensation than the tenant. But the responsibilities and amount of possible loss are much greater, of course.

A beerhouse, licensed only for the sale of beer, would probably need a capital of only about £150 for a trade of £100 per month. The licence duty and working expenses are somewhat less than in the case of the fully-licensed house, but the trade is on a lower grade and the profits and possibilities smaller.

Choosing a House. A good training for a landlord of small capital, new to his responsibilities, is afforded by a tenancy—under brewers of standing, of course—in a semi-working-class neighbourhood, where most of the houses are classed as "small property," and where there are plenty of people walking about. The trade is more easily worked than any other town trade. Beer is the article mostly sold, for the English working man drinks little or no spirits. The day trade in the jug department will also be good. This class of house has an advantage over a larger establishment, in that it depends mainly upon regular customers, who, if well served, will not be drawn by the larger house with many lights, which depends more and more upon passing custom as its size increases. Brewers' rents for these houses are very variable, and are usually more than the ordinary rental value of the property. They may be anything from £50 to £100.

The man with little capital may also do well with the tenancy of a small country inn. The prices obtained will be lower, and the profits smaller than in town, but the rent will probably be nominal (£20 to £40), and there will be the advantages of grounds, fruit gardens, poultry keeping, and stabling, all of which will contribute to the income. Grounds and outbuildings will enable him to cater for motorists and cyclists; fruit, vegetables, and poultry will supply visitors' meals. In a small country town the tenant may let the stabling, if he does not wish to work it himself (which entails the expense of an extra man), at from £10 to £15 per annum, to a local jobmaster, who will work it in association with him.

New houses are very rare in the trade. The capital required, and the risks of losing it, are considerable. Justices will grant new licences only for entirely new districts, and even then are generally very reluctant to do so. The licence is granted before building, if the justices approve the plans and other details, but the licence has to be confirmed when the house is ready to be opened, which means that the battle has to be fought over again with the possibility of confirmation being refused. If confirmed, it is granted for a period of seven years, and at the end of this period has to be renewed as a new licence, with no right to compensation if extinguished. To open a new house of the type above indicated would require a capital of from £3,000 to £5,000, according to the location—country or town.

The Broker. In the actual choice, the services of a trade broker are indispensable, partly because the market is entirely in the brokers' hands, and also because the many legal formalities incident to entry to the trade are likely to entrap the novice. If reasonable care be exercised in the choice of a man, those who offer El Dorados for trifling sums being shunned, there will be little cause to regret the small percentage on the amount of the transaction absorbed by the broker. Having obtained from the broker particulars of houses likely to suit his desires and capital, whether in town or country, the prospective landlord should personally visit the house offered, and decide the choice for himself. He must investigate the duration of the lease, the total loan burdens on the house, and the reputation which the house has with the local authorities, inquiry being made of the clerk to the licensing magistrates, in order to ascertain whether the Register of Licences (which is open to inspection) contains any record of transgression by a former holder of the licence. These matters are most important, and there is much room for the novice to buy dear experience. They should all, therefore, be rigorously investigated by his broker, and only when he is satisfied should further steps be taken.

Profits. In taking over any business, that which ultimately decides the question of purchase is the quality and quantity of trade done, and in this trade it is paramount. A tenant who is tied only for his beer, should make not less than from 33 per cent. to 37 or 38 per cent. total gross profit on his takings, and from 30 to 35 per cent. if he be tied for spirits as well as beer. These figures do not pretend to finality, but indicate what the prospective purchaser may reasonably require for the class of trade outlined. If, for any reason, the figures supplied by the vendor are suspected, the receipts for the amounts paid to the brewer and distiller will give definite information as to the quantity and quality of the business done by the house, and the purchaser may reasonably require their production.

Loans and the Purchase. Although starting in business in the licensed trade on loans raised by mortgage to brewers and distillers is a feature of the trade, it is highly undesirable, as elsewhere, to saddle oneself with the burden of loans from brewers or from private sources. The man whose house is heavily mortgaged, and who is accordingly stringently "tied," is fettered in all ways, and proper development becomes difficult if not impossible. Certainly, the man who takes the modest tenancy here referred to should not need to borrow.

A house may be bought "all at" or by valuation. The first term means an inclusive price for the lease (if any), the fixtures, and all utensils appertaining to the business, but excluding the stock, which must be valued. The inventory of the trade accessories and fixtures should be shown to the representative of the brewer to whom the house belongs, to ensure that none of the articles catalogued belong to him, which, of course, the vendor cannot sell. Buying a house by valuation simply means that the price is based upon inventories made by the representatives of the seller and the buyer of everything, including the stock. When the tenant or purchaser formally takes over the business, the ceremony called the "change" takes place, when the valuations are checked and the purchase money is handed over—always in cash, never by cheque.

The Legal Transfer. The transfer of a licence is attended with many legal complexities. Before the "change" is accomplished the incomer's broker secures for him a "protection order," to enable him to sell excisable liquors until the next meeting of the Special Licensing Sessions, of which from four to eight are held during the year. Full details of the formalities will be supplied by the broker, or will be found in such a book as Mr. W. Makins' excellent "Licensed Victuallers' Handbook," wherein will also be found much legal and practical information relating to "the trade."

The Licence and its Renewal. In reality, the licensed victualler has two licences—the Justices and the Excise. But as the issue of the latter is entirely dependent on the granting of the former, it is usual to regard them together as "the licence."

Publicans' or victuallers' annual licences in the United Kingdom for spirits, beer and wine to be consumed on or off the premises are of three kinds: (1) the full licence, for the sale of excisable liquors during all the hours not specified by the Act of 1874; (2) the six-day, or early-closing licence, in accepting which the licensee agrees to remain closed during Sunday, or to close an hour or more earlier than the time stipulated by law; and (3) a licence which combines the features of which are alternative in 2. The duty on the second and third licences is respectively one-seventh and two-sevenths less than that on the first. The choice of the licence will be determined by local conditions.

The duty is based on the rateable value of the premises, and varies, for the full licence, from £4 10s. for premises rated under £10 to £60 for premises at or above £700. For houses whose rateable values are between £50 and £100 the duty is £25. The assessment is based on the rent payable.

It has been held that holders of existing licences have a *primâ facie* right to renewal, and the power of refusal, on other than certain well defined grounds connected with the fitness of the holder or his premises, is vested in Quarter Sessions, on reference from the justices and on payment of compensation from the trade fund instituted by the 1904 Act. The licensed victualler has, therefore, now more prospect of continuity in his business than formerly; but if he be only a brewer's tenant his share of compensation is rarely, if ever, sufficient to cover his losses on the extinction of the licence.

Preserving the Licence. Keeping the licence when it is obtained is not an easy matter. It may be directly forfeited upon conviction for seven particular offences, including felony, keeping a disorderly house, selling spirits without a spirit licence, and making intercommunication between licensed and unlicensed premises. Further, convictions for serving drunken persons or children under 14 in open vessels, allowing the premises to be used for betting, gambling, or allowing customers to be on the premises, or billiards to be played, after prohibited hours, are entered upon the Register of Licences, and regard is had to them by the justices when a renewal or transfer is wanted.

The staff must keep very wide awake to prevent betting slips being passed, though it is very difficult to detect this. If the loser of a bet pays it by paying for drinks it is an offence under the Gaming Act. The laws affecting the public-house and the preservation of its licence are many, and the licensee must be thoroughly acquainted with them. The trade year-books, or Mr. Makins' "Handbook," give full information on all these matters.

Fittings. Under the 1902 Act all alterations or additions of a structural nature have to be approved by the justices, and there is no appeal from their decision. Plans should be submitted before such alterations are carried out, or the justices may order the premises to be reinstated in their former condition. Structural alterations include shifting a counter or a screen, but not the renewal or addition of beer engines. The result of the restrictions is that alterations are expensive, and rarely carried out. When they are, it is a matter for local architects and builders, for there are practically no firms of public-house fitters. In the case of the tenant such expense, where necessary, falls upon the brewer. A semicircular bar is the most convenient shape where possible, for it is more easily supervised, and can be worked with a smaller staff than the bar of square or three-quarter circle form.

For the bar-floor mosaic is best, but is expensive. A good inlaid linoleum is also hygienic. Sawdust absorbs moisture, but a non-absorbent floor is cleaner.

All fittings and utensils will be included in the transfer, and it will not be necessary, therefore, to deal with them here in detail; when renewal is necessary the catalogues of good firms of bar-fitters will show what can be done. It may be noted that liberal lighting with incandescent gas-lamps is a feature of the publican's show. Electric light is more costly.

Country Trade. The country publican will trade as an innkeeper, which entails the compulsory reception of guests. The trade is included in the full victualler's licence. In the case of the small house there will be little profit derived unless visitors are more or less regular. Supplying meals to cyclists, motorists, and other road travellers may be made very profitable if it can be done in quantity. Small trade means much waste. On ordinary catering a gross profit of at least 50 per cent. should be made. As much as 75 per cent. gross profit may be made on teas if they be purveyed in large numbers. The profit on luncheons is more precarious, but country produce will help. Outbuildings for storage are almost essential to the man who caters for cyclists and motorists. In them petrol and calcium carbide can be stored and supplied at profitable rates. Licences, costing 5s., must be obtained from the local authorities in each case. Cyclists and motorists are always appreciative of good service and catering, and a permanent connection may be built up. If the landlord can persuade a cyclists' club to make his house its country headquarters it will pay him The same remark applies in greater force to Masonic and other lodges.

The Cellar. It is probably not too much to say that profits are made or lost in the cellar, and the importance of method can hardly be overestimated. In a small business it will usually pay the publican to be his own cellarer so far as its management and arrangement are concerned. In any case he should "break down" spirits himself, and possibly also "fine" the ales. "Breaking down" is a mathematical operation which should be conducted strictly with the aid of the hydrometer and sliding rule, and according to published tables for spirit strength reduction. "Fining" is the clarification of ales by the addition of isinglass or other "finings."

Drinks must be appetising. Wine and beer must be clear and aerated water sparkling Aerated waters are, happily, becoming more and more important in their relation to the prosperity of the licensed victualler. To ensure the proper condition of liquors it is necessary to adjust carefully the storage conditions for each article. Beer in casks and bottles should be kept at a temperature of about 55° F., port and similar wines at 60° F., and light wines and spirits at about 40° F These temperatures must be carefully maintained, which can be done conveniently by means of a set of thermometers (such as Hicks's), indicating the temperatures for the respective articles.

The cellar must be well ventilated, for bad air deteriorates the stock. To keep it sweet it should be washed out once or twice a week, and the walls whitewashed annually. Care should be exercised to avoid spilling beer, for spilt beer is apt to breed vermin.

Burtons and bitters should be stocked a fortnight before sale, so that they may become bright by depositing the sediment.

Racks must be provided for empty bottles. Much waste occurs if they are not preserved from breakage, for the price of the bottles represents the total profit on many bottled articles.

The gantries, or stillions, on which the casks rest, must be solid and substantial, so that the beer or spirit may not be shaken up. To preserve the liquor from the effects of the vibration which is often observable in towns, they frequently rest on sand.

The pipes connecting the cask with the bar engine must be kept scrupulously clean, or the best liquors kept under the best conditions will be spoilt. The pipes are preferably of fine tin in 6-in. sections, connected by special joints of pure rubber, and it must be one of the chief duties of the cellarman to look after them. They should be washed out frequently with hot soda solution, followed by plentiful flushing with fresh water.

Sidelines and Amusements. Though dealt in by all publicans, and therefore not strictly sidelines, tobacco, minerals, cider, and wines may be briefly referred to here. The licence for tobacco and snuff dealing is always taken out with the liquor licence, and costs 5s. 3d. per annum. The profit will not be more than 25 to 30 per cent. gross, and considerably less in the case of those provincial houses which are tied to the brewer for tobacco, and the trade will not be large. It is quite an easy trade, however. On minerals, the gross profits should not be less than from 25 to 30 per cent. for bottle sales, and 35 to 40 per cent. for sales in glasses. The trade is considerable, and is easily cultivated. Cider and wines will be very little sold in th small house, and even in the larger houses the trade is not large. It is chiefly absorbed by wine and spirit merchants.

Amusements in licensed houses are so frequently the source of trouble with the police that in many cases publicans have ceased to supply them. Automatic pianos distinctly tend to cause disorder, and may be removed as public nuisances on the complaint of householders. To keep a public billiard table, a special licence is necessary, full-licence holders, however, being exempt. It has to be applied for at the annual Licensing Sessions, and the conditions which apply to liquor licences also apply to it, except that it expires on April 8th in each year The holder must display a notice to that effect similar to the liquor licence signboard. A good room with two tables may bring in as much as £5 a week, of which 15s. to 30s will be absorbed by the extra staff required.

Trade Papers and Societies. The trade newspaper is, of course, the "Morning Advertiser." Weekly trade journals are "The Licensing World," published by the Licensed Victuallers' Central Protection Society of London, 35, George Street, Westminster; and "The Licensed Victuallers' Gazette," published at 81, Farringdon Street, London, E.C Both journals publish useful year-books. The Central Protection Society also publish pamphlets and booklets stating the publican's side in the many controversies affecting the trade. This and similar protection societies throughout the country look after the legal interests of publicans, conducting police-court and similar cases for their members. The Incorporated Society of Licensed Victuallers, in connection with which the "Morning Advertiser" was started, and the Licensed Victuallers' Asylum afford relief to distressed victuallers, and look after their interests.

MANICURISTS

The practice of manicure—probably in almost as complete a form as present-day treatment—comes to us from a period in the world's history as remote as the time of the Roman Empire. The Egyptians also affected some form of it, but in a ruder way—little beyond the shaping of the nails and staining with the pigments peculiar to this race. Such observations as can be relied upon point to the treatment being confined to shaping the nails in elongated form, and staining beyond the light arc circle. Possibly the cuticle also received attention, together with the removal of dirt and debris from under the edge of the nail; while the brightening and cleaning, and even the bleaching of this portion, may have formed a part of the Egyptian process.

Coming to later French history—say, during the Louis period—the art of manicure was well understood, and freely patronised. Marie Antoinette, with all her mystic aids to beauty, did not neglect it. The apartments and secret drawers in the boudoir furniture of this epoch, together with the peculiar chinaware and implements then in vogue, all bear evidence of the employment of this art.

Manicurists Abroad. At the present day the practice of manicure is probably more general in the large cities of the United States than anywhere else, though Paris and Berlin, and even Vienna, occupy prominent positions in this respect. To Paris should fairly be awarded the credit for the best work, although here, again, New York cannot be omitted from recognition. London certainly shows signs of advancement, but at present the number of practising manicurists in the English metropolis is meagre in comparison with the capitals of France and the United States. Performers of moderate skill and little experience are fairly plentiful. Obviously, it should be the aim of all who practise manicure as a livelihood to excel in ability, and there is more scope for individuality than may appear at first sight.

Treatment of the Hand. The shape of the finger nails, and their appearance on the completion of treatment, vary in different countries. In England, the true filbert is generally accepted as becoming and proper, and very handsome can the hands be made when thoroughly treated in this style. The cuticle is dressed down to an artistic bevel, the light arc accentuated, and the shell pink heightened in the centre of the nail, the extremity of the latter being imperceptibly bevelled clear of the quick, and showing, of course, the transparency of the outer end or edge. In the best style of manicure practised in England the polish of the nails, although equal in smoothness, lacks in brilliancy, and the tinting is much less pronounced than in the treatment on the Continent and in the United States. Probably it would be correct to say that in our own country the work done with the file and manicure knife is more in evidence than is the use of the nippers and polishing materials. In France and America, the reverse is the case.

Russians, Viennese, and Germans favour the elongated nail, or accentuated point, and also a distinct pink polish. Racial distinction may have some influence on shape, but certainly the two nationalities first-named, and in a somewhat less degree the Germans, cultivate the nail of narrow width, giving quite a pointed appearance. The pink tinting and glossy polish are also unmistakable. This style of treatment is affected, too, to some extent, in America—a fact which English manicurists should not overlook, although, as a general tendency, the English filbert is the mode that should be practised.

Operators and Salaries. Manicure is largely in the hands of women, but the highest exponents are men—chiefly hairdressers—who take up this branch and abandon their original work. It is largely a personal business, few assistants being employed for manicure alone. Excepting in the best establishments of the West End of London, and their equivalents in other capitals, the assistants are required to take their turn in other departments.

When manicure is practised by hairdressers' assistants, the commission they receive is usually 3d. in the shilling, but less in some instances. The girls are paid 20s., 25s., and 30s. weekly, with a commission of about 5 per cent. on the takings. There are some establishments which confine themselves exclusively to manicure and facial massage, and in such cases one or two rooms on a floor above the street level usually suffice.

Equipment. Manicure and facial massage (the latter is dealt with in a separate article) are nearly always undertaken in conjunction, and the same apartment is generally adapted for both. The proper equipment of the parlour embraces the following: A lavatory basin, costing from 45s., with the plumbing in addition, according to the circumstances of the apartment; a special chair for the patient's use, often made with a reclining back and fitted with cups in the arms, so that the hands may be moistened in the softening preparations, and otherwise prepared for treatment with the manicure appliances—such a chair costs from 45s. to 50s.; a stool for the operator, which can be purchased for about 2s. 6d.; and usually a portable standard lamp, fitted for electricity or gas (generally the former), for throwing a good light on the fingers, and costing from 7s. 6d. to 21s. If the lamp is adapted for electricity, the installation of the current may, of course, be a further item in the expenditure.

Ordinary manicure outfits are not costly, though some specialists have their own personally-selected tool caskets, at an outlay of anything up to £5 5s. The charges for treatment in the general category of shops are 1s., 1s. 6d., and 2s., while the best practitioners obtain from 3s. 6d. to 5s.

Beginners give time—three months or more—in return for tuition and experience, or pay £5 or £10 to be under well-known men. No wages are paid in either case. There is a good living to be made ultimately by those who really acquire proficiency and keep themselves versed in the best and latest methods of treatment.

MASSAGE SPECIALISTS

The particulars given here should be read in conjunction with the article on Manicurists, the usual practice being for massage and manicure to be undertaken as a joint venture.

There are two kinds of massage—manual and mechanical—the one being done by the hand, and the other given by a vibrating machine The hand form is probably as old as civilisation, but mechanical massage is quite a modern acquirement in England, although it has been in vogue in America for several years. As a general and genuine remedy, there are many operators who claim that there is still no better method than the hand treatment. But against this there is the fact that the use of mechanical appliances is extending and attracting public favour.

Massage Treatment. Opinion is likewise divided as to correct procedure. Some experts hold that nothing beyond the creams, lotions, or oils should be used, while another section favour the steaming of the face in order that the pores of the skin may be first opened and the flesh rendered supple, and free to absorb the customary preparations. In most cases, the latter treatment is accomplished by hot towel bindings—that is, towels wrung out from quite hot water and wrapped round the face. Some operators, however, favour direct steaming. This can be done with appliances technically termed *vaporisers* (their effect is similar to that of a steam kettle on a smaller scale), or by holding the face over a vessel containing hot water.

Charges. Facial massage, as in the case of manicure, is usually a department of the hairdresser's establishment, the operator being paid a commission for this service in addition to his usual wage. The sum varies, but 3d. in the shilling is general. Outside a few of the West End London houses, assistants are not employed for facial massage alone. Young ladies as masseuses and manicurists are paid from £1 to £1 10s. per week and commission (about 5 per cent.).

The charges made for massage treatment range from 1s. 6d. to 3s. 6d., with 2s as the average. In good class barbers' shops, where mechanical appliances are in use, gentlemen are treated for 1s. 6d., and for 1s. if only massage by the hand is given. In America, massage is far more general than in England, and is always done by barbers. The average charge is 1s. 6d., and 2s. if given by means of the vibrating machine.

The Massage Parlour. When an apartment is devoted to massage, it usually takes the form of an ordinary reception-room, with additional fittings as noted in the article on Manicurists. But massage for gentlemen is often given in the ordinary hair-dressing saloon, and the American haircutting chair, as illustrated in the article dealing with Hairdressers [page 3297], is then used. If mechanical massage is to be given, an electrical vibrating machine of the best make costs £25, and, of course, a supply of electricity must be in readiness for its working. As indicating what these vibrators are capable of doing, it may be stated that they are fitted with levers which can be shifted at will, producing vibrations to suit the operator's requirements, from one to seven thousand per minute. A portable electrical vibrator can be purchased for £7. There are also hand machines at about 30s. each, but these are usually intended for private use.

The conditions which govern the learning of the business and gaining an entry into it are similar to those described in the article on Manicurists.

MILLINERS

The word milliner is derived from Milan, a town which at one time gave the law to Europe in matters of taste and elegance, and which has always been noted for the excellence of its silks and velvets, so that, in course of time, one whose business it was to shape these materials into the different varieties of feminine head-gear came to be called a Milaner, or *milliner*. In former years the word appears to have had a masculine significance, but in modern times this is one of the trades in which women have managed to keep the monopoly, and in which they have been, on the whole, very successful. There have, of course, been a number of cases foredoomed to failure from the start. Within the past ten or twelve years there has been a great increase in the number of milliners' shops, especially in London, and a large percentage of these shops, after struggling for existence during a few years, have come to an inglorious end in the Bankruptcy Court. As a rule, the women of this country are far behind those of France and America in the conduct of commercial enterprise, and the reason for the majority of these failures may be found in the fact that many who possess *some* of the qualifications which make for success in millinery rush into this particular business without having had any practical experience, or without having undergone some preliminary training in the elements of shopkeeping. The result could hardly be other than disastrous

Training. It is not difficult to obtain a thorough training in a comparatively short time, and at a reasonable cost, in one of the various schools of millinery which are now established in London and some of the chief provincial towns. At these schools the pupils receive instruction in the whole art of millinery. They are taught to make the wire shapes, to make French flowers, to shape and plait the straw, and to copy with absolute accuracy the most elaborately-trimmed of Paris models. The course at The Studio (School of Dressmaking and Millinery), Artillery Mansions, Victoria Street, S.W., lasts for one year of three terms. The fees for the course in millinery and French flower making are £12, or for millinery alone, £6. At the end of that period, the pupils sit for the London Higher Technical Examinations, and diplomas are awarded to successful candidates. The examiners are drawn from education centres, and from different West End firms representing the trade. Having passed her examination, the intending milliner should spend at least six months in the work-room of a good house, and, if possible, should spend a short time in the show-room also, in order to obtain some practical knowledge of business methods. She should also know how and where to buy all chiffons, silks, and other materials, as well as how to take and keep stock ; and, if her ordinary school curriculum did not include bookkeeping, lessons should be taken in that all-important branch of commercial education before she can consider herself ready to begin work.

Capital. With reference to the amount of capital which would be required to commence business as a milliner, it is not possible to fix any definite sum. Various considerations should be taken into account, such as the locality chosen for the start, the class of business to be done, and the character and capability of the individual. It may, however, be laid down as a safe rule, that no enterprise of this kind should be embarked on unless there is a sufficient sum of money in hand to purchase all the stock and furniture required, and to pay all working expenses for at least one year. The expenses to be allowed for would include rent, rates and taxes, lighting and heating, wages, and the stock for each season, in addition to all personal living expenses. Advertising should also be allowed for, and unless one had a large connection, a considerable sum should be spent in this way. A milliner, even more than a dressmaker, finds it profitable to keep a regular series of illustrated advertisements in two or three of the ladies' papers, and money should also be spent on tasteful circulars, printed on good paper, and showing illustrations of each season's hats, which should be sent out four times a year.

Starting in Business. Locality and position will probably depend upon the amount of capital available. The risk of failure is often less in a fashionable seaside resort, or a provincial town, than in London, where expenses are so heavy, and where competition is so keen. Too much care cannot be given to the artistic fitting up and furnishing of the rooms. The fashionable London milliner usually trades under a fancy name, such as "Monica," "Dolly Varden," or "Lucile." Her show-rooms are like handsomely appointed and luxurious drawing-rooms, with the softest of carpets, choice bric-a-brac, and Louis Quinze furniture ; very little is there to show any connection with millinery, except a few hats, laid here and there, as if by accident, a few more on stands in the corners of the room, and deep oak drawers running all round the walls. The most private and expensive milliners are usually established up one or two flights of stairs, or, if on the ground floor, not more than two or three models are permitted to be exposed to the vulgar gaze, all exclusive designs being jealously hidden away under folds of tissue paper in boxes or drawers. The suburban milliner, on the contrary, pays especial attention to the dressing of her window, everything that is new and showy being displayed in order to catch the eye of the casual passer-by. In both cases, it will be necessary to spend a good deal of money on carefully selected models, although all materials should be stocked in as small quantities as possible, as they can be purchased from the wholesale houses when required. Unless the West End milliner starts with a large connection, she will obviously require a substantial sum for advertising, as her windows count for little or nothing in this respect. In addition to the usual stock-in-trade, ready-made blouses, lace, ruffles, scarves, etc., and sometimes *lingerie* and corsets are frequently sold by milliners. This is more than ever the case since the advent of the motor-car, which is said to be ruining the millinery trade. Where formerly four or five hats would have been sold, nowadays only one, and a few cheap motor caps and veils will be considered sufficient.

Practical Hints. One experienced assistant, costing from 16s. to 21s. a week, with two or three improvers at about 6s., will probably be sufficient hands to begin with, and when increase of business justifies the engagement of another assistant, she should, if possible, be a Frenchwoman, or, at any rate, she should have spent some time in France. In addition to the ordinary fashion journal and circular advertising, any plan which might suggest itself as likely to bring people to the show-room should be tried. In one case, a good connection was established in a very short time chiefly owing to the fact that afternoon tea was served to customers every day. The particular premises referred to happened to be unusually suitable, and the outlay and trouble involved were trifling, while the increase of custom was remarkable.

To make the business an artistic and financial success, it is not sufficient to possess only quickness of observation and the power to imitate and adapt, as well as the talent necessary to make a hat. To all this must be added the art of the saleswoman. It is all-important to remember that the great object, especially of the beginner, is not so much to sell a hat as to please the customer and bring her back to the shop, probably with a friend next time, if the first choice be something really suitable and becoming. Whether living in town or country, frequent trips to Paris should be made.

MUNICIPAL POSTS IN THE COLONIES

Openings for Teachers, Nurses, Engineers and Surveyors, and Medical and other Officers in British Colonies

By ERNEST A. CARR

WITH few exceptions, municipal activities are naturally far less developed in our Colonies than in the ordered and close-knit life of the home country. But as the townships overseas grow in size and wealth, and the need for some sort of public control becomes increasingly evident, a system of local government grows up apace—based for the most part on English models—and affords employment for an official staff. To select a few striking instances, such towns as Melbourne, Wellington, Cape Town, and Johannesburg enjoy a municipal system of local service as fully developed in many respects as that of London, and examples are not wanting of Colonial corporations with profitable undertakings in gas, electricity, and similar "municipal trading" ventures.

Openings for Englishmen. For readers in this country the greatest interest attaches to the practical question, "What demand exists in the Colonies for municipal officers from England?" It must be admitted at once, in reply, that the general position in respect of municipal employment closely resembles that described in our preceding article with reference to the Government service. The Colony itself, in a word, is usually able to meet its own demands for candidates.

But this rule is not without many exceptions. Owing mainly to the local lack of training facilities, the leading Colonial towns apply from time to time to English sources for suitable officers—and particularly for such skilled servants as school teachers, nurses, medical officers of health and sanitary inspectors, and municipal engineers and surveyors.

In such cases the selection of a suitable English candidate is usually entrusted by the corporation concerned to its agent in London, who advertises the vacancy either in an organ of the particular calling from which applications are sought, or in one of the weekly or monthly papers devoted to municipal affairs. Among publications of the latter class, that in which announcements of Colonial appointments most frequently appear is probably the "Municipal Journal," published at 12, Salisbury Square, London, E.C.

Public School Teaching. The department of public education, which in some corners of the Empire is in the hands of the responsible Government, but is generally controlled by urban or district authorities, affords greater scope for candidates from Great Britain than any other branch of the Colonial public services. Not that teachers from the Mother Country are in general request throughout the Colonies. In Canada, for example, although British qualifications are recognised, the supply of teachers trained within the Dominion is, except in the North-West Territories, ample for the vacancies that arise. The same is true of Queensland, New South Wales, and South Australia.

On the other hand, there are several Colonies in which a demand for educational volunteers from home occasionally arises, New Zealand and West Australia being instances in point. And in the South African Colonies, in particular, the dearth of qualified teachers occasions a constant request for outside applicants.

Prospective emigrants should remember, however, that the lack of local teachers often arises, at least in part, from the scanty remuneration offered by Colonial school authorities, and that the value of a salary is determined, not by its amount, but by its purchasing power. Western Australia is a case in point. On the Goldfields, and in other districts of the State, the cost of living is notoriously high, yet the average stipend of teachers is only £143.

Salaries of Teachers. The following tabular statement has been compiled to show approximately the range of salaries in those Colonies in which a substantial demand for British elementary teachers at present exists Further details as to the prospects of Colonial teaching will be found in the invaluable "Professional Handbook" mentioned on page 3550.

SALARIES OF ELEMENTARY TEACHERS IN CERTAIN BRITISH COLONIES

District	Principals		Assistants		Remarks
	Male.	Female.	Male.	Female.	
	£	£	£	£	
South Africa:					
Cape Colony	250–420	160–350	120–350	80–240	Demand considerable.
Transvaal	300–500	300–400	150–390	90–300	
Orange River Colony ..	250–450	150–225	150–250	90–200	
Western Australia	80–450	70–350	80–220	60–200	Many vacancies in certain areas.
New Zealand..	60–375*	60–221*	100–245	80–205	Openings for well-qualified teachers.
N.-W. Territories (Canada)	130–280	80–175	100–200	65–130	Demand constant.

ith house allowance of £10 to £50

South African Appointments. Vacancies for science teachers and for instructors in special subjects, such as gymnastics or cookery, are occasionally advertised in the English educational papers. In such cases a second-class passage to the Colony is usually provided gratis, the selected applicant, in return, entering into an engagement for three or five years' service. The remuneration is fairly liberal ; fully certificated women teachers of cookery, hygiene, or physical drill receive £130 to £180 a year, and the rates for male technical teachers are about double these figures.

In the absence of an agreement of this character, trained teachers in quest of employment in Cape Colony are recommended by the Emigrants' Information Office to arrange, if possible, for a friend in the Colony to apply on their behalf for any suitable vacancy that is advertised out there. They should also address a written application for an engagement to the Secretary, Education Office, Cape Town. And if a candidate sends a statement of his or her qualifications and experience to the Department of Public Education at Cape Town, it will be inserted in the "Education Gazette"—an official organ circulating among school managers and principals. British qualifications, it should be added, are recognised in the Colony. Teachers in the Western Province are required to be able to speak both Dutch and English.

In the case of female teachers—and these form the majority of the educational staff at the Cape—application for employment may usefully be addressed to the Educational Secretary, South African Colonisation Society, 47, Victoria Street, London, S.W. Those who desire to complete their training in the Colony as elementary, secondary, or kindergarten mistresses can obtain from the same Society particulars of the Training College for Women Teachers at Grahamstown, which is open under certain conditions to candidates from home.

Alike in Cape Colony, the Transvaal, and the Orange River Colony, the supply of trained teachers is still inadequate to the demand, and there are, therefore, good openings for qualified candidates. But women teachers, especially if uncertificated, should not go out to either Colony on the chance of securing an engagement unless they have friends with whom they can reside while seeking employment. They are recommended instead to seek the aid of the officials of the Emigrants' Information Office, on whose advice they may rely implicitly.

Teaching Posts Elsewhere. Degrees and training certificates obtained in the United Kingdom are accepted in Western Australia, where teachers are generally in request. But we have already mentioned as the chief cause of this demand the low salaries which fail to attract qualified officers. In view of the high cost of living, the maximum of £220 for assistant masters, and £200 for their feminine colleagues, is admittedly inadequate.

In New Zealand, although the average of salaries is scarcely higher, the expenses of living are far less, and there is consequently a good local supply of candidates. But well certificated British teachers are in request, and those who can await the occurrence of suitable vacancies may find excellent openings from time to time in the public schools of the islands.

Full information as to the prospects of employment in the Canadian North-West Territories may be obtained from the Department of Education at Regina. Masters and mistresses trained in England are first admitted on an "interim" certificate, and must teach in the Territories for a year before receiving a full "professional" standing. As a teacher's salary depends on the class to which he is admitted, candidates are recommended to ascertain from the Education Department before going out the standing to which their British qualifications would entitle them.

Public Nursing. The official handbook for emigrants contains a paragraph on nursing in the Colonies which, though not restricted to municipal nursing, summarises so justly the prospects afforded by that particular service that it merits quotation :

"There are occasionally openings in the Colonies for a few trained hospital nurses. There are Homes for providing trained nurses in some Colonial towns, but, as a rule, the Colonies do not offer any great attraction to nurses ; the openings are not very numerous, and the pay is small as compared with that of other callings."

In nearly all British dependencies of every sort nurses who have been trained in the hospitals of the Motherland are readily admitted to practise, and have at least equal chances with locally-trained rivals in competing for appointments in the asylums and hospitals of the Colony. Such positions, however, are not often advertised in this country, and are generally secured by candidates who are on the spot.

Trained nurses employed in the public service in the New South Wales hospitals receive from £65 to £97 a year, without board and lodging, or £20 to £60 in addition to those allowances. This State possesses an Army Nursing Service Reserve, for which nurses are eligible between the ages of 21 and 40, provided that they have had three years' training in a civil general hospital. In Western Australia the rates of pay are £36 to £90 for nurses, and £50 to £150 for matrons, with food and quarters ; but the highest figures are given only on the Goldfields, where all the necessaries of life are dear.

In the municipal and Government hospitals of South Africa the remuneration is also generally high. Trained nurses receive from £60 to £95 a year, and matrons £100 to £180, in some instances with free quarters and washing. British hospital nurses in quest of appointments under the Rhodesian Administration should apply for terms to the London office, 2, London Wall Buildings, E.C. Applications for an engagement should be addressed to the Medical Director at Salisbury, Rhodesia, enclosing duly certified copies of certificates and testimonials.

Asylum Staffs. Nurses in lunatic asylums in Australia are paid from £35 to £75 a year, with free quarters and rations ; and matrons generally between £100 and £160, with similar emoluments. The rates for asylum warders in the Commonwealth vary considerably in the several States, the highest pay being in Western Australia (£90 to £150, with quarters and rations) and the lowest in Tasmania (£60 to £80, with a like allowance). Candidates for posts as nurses or warders in Victoria must be between 21 and 40 years of age.

In South Africa the remuneration of asylum officers, in addition to full or partial allowances, ranges within the following limits: Nurses, £40 to £75; matrons, £85 to £150; and warders £50 to £120. Salaries are generally lower in the asylums of Cape Colony than in those of the other South African territories.

Although in strictness a private and voluntary movement, this Association has now been accorded a semi-official footing, by the action of the Colonial Office in employing it as the chief source from which nurses are drawn for Government service in the Crown Colonies. Apart from its most useful efforts in the direction of private nursing, the Association is thus in the position of an agency for State employment, and as such should be mentioned in our columns. The trained nurses furnished by this organisation to the Colonial Government are employed chiefly in British West and Central Africa, Ceylon, Hong Kong, the Malay States, the Straits Settlements, and the West Indies. The term of service is usually either three or five years. Nurses seeking an engagement of this nature should apply to the Hon. Sec. of the Association, Miss Mowbray, at the Imperial Institute, London, S W.

Engineering and Surveying Posts. The prospects of British engineering experts outside their own land is considered in the course on Civil Engineering, and it is necessary to add but a few words on the municipal side of their profession—which is generally less remunerative, by the way, than private practice.

Colonial engagements as municipal engineer or surveyor are not often available to candidates in this country. The exceptions occur when a very responsible position has to be filled—such as the chief surveyorship of a growing city—and there is a dearth of local candidates of the requisite experience. Vacancies of this class are announced in the English engineering journals as they arise. Minor appointments are usually made from among applicants in the Colony

British qualifications, however, are widely recognised, the M Inst.C E., in particular, being as valuable in the Colonies as in this country. In Victoria, corporate members of that Institute, and those who have passed the examination of the Association of Municipal and County Engineers are eligible under certain conditions for appointment as municipal surveyors, and as such may undertake the construction of roads and bridges for the local authorities. On the other hand, the Lands Survey branch of the State Service is recruited mainly by surveyors trained in the department itself.

Apart from professional posts in technical colleges, the Colonial municipalities afford but few openings for chemists. The most important corresponds with the position of public analyst in an English borough. In the Canadian Dominion such officers are required to pass an examination in chemistry and microscopy. Analysts to local authorities in New South Wales must be approved by the Board of Health, which in future will recognise only the Associateship and Fellowship of the Institute of Chemistry; and the Victorian Health Board, which has similar powers, is scarcely less exacting. In many other parts of the Empire, however, the detection of adulterated food supplies has not become a pressing matter, and thus the field for local government analysts is still very restricted.

Other Offices. Other vacancies for municipal officers of various grades in the Colonies are announced from time to time in the English Press—generally on terms sufficiently high to attract fully competent candidates. Thus, for the positions of treasurer and assistant treasurer to a leading South African corporation, the respective salaries of £1,500 and £600 were lately offered. Medical men possessing the public health diploma, and willing to sign a three years' agreement, were invited by the agent of a Natal municipality to apply for the appointment of medical officer of health at a salary of £650 a year, rising to £750, with a first-class passage out. Again, a vacancy as chief of a corporation fire brigade in Cape Colony, with a remuneration of £600 yearly, and free quarters, was recently advertised in this country. It may be added that this post was secured by a candidate who, as the head of a considerable English fire force, had been in receipt of a salary of £130.

Such instances serve to show that a well-qualified and fortunate municipal officer may rapidly advance his ambition by emigrating. But there is no Royal road to such advancement. Suitable vacancies are rare and eagerly contested, and there may be long waiting and many disappointments to endure ere the aspirant ultimately attains success

A Last Word. In concluding with the present article our survey of the Imperial section, we complete also that greater subject of the Civil Service of which this forms part. As we have sought to show, the Civil Service of the Empire is of unmatched variety and extent, affording scope in one or other of its three divisions—Municipal, National, and Imperial—for the most diverse talents and ambitions; and the liberal though not extravagant rewards of each section are available, without let or hindrance, to men of the requisite abilities. We may, perhaps, be forgiven for emphasising anew, in conclusion, the qualities that make for success. They are, firstly, a sound training, and lastly, strenuous and thorough work. In the Civil Service, as elsewhere, there are some incompetents and many mediocrities. But the men who succeed—the men who "run through the ruck" and win the prizes of the Service—are they whose keynote is Efficiency.

Civil Service concluded

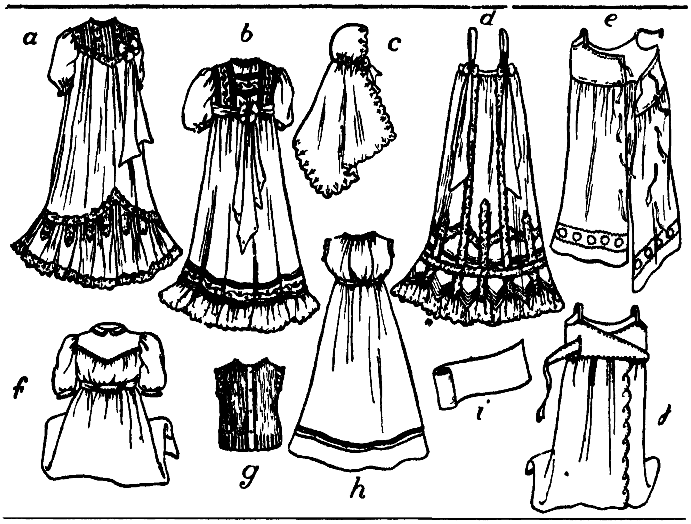
CHILDREN'S CLOTHING

Suitable Material for Infant Wear. The Layette. A New Hygienic Set. Stitches and Methods of Sewing Employed

By AZÉLINE LEWIS

THE clothing of an infant should be light, warm, and easily put on; tightness of any kind and heaviness are unhealthy and unwholesome. All hard seams and ridges should be avoided; the fewer seams there are in a garment the better, whilst all armholes should be loosely fitting.

Materials for Baby Wear. As to the material, medical opinion is unanimous that it should be woollen, preferably all through. Dr. Gordon Stables says: "The woollen garments may be as light as you please, but let them be wool. Wool keeps up the warmth more equally, and, if light, it does not 'plot' the skin. Cotton cools down too soon, and, indeed, it may get cold while still wet with perspiration. The animal heat of the body is carried away too rapidly, and a chill to the delicate frame is the inevitable result."

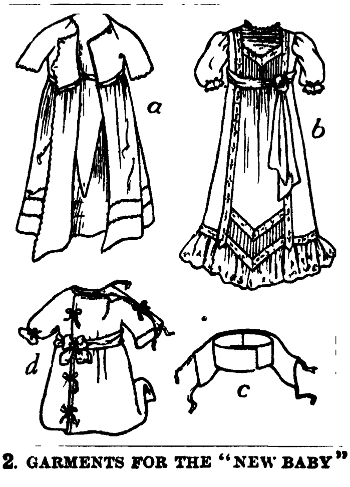


1. THE LAYETTE

Flannels, and woollen materials too, are now made in such beautiful qualities, and of such fine makes, that there need be no fear of the little one not being daintily clad. Cambric and lace may, of course, be used, but such things should only be employed for the over garments, as frocks, petticoats, pinafores, slips, skirts, etc.; nothing stiff or starchy should come near the face, neck or hands.

In baby attire simplicity and daintiness should be the essentials; the wee mite wants to kick and move its arms freely, and not become tangled up in a mass of meaningless frills. As a baby should spend the first months of its life in sleep and much of the first period of its existence on its back, it follows that no ribbons or strings should be tied here to cause pressure on the spine. Further than this, the ideal baby garments should all fasten either in front or at the side, never at the back, as no matter how soft the ribbon, how small the bow or buttons, these must cause pressure and irritate the soft and tender flesh.

Layette. A layette, like a trousseau, varies, of course, in the number and quality of its component parts, according to means and circumstances. There are, however, certain things which are indispensable to any baby's comfort and needs, the numbers of which may be added to with great advantage, whilst the cost and fineness of the materials with which they are fashioned can be increased accordingly.



2. GARMENTS FOR THE "NEW BABY"

The following, then, may be taken as a fair list of the least number of articles required for a layette:

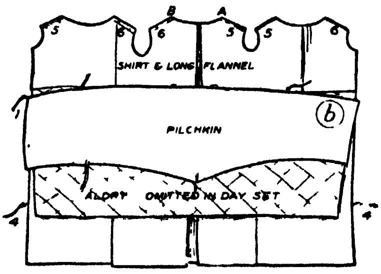
2 Binders
4 Woolly vests
4 Long flannels
6 Day gowns
4 Nightgowns
4 Petticoats
2 Doz Towels
3 Pilchkins
3 Head flannels
1 Small soft shawl
1 Large shawl for outings, or a long cloak

Bibs, bootees, gloves, veils, are all accessories for which no list can be given. For a town baby two silk skirts will be found very useful to slip on over the day gown, when it takes its everyday outing, whilst a little silk or cambric teagown is a very delightful addition to baby's wardrobe, in which he can be smartened up in a few minutes, without changing.

The ideal shape for this garment is the Aliône which set is referred to later on.

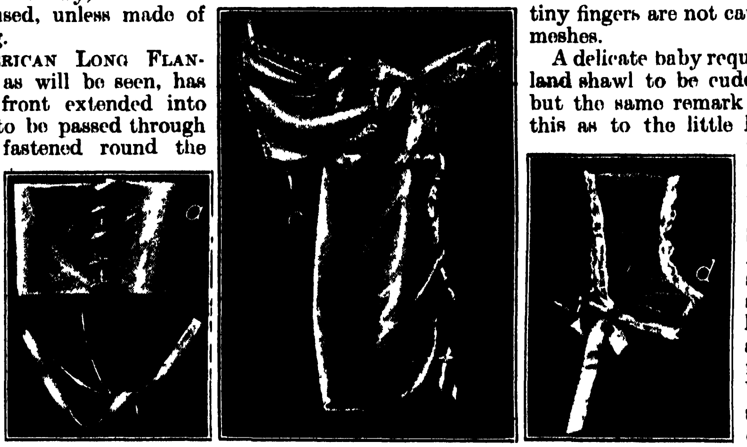
The Garments. Fig. 1 shows the various garments of the usual shape:

The Binder. This consists of a straight piece of flannel, 5 in. or 6 in. wide and about 27 in. long, or more. It should be simply torn off and left raw-edged, and then there will be no ridge to press on the baby's body (*i*).



The Vest. The vest should be of the finest wool, opening in front, as it will be easier to put on, and there is less risk of twisting the little arms (*g*). If the idea cannot be abandoned that baby is not properly clothed without the shirt, this can come next, but is quite unnecessary, and is very little used, unless made of nuns' veiling.

The American Long Flannel. This, as will be seen, has the bodice front extended into points, one to be passed through a slit and fastened round the body (*j*). There is another long flannel of somewhat simpler shape, which has the advantage of being equally useful during the short-coating and later periods by merely shortening the skirt. Note that the shoulder-straps fasten over in front and are of fairly good width, narrow tape being likely to cut and hurt the infant (*e*).



3. THE ALIÔNE SET

The Petticoat. As to the petticoat, there is a slight diversity of opinion about it, some holding it to be necessary and others not, but a woollen-clad baby's wardrobe would not contain it. It is usually made of fine longcloth, lawn, cambric, or linen, tucked and trimmed according to circumstances. It should be only very loosely gathered round the neck (*h*).

The Day Gown. This may be of cambric, fine hair-cord muslin, gauze flannel, nuns' veiling, or Japanese silk, the last being preferred by many, as it is soft and washes so well. Trimming and materials are, of course, matters of taste (*b*).

4. OUTDOOR GARMENTS

The Nightgown. The nightgown should be of Viyella, gauze flannel, fine white wincey, or nun's-veiling The pattern is the same as that for the day gown (*f*).

Empire Gown or Robe. The robe can be as smart as possible, the little bodice being formed of strips of insertion and tucking (*a*).

The Head-Flannel. This should be a sensible square of fine flannel, 36 in. or 45 in. wide, not the small thing usually made, which is always slipping off. One corner is rounded off, and has a casing run round to form a hood, as the sketch shows. This should be large enough to go over the head comfortably (*c*). A crochet or knitted shawl answers this purpose equally well, if not better, provided it is of a close make, so that the tiny fingers are not caught in the meshes.

A delicate baby requires a Shetland shawl to be cuddled up in, but the same remark applies to this as to the little head shawl with regard to the make.

Silk Slip Skirt. Fig. 1 (*d*) shows this skirt, which has been already referred to. With respect to the out-of-door attire, a woollen shawl, of firm, close make, is really better and warmer for a baby than the usual long cloak, unless this be made with sleeves to protect the arms and hands.

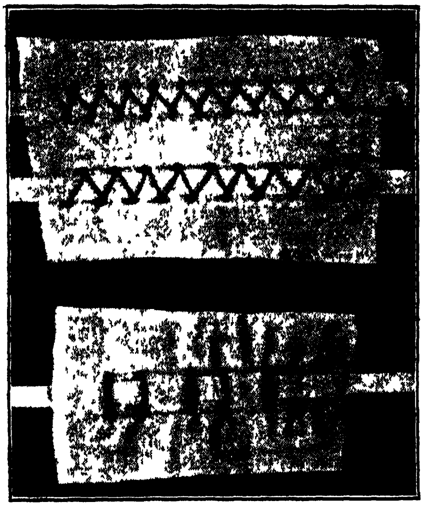
A little knitted hood is worn by both boy and girl babies for the first few months, but head-gear is mentioned later.

As to the towels, of which several dozens can well be added to the list, these may be of birdseye or other diaper, but the best are good-sized squares of turkish towelling, which can either be bought ready-made, or made from the wide make of this material sold by the yard. It can be left raw-edged, or simply overcast loosely with soft cotton, as a hem makes a ridge which is likely to hurt, and is not advisable.

The next diagrams show the revised editions of baby garb, by the aid of which he can be dressed in five minutes, or less, without any twisting or turning at all.

Fig. 2 shows the few and simple garments required by the "New Baby." The binder, consisting of two strips of flannel (*c*), the inner one longer than the outer; the little woolly vest and the revised long flannel (*a*). This is cut with armholes and sleeves extending to the shoulders, obviating the tightness of the usual shape, and avoiding the objectionable practice of bending back the infant's arm, which is necessary with the round arm opening. The same pattern will do equally well for the small nightgown, for which the sleeves will be a little fuller, and a little ornamentation added, according to taste, either by feather stitching, lace, or embroidery.

The long sleeves make a flannel vest or barrow coat unnecessary, whilst the skirt portion, being buttoned to the bodice, makes a frequent change possible without undressing the baby.

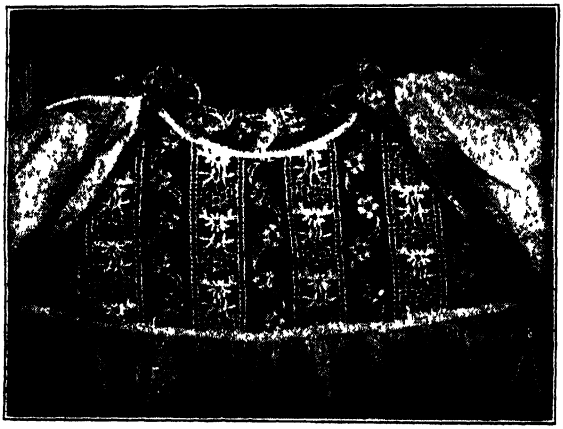


5. RIBBON INSERTIONS

The little pilchkin is an addition which mothers and nurses will appreciate, its object being to prevent the towels slipping off. It is made either of flannel or bath towelling, and is merely a long, narrow strip of the material tapering off to a point at one end, the broad end being secured by a button or safety-pin to the back of the long flannel, the point being brought up and fastened in front, either to the long flannel or the binder.

Fig. 2 (*b*) shows a Princess day or night gown, as the pattern will do for either. It could be made of dainty woollen or cotton goods, as preferred. This shape fastens over at the left side, the back being plain and seamless.

Fig. 2 (*d*) shows another shape of nightdress of most delightful simplicity. It can be cut all in one piece, or to fasten at the side, and for the vaccination period will be found invaluable.



6. TRANSPARENT YOKE

In Fig. 3 we have the ideal baby garments, known as the *Aliône*, but as they are registered, the patterns can only be obtained from the inventor.

In these, as in the others just mentioned, a baby can be dressed in from three to five minutes, each garment being placed in its proper position, and the baby last, when they are fastened as shown, by tapes and buttons only, without once moving the child. The sleeves, it will be seen, button down the side of the arm. (*a*) shows the binder; (*b*) the set ready for putting on; (*c*) the nightdress; (*d*) the ear cap to prevent prominent ears. The "softie" pilch belonging to this set, and brought out by the same lady, is the most comfortable thing ever invented for a baby's underwear, and should be in every baby wardrobe.

Fig. 4 illustrates some other garments necessary to the baby's comfort: (*e*) shows a square kimono; (*d*) a circular one; and (*b*) a tea jacket or outdoor coat. The two first should be of woollen material, whilst the last one may be more elaborate.

Fig. 4 (*a*) shows the cloak, which, it will be noticed, is cut with sleeves, and is of ample fulness. (*c*) illustrates a hood cut all in one, the shaping being done by means of darts. This can be fastened to the cloak and all be put on together. A knitted woollen hood or hat, however, is equally warm and comfortable. The cloak can be of cashmere, Oriental satin, or Bengaline interlined with domette; the lower cloak should be lined with nuns' veiling, and the upper ones with silk.

The Making of the Garments. The actual making of baby garments is simple, but the workmanship should be of the finest and best, whether it is done by hand or machine.

For the sleeves of flannel garments it is far better, for obvious reasons, that they should not be set into a band, but drawn up by ribbon run through fancy stitches worked outside. Fig. 5 shows three ways of accomplishing this. The third merely consists of perpendicular buttonholes, and makes a little more work than the two upper ones. It is especially suited to the head-flannel shown in Fig. 1.

Insertions should always be transparent, whether for bodice, cuffs, or lower part of skirt. Fig. 6 shows a transparent yoke of cambric insertion and lace, and the method of finishing off at neck and lower edge.

ELECTRIC OSCILLATIONS

Conditions for Oscillation. Mechanical Analogies. Oscillating Electric Sparks. Resonance

Group 10
ELECTRICITY
26

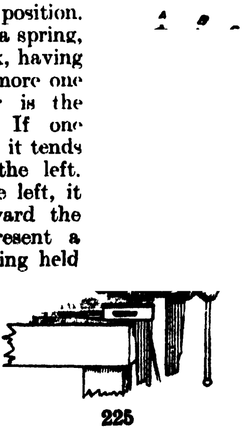
Continued from page 3581

By Professor SILVANUS P. THOMPSON

OSCILLATION, in its mechanical sense, is the name given to a repeated to-and-fro movement like that of a pendulum or a vibrating spring, or to the movement of a shuttle in the loom. If a pail full of water be set down upon the ground with a jerk, the water in it oscillates from side to side of the pail, the movement gradually subsiding till the water comes to rest. Electricity, too, can oscillate, as we shall see ; and electricity in oscillation possesses certain peculiarities which are different from those of electricity at rest, or of electricity flowing steadily.

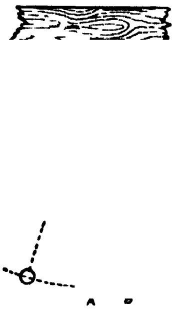
Mechanical Oscillations. The most obvious type of natural oscillations is furnished by a pendulum, consisting of a weight hung on the end of a thin string which, if drawn on one side and released continues to swing with periodic regularity. Another simple example is that of a loaded spring. If we take a long, thin strip of steel, such as is used for clock springs, or for busk steels, and fix a bit of lead at one end of it, and clamp the other end in a vice, then if we give it a push on one side it will immediately be set swinging, oscillating from side to side until it comes to rest. Some people would describe these to-and-fro movements of the pendulum or of the spring as *vibrations;* others would describe them as *oscillations*. It matters little what name we give to them provided we understand why they occur.

Forces of Restitution. The first thing to understand is that oscillations never occur unless there are forces that tend to restitution. That is to say, there must be present forces which tend to bring back the oscillating body, whether pendulum or spring, to its initial position. Everyone knows that a spring, when bent, will fly back, having forces of recoil. The more one bends it, the greater is the force of its recoil. If one bends it to the right it tends to fly back toward the left. If one bends it to the left, it tends to fly back toward the right. Let **225** represent a piece of stiff steel spring held upright in a vice, and having a lump of lead screwed tightly to its top. When at rest it stands upright, with its top at A. Suppose that we now exert a force sideways tending to bend it to B. The amount of force needed will depend on the stiffness of the spring and on the amount of the displacement or distance from A to B. Suppose the spring were so stiff that a force equal to the weight of an ounce, when applied at the top, would push it aside by 1 in., then to push it aside 2 in., to C, would require a force equal to the weight of two ounces. When pushed aside to B the force tending to restitution would be one ounce; when pushed aside to C the force tending to restitution would be doubled. This is in accordance with the simple law of elasticity, that the force tending to restitution is proportional to the displacement.



225

A similar law governs the movement of the pendulum. Let **226** represent a simple ball of lead hung by a thread from a hook. If one sets it swinging, the ball swings along the arc of a circle ; it swings to and fro along a curved incline, being constrained to keep in that path because it is tied to the hook as a centre of motion. Let its position of rest be called A. Then by applying a side-way force one can displace it to B. But if pushed to B and released it will not stay at B. It immediately moves back again to A. The force tending to restitution in this case is not elasticity, but gravity. The earth pulls it downwards ; but as it is constrained to move along the curved path only a certain resolved part (depending on the steepness of the incline at B) acts as a force urging it back toward A. If we give it a displacement twice as great, to C, it experiences a force of restitution almost exactly twice as great as it did at B, because the steepness of the incline at C is almost exactly double the steepness of the incline at B. So here again we find that the force of restitution at any point along its path is (approximately) proportional to the displacement.



226

Inertia. But everyone knows that the pendulum, when displaced aside from A to B or to C and then released, when it returns to A does not stop there but swings on beyond to almost an equal distance on the other side, and then comes back again. Why should the pendulum swing thus ? If the forces of restitution are zero at A, why does the pendulum, on returning from B, swing on past A ? The answer is undoubtedly to be found in the property called *inertia*. Every mass, whether of lead or any other material, when it has been set into motion, tends to go on moving. Every moving mass, as explained on page 290, possesses energy of motion, also called *kinetic energy*. When the pendulum bob was pushed aside it moved a little up the incline, and in doing this work some energy was spent upon it. That energy thus given to it, it transforms, as it descends the incline, into energy of motion, which energy is still in it as it flies through the point A; and it expends this energy by climbing up the inclined curve on the other side to an equal height. As it comes down again, it again gets up speed, which will again, because of its inertia, carry it up once more to B or C. And so it oscillates backward and forward, the energy given to it during the first displacement being transformed into kinetic energy as it comes down, and retransformed into potential energy as it goes up the curve.

It is similar with the loaded spring. In bending the spring, we give it potential energy [see page 289], which, during the recoil, is transformed into kinetic energy, the power of the spring being employed in putting the leaden mass into motion; and the inertia of the moving mass carries it back past the point A, and it flies over to the other side, retransforming the energy of motion into the potential energy of the bent spring.

Necessary Conditions for Oscillation. We see, then, that the necessary conditions for mechanical oscillation are two in number: there must be (*a*) forces tending to restitution; and (*b*) inertia. Further than this, a very few experiments will convince us that the frequency of the oscillations depends on both these things. For, consider the spring [225] already described. It has a certain stiffness, and it is loaded with a certain mass. If we make it stiffer (by shortening it, or by substituting a thicker piece of steel of the same length and quality), it will recoil more quickly, and the frequency of the springs will be increased. If we make it weaker (by lengthening it, or by substituting a thinner spring of the same length), it will oscillate with slower swings. Or, again, if, keeping the stiffness unaltered, we load the spring with a heavier mass it will swing more slowly, and the frequency of the oscillations will be reduced. The exact rule governing the matter is that *the square of the frequency is directly proportional to the stiffness of the spring and inversely proportional to the mass.*

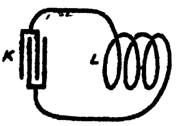
Decay of Oscillations. Any vibrating spring or pendulum will gradually come to rest, the amplitude of the oscillations gradually decreasing until the motion dies out. This is because of friction. There is friction at the point of suspension, if the pendulum rocks about a point, or in the cord if it has to bend where it is tied up. There is internal friction in the bending part of the spring. Also both the pendulum and the vibrating spring stir up the air in their movement, and waste a fraction of their energy in fluid friction at each swing, so that at each recurrence of movement the amplitude of the swing is a little smaller than it was at the previous swing; and this waste of energy by friction, however slight, will gradually cause the motion to decay and the oscillations to die away. The time taken for the amplitude to die down to half of its initial value may be regarded as a measure of the rate of decay. If the swinging part presents a large surface to the air, it sets up much air friction, and the oscillations will be quickly damped out.

Production of Electric Oscillations. Now, what is true about mechanical oscillations is true—by physical analogy—of electric oscillations. In order that electricity should oscillate at all, the system must fulfil two conditions: There must be (*a*) electric forces tending to restitution; and (*b*) something acting as electric inertia. We must inquire what these things can be.

In the last article [page 3579] we saw that when a condenser is charged it tends to discharge itself. While an electric current is being forced into it its potential rises, and the greater the charge given to it the more powerfully does it react, tending to drive the charge out again. In fact, the layer of dielectric in a condenser, whether glass, mica, or air, acts as if it possessed electric elasticity. The larger the area of its coated surface, and the less its thickness, the more easily is it charged. The thicker the dielectric and the smaller the area, the more stiffly does it react. The forces of restitution which it offers to the operation of charging are inversely proportional to its capacity, and directly proportional to the charge that is in it, and they are electromotive forces, not mechanical forces.

Further, it was pointed out on page 1362 that whenever a current has to flow round a coil or spiral so that it does some magnetising there is a reaction due to the interlinkage with the magnetic lines. This reaction manifests itself during the time when the current is growing by causing the current to grow more slowly—in other words, by producing a lag. It has another effect on a current that is dying—namely, that it opposes the diminution of the current, and keeps it flowing even after the electromotive force has ceased. This reaction, caused by the magnetism of the circuit itself, is termed *self-induction*, and it is purely conservative. It opposes all change. When the current is growing, it opposes growth; when the current is decreasing, it tends to keep it up. The effect, then, of the presence of self-induction in a circuit upon the flow of the current is exactly analogous to the presence of inertia in mechanical systems. Judging, then, by analogy, we should expect *electric oscillations* to arise in an electric circuit if that circuit fulfilled the condition of containing (*a*) a condenser, and (*b*) a magnetising coil. In other words, there must be in the electric system both capacity and self-induction.

Oscillating Electric Sparks. Suppose that we take a condenser, consisting, as described in the last article, of glass plates between sheets of tin foil, and join it up in a circuit along with a self-induction coil. Fig. 227 represents such



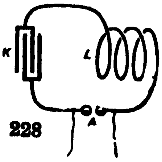
227

a circuit, K being the condenser, and L a self-induction coil made of a number of turns of insulated copper wire wound on a suitable wooden frame as a bobbin. Such a circuit is suitable for electric oscillations, and the frequency of them can be calculated if the capacity and self-induction are known. The formula is:

$$f = 1 \div (2\pi \times \sqrt{KL});$$

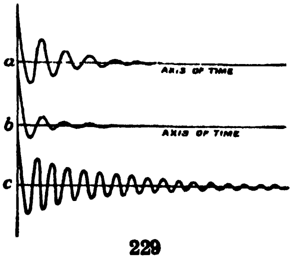
where f is the number of oscillations per second, K the capacity in *farads*, and L the self-induction in *henries*. Thus, if the capacity be 10 *microfarads* (that is, $\frac{1}{100000}$ of a *farad*), and the self-induction is $\frac{1}{10}$ *henry*, the frequency will be 1,591 oscillations per second.

But although such a circuit may be adapted for electric oscillations, and have in this sense a frequency of its own, the difficulty will be to set up any oscillations in it. For many years it was not known how to set up such oscillations. What is wanted is some electric operation that will correspond to the operation, in the mechanical analogy of the loaded spring, of producing a displacement and then letting it go. For this purpose the circuit must be provided with a gap, as shown in **228**. The wires at the two sides of the gap should be furnished with brightly-polished metal balls set about $\frac{1}{4}$ in. apart, and connections should be made as shown to some suitable high voltage source such as an influence machine or an induction coil capable of giving sparks. Then what happens is this: The current running in from the source charges the condenser, and gradually raises the difference of potentials between the two balls until the air insulation between them breaks down and a spark occurs at the gap. This spark will be noticed to be bright and noisy. It really consists of a whole series of sparks oscillating rapidly to and fro.



228

Nature of Oscillating Sparks. Half a century ago Lord Kelvin predicted from mathematical considerations that the dicharge of a Leyden jar through a wire coil would be oscillatory. Some years later Feddersen proved it to be so by observing the spark in a revolving mirror, when it was found to consist of a number of separate sparks that rushed in rapid succession across the gap in alternate directions. The necessity of the gap was pointed out in 1875 by the present writer. The explanation of the oscillations is as follows: As the condenser is more and more charged, its electric elasticity tends to drive the charge back more and more, until the moment comes that the insulation at the gap breaks down. Then comes a sudden surging of electricity out of the positive coating of the condenser, rushing along the circuit across the gap and into the negative coating of the condenser. But because of the self-induction of the circuit this rush of electricity goes on after the condenser is empty, and in so rushing on charges it up the other way. Then comes a rush back across the gap in the converse direction, and so backwards and forwards. The nature of an electric oscillation may be indicated graphically by the diagram **229a**, in which the horizontal distance represents time, and the vertical distances the charge, positive or negative. The whole series of surgings begins with a sudden rush, followed by the subsequent alternations at a regular frequency. But each rush is feebler than the preceding one, and they die out, just as mechanical vibrations do. If the circuit offers a high resistance—as, for example, is the case when a wet pack-thread is introduced into it—the train of oscillations will be rapidly damped out. Also, if the arrangement that acts as condenser has much exposed surface, some of the energy of the moving electricity may escape as electric waves (as will be explained in the next article), and then also each train of oscillations will consist of but a few members, as **229b**. If there is no appreciable resistance, and no appreciable radiation of energy in waves, the oscillations may be persistent, each train consisting of some thousands or even hundreds of thousands of successive oscillations. Fig. **229c** shows a more persistent train of oscillations than either *a* or *b*.



229

Resonance. If two circuits be constructed as to capacity and self-induction so that they have the same natural frequency, they are capable of resonating one to the other—that is, if electric oscillations are set up in one of them, it can induce oscillations in the other. Sir Oliver Lodge has shown some exceedingly beautiful experiments on this plan with two circuits, which were *tuned*—that is, brought into syntony with one another. Let K_1 and L_1 [**230**] represent a capacity and a self-induction coil of a circuit having a spark-gap at A, connected with wires to a suitable charging source such as an influence machine. Let the second circuit be arranged with capacity K_2 and self-induction coil L_2, and a spark gap B. The two must be tuned by altering either K_2 or L_2 until the condition is attained that $K_2 \times L_2 = K_1 \times L_1$. Also, the two self-induction coils must be put near each other so that they can act inductively (like primary and secondary of a transformer) on one another. Then, whenever a spark is made at A in the one circuit a spark will occur also at B in the other circuit. But if the timing be spoiled by having L_2 either too great or too small, then there will be no sparks at B. Sir Oliver Lodge showed this experiment with two Leyden jars and two simple semicircular arcs of wire.

RAILWAY CONSTRUCTION
continued from page 3616

TRAMWAY CONSTRUCTION

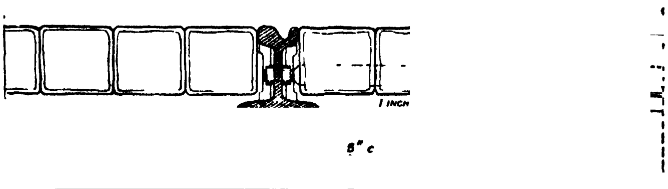
Utility of Tramways. Bed, Rails, Rail Joints, Crossings, and Paving. Tramway Construction Costs

By R. W. WESTERN

THE distinction between a tramway and a railway is hard to define. The word *tram* first appeared in the engineering world as the name given to a sort of waggon used for coals, and a tramway was a *way* for such a waggon. Historically, tramways came first, and the railway is, in fact, a development from the tramway.

The first tramways were rails of timber laid from various collieries to the nearest wharf exactly straight and parallel. As the wood was quickly worn by the rough traffic, wooden rails were nailed on the top of the others, and could be easily detached and renewed as required. Then wrought-iron laths were introduced for the like purpose, but without much advantage to economy on account of the high cost of the metal.

The First Tramway. In 1767, from some adventitious circumstances, the price of pig iron became very low, and the Coalbrookdale Iron Company, in order to keep their furnaces in, thought it would be the best means of stocking their pigs to lay them on the wooden rails, as this would help to pay interest, by reducing repairs of the rails, and if the price of pig iron rose, the pigs could be taken up and used as cast iron This is a good illustration of how the development of the construction of ways of communication is governed by the relative cost of materials.



71. SECTION OF TRAMWAY SURFACE AND RAIL

With the invention of the steam locomotive, which required a road to itself, tramways almost disappeared from this country. They were no longer wanted for the collieries, and on the ordinary roads the public would not have them.

In America, however, where ordinary vehicular traffic was but meagrely developed, tramways grew up freely, and underwent many modifications and improvements as the use of iron and steel increased. They were introduced into English cities by an American engineer, Mr. G. F. Train, during the 'sixties, in spite of great opposition.

What is a Tramway? As now used, the word tramway may mean a light, temporary railroad used by contractors for various purposes; a permanent railroad of narrow gauge within the precincts of a factory or colliery; or a railway laid level with the surface of an ordinary road, so that other and unadapted vehicles can move freely over it and across it. In the United States of America, however, the last of these is more commonly described as a *street railway,* in many respects a preferable term.

A tramway will generally, therefore, differ from a railway mainly in the following respects—lighter loads, slower speeds, more frequent service, sharper curves, and steeper gradients. All these have modifying effects upon construction.

Street Railways. The design of these must provide that the special rolling stock will be confined to the rails, while all other vehicles are free to move on and off. An infinity of devices have been proposed and tried to effect this object economically. By process of survival of the fittest, the form of rail shown in 73 is now most generally used, together with wheels having flanges on the inside as described for rolling stock of railways.

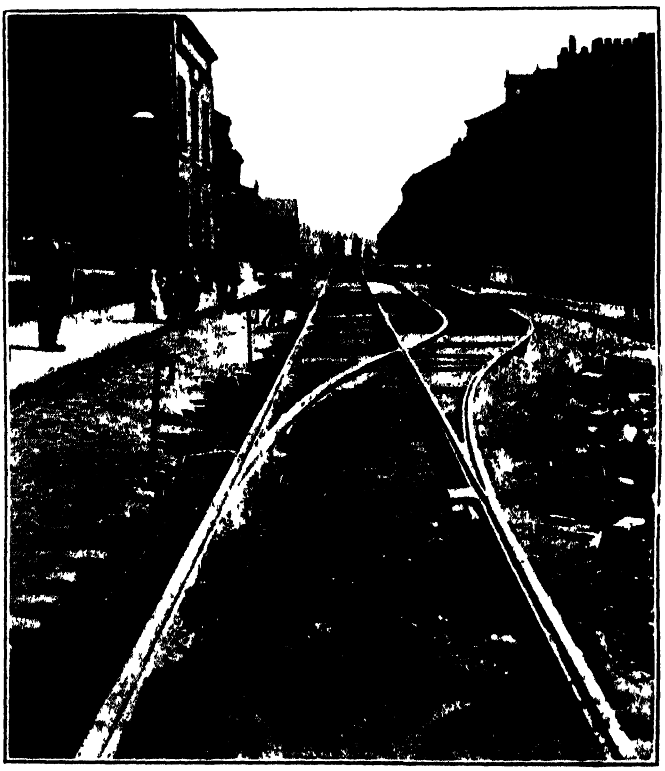
Unsettled Ground. In cases where a tramway must be laid upon ground which cannot be relied upon to sustain the traffic permanently, it is best to adopt the sleeper construction, as for an ordinary railway. Then, when and as the settlement proceeds, the paving of the road may be taken up and the level of the rails raised by packing more ballast beneath the sleepers.

Usual Construction. Under ordinary circumstances, the rails are laid upon a bed of concrete about 6 in. thick, more or less, as conditions require [71]. The photographic reproduction [72] illustrates a tramway line under construction. It must be seen, however, that the concrete itself rests on a solid, compacted foundation, so that it shall not be subjected to irregular cross strains sufficient to cause cracks. The concrete may be fortified by introducing iron rods into the lower layers while it is being put in. Such rods may be ¼ in. or ⅜ in. in diameter, and laid both longitudinally in the direction of the rails and transversely to them. In this connection the articles on reinforced concrete [pages 1554 and 1643] should be consulted.

This rigid method of construction is very suitable to the streets of towns, but, as readers of the foregoing will readily appreciate, it is possible only on account of the comparatively light loads and slow speeds to which the tramlines are liable. And already in cities where the speed and weight of the tramcars are more than the average, its disadvantages are becoming apparent. It suffers much from the hammering effect of the wheels, and immediately any part is loosened, the hammering or pounding becomes aggravated at that place, rapidly causing destruction of the part. The introduction of wood between the rails and the concrete is therefore desirable where heavy traffic is anticipated in order to provide sufficient "give" to absorb the shocks.

The concrete may consist of four parts broken stone, two parts sand, and one part cement. The chief advantage of concrete beneath a street is that a uniform profile is more easily maintained upon the surface, which assists drainage and has the good appearance which the public demand.

Laying the Rails. The setting of the rails upon the concrete may be done in several ways. After the concrete is set it will always be found that the surface is not true enough to enable a rail to be simply placed upon it. The concrete may therefore be laid within a short distance of the level of the base of the rail and the intermediate space—say an inch — made good by blocks or wedges. Then, when the rail is in position, the space may be completely filled in with fine concrete. In places where the concrete is unduly high this is not always easily done, and then there remains but a thin, imperfect layer of cement, very liable to crumble under the traffic.



72. CONSTRUCTION OF A TRAMWAY

Granite chips are sometimes introduced to fill the space, or the rails may be placed first in their correct positions, and held by temporary supports, while the concrete is put in beneath them and carried up over the base of the rail, so as to include it. To effect this the concrete must be rather wet, and care must be taken that it is well worked in beneath the rail and smoothed off before it sets. If wood be used as a cushion beneath the rail, the laying of the concrete is done in the same way, except that it is seldom carried above the level of the bottom of the wood. The wood is commonly made 7 in. wide and 4 in. deep, and should, of course, be thoroughly creosoted. One of the objections to concrete beneath the rails is the time required for it to set; this greatly interferes with rapid completion of the work, since it would be its destruction to allow traffic to begin until the cement had hardened. There is, consequently, a great temptation to use very quick-setting cements for this work, whereas the cements that show the greatest durability are slow setting cements.

The gauge in a tramway of this kind is not so easily defined as on a railway, on account of the wheel flanges running in a groove. To take rolling stock as made for a railway of the same gauge, the distance from the outside edge of one groove to the outside edge of the other should be half an inch less than the railway gauge, and the groove rather larger than it is ordinarily permitted to be made for tramways. The gauge is maintained by tie-bars, placed at intervals of 6 ft. or more between the rails. See the half section in 71.

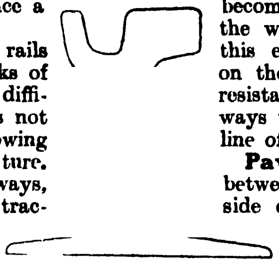
Rail Joints. The joints of the rails are even more troublesome upon a tramway than on an ordinary railroad, since they are covered up and inaccessible, except at the cost of taking up the roadway. Sometimes boxes are provided alongside to enable them to be got at, but unless the boxes are large enough to enable the whole of the joint to be examined, and the bars to be removed and replaced, they are not of much benefit.

When a joint becomes loose, dirt and grit work in between the parts and prevent any efficient tightening up, so that the parts must be taken out and cleaned before being tightened.

The rail joints of a tramway may be examined by placing on the top of the rail, over the joint, a straight edge 5 ft. long. If a depression of as much as $\frac{1}{16}$ in. appear at the joint, it must be seen to.

Another system, that does not necessarily exclude the above, is to overhaul thoroughly all joints at regular intervals—say, once a year.

One advantage of having the rails hemmed in on both sides by blocks of wood or granite setts, is that the difficulty of making good joints is not complicated by the necessity of allowing for the expansion due to temperature. Since the track cannot move sideways, the only effect of expansion or contraction is to produce stresses of tension or compression in the rails themselves, which they are well able to sustain.



73. TRAMWAY RAIL

Continuous Rails. The rails may therefore be made continuous by welding each one on to the next, so that there are really no joints at all. The welds may be effected by means of cast-iron, by electricity, or by *thermit.* The first requires a miniature blast furnace to produce the cast iron, the second a formidable electric apparatus, but for the third only a few pounds of mixed ferric oxide and finely-divided aluminium is wanted. This, on ignition, supplies a quantity of superheated molten iron, and by means of this a very intimate union is effected between the two rails. The chief drawback rests in the possibility of failure. Bad workmanship on an ordinary joint may be rectified without much trouble, but if a weld fail, the ends of two rails are ruined. The heat involved in a weld is so great that time must be allowed, before proceeding too far, for cooling to take place, with its accompanying contraction of the rail. This somewhat limits the speed with which a tram-line can be laid with welded joints.

Points and Crossings. The curves and angles being necessarily sharper upon a street railway than upon an ordinary railway, the points and crossings cannot be straight; they must in all cases be specially constructed to the angle and to the degree of curvature to be laid out in the place they are to occupy. This special construction takes time, and all frogs, etc., that must be specially made, should be ordered from the manufacturers as early as possible, since the completion of the work is necessarily delayed until they are delivered and put down.

Whether for facing points or trailing points, a single tongue is sufficient, and most commonly used. Its use obviates the need of a pointsman, except in times of very heavy traffic.

On less frequented roads, the motorman stops just over the point as he comes up to it, and, leaning over the dashboard, can alter its position by means of a hooked end iron hanging there for the purpose. The actual point in the frogs and other parts liable to special wear are usually composed of specially hardened metal, and the groove may here be made more shallow, so that the wheels roll on their flanges while passing the gap, and thus diminish the bump, which cannot be entirely avoided.

Resistance. When the groove of the rail becomes choked with dirt and stones, the wheel flanges grind upon it, and this effect, together with the friction on the sides of the flanges, causes the resistance to traction on such tramways to be double that on an ordinary line of railway.

Paving. The paving of the road between the tram-lines, and on each side of the rails, is a matter of great importance to the proper maintenance of the way. Wood paving is often insisted upon, and there is danger that the swelling of the wood between two rails after prolonged rain should destroy the gauge by bending the rails or tilting them. When wood paving is used, it is therefore necessary to have substantial ties, placed closer together than would otherwise be necessary. The wood blocks will then sometimes arch themselves between the rails, causing a hollow beneath, while the swelling lasts. For facility in making repairs, asphalt is to be preferred as a paving material; it is also to be preferred for hygienic reasons, giving less access to unwholesome organisms. But for durability and economy, hard woods give better results than asphalt, and a safer footing for the horse traffic. Granite setts are not tolerated in most towns on account of the noise made by the traffic over them. They form, however, one of the best defences to that most troublesome form of wear which is occasioned by the tendency of the other vehicular traffic to run close to the tram-rails.

The tram rails themselves form a track of least resistance, at which the horse traffic seems to aim by getting at least one wheel on a tram-rail. Even if this be successful, unless the gauge of the vehicle is the same as that of the tram-line, the other wheel will be just off; and usually both wheels are running off and on all the time, causing excessive wear to the road in the neighbourhood of the rails, which is unduly expensive to make good.

Tramway Costs. The cost of laying a street railway will be approximately £4,500 to £5,500 per mile of single line. Of this, the rails and fastenings will account for 20 to 22 per cent.; special work in points and crossings, etc., 9 to 10 per cent.; ballast, sand, and materials for concrete, 13 to 15 per cent.; paving material, 29 to 32 per cent.; labour, 15 or 16 per cent., the remainder being miscellaneous.

CARPENTRY

continued from page 3547

By WILLIAM J. HORNER

In the working of timber in the shop, there is usually some preliminary marking out necessary, and then the first tool used is the saw, including in the term every kind, both machine and hand saws. The saw is by far the most important of all woodworking tools, and its value increases rather than diminishes, notwithstanding the great variety in modern tools.

Workshop Economy. Careful workmen, no matter what class of work they may be doing, always try to avoid waste of material. In cutting up timber some amount of waste is inevitable, but this may be needlessly increased by want of forethought in selecting and marking out. Small pieces, for instance, should not be cut from boards if it be possible to get them economically out of other small pieces—the odds and ends left over from previous sawing. The aim should be to have these scraps left over in as few pieces, and as large as possible, so that they may be utilised for other purposes.

In cases where the shrinkage of timber would be very objectionable, the marking and sawing out of material should be done as long as possible previous to planing or otherwise finishing individual pieces to exact dimensions. If pieces are finished to dimensions immediately after being sawn, and are then allowed to stand while other parts are being got out, or even if they go into place immediately, they will shrink or become distorted to a greater extent than if the freshly-sawn pieces were allowed to stand for a few days to shrink and spring as much as possible before their final reduction to size.

Saws. In well-equipped shops there are always band and circular saws, but we do not propose to discuss them here. They are dealt with in the section on Woodworking Machinery. The various saws for use by hand are always employed, more or less, in those shops where there are machine saws also, because it is often inconvenient or impossible to carry the work in progress to a machine, and in many cases it is not worth while. In the majority of instances, also, the first cut to be made is taken across a board or plank, and as a rule this can be done only with a hand saw, or a two-handled cross-cut for thick planks and squared timbers, or with a circular saw at the end of a swing arm. The last-mentioned type is used only for cross-cutting large pieces of timber, and consequently is kept only in shops where very large amounts of material have to be dealt with, but even then the ordinary hand saw is not dispensed with entirely.

The tenon, dovetail, panel, bow, and pad saws also have their uses even in the best machine-equipped shops, notwithstanding that the larger saws, such as the two-handled cross-cut, the pit saw, the rip, and half-rip, have all been reduced in importance by the increasing use of machine saws, and by the greater variety of sizes in which timber is supplied from the mills, thus lessening the amount of heavy sawing which the consumer has to do. The two-handled cross-cut is still very useful in the same way that the hand saw is, except that it is employed for a heavier class of work; and most carpenters possess a half-rip saw for ripping with the grain. The rip and pit saws may be regarded as almost obsolete.

Saw Teeth. Saws vary in general form, and in the shape and size of their teeth, according to the kind of work for which they are intended. As a general rule, for large work, large types of saws with large teeth are required, and for small work the reverse. The teeth angles vary according to whether the saw is intended for cross-cutting or ripping, or for hard or soft wood. Figs. **77**, **78**, and **79** show the angles of ordinary teeth. Saws for ripping [**78**] have more hook or forward rake than those for cross-cutting. The amount of *set*, or extent to which the teeth are bent slightly to each side alternately, varies, for the same reasons, from nothing to a considerable amount. Saw blades are always made as thin as possible consistent with strength. This is because the less material the saw removes the more easily it does its work.

The Hand Saw. The ordinary hand saw, although it is the largest one in common use, is the most necessary to wood workers. It is intended chiefly for cross-cutting, but is used for ripping also, unless a half-rip be available. In a shop where there is a machine saw of any kind, only small amounts of ripping are ever required by hand. The usual length of the hand saw is 26 in., with five or six teeth to the inch, often slightly diminishing in size and consequently increasing in number towards the point or farther end of the saw. The blade also is generally slightly thinner here than at the handle, where more strength is required, and the back is thinner than the portion where the teeth are, so that the blade will pass through the cut with as little friction as possible. A good saw blade should bend easily, and spring back perfectly straight again. The bending should be uniform, indicating that there are no inequalities in thickness and in temper. No twists or lumps should be visible when the surface of the blade is viewed edgewise. Neither should there be any local slack or strained places in the blade. These, if they are bad, will be visible in the want of truth of the surface, but they may be detected more readily by a peculiar rattling sound which the blade will emit if shaken. The handle should be securely attached. If there be the slightest looseness between the blade and handle, it will become worse in course of time.

Setting. The *set* of a saw is the amount to which the teeth are bent sideways, as shown in **77** and **86**. The purpose of this is to make them cut a kerf wider than the thickness of the blade, so that the latter will follow easily. The maximum amount of set is required in saws intended for cross-cutting soft wood, especially if the wood be not thoroughly dry, and the minimum for ripping hard dry wood. There are a number of methods of imparting this set to the teeth, and it is necessary to do it periodically, though not every time the saw is sharpened. The simplest method is by means of a handset [**80**], with the saw held either in a vice or in the hand. As it is important that the degree of set should be uniform, this method cannot be recommended unless there is also an attachment for stopping the set at a certain point. Another simple way is by means of a hammer on a bevelled or round-edged block [**81** and **83**]. This also requires some amount of skill in order to ensure satisfactory results, though it is the one commonly adopted by professional saw sharpeners. A more exact method is by means of a block and punch [**82**], four different bevels being cut across the block, and the saw set on the one best adapted for it. Another, suitable for small saws, is to punch them on the end of a block of hard wood. There are also a number of useful appliances sold, such as **85**, that ensure precise results. Instead of being set, teeth are sometimes swaged or compressed by a suitable appliance to an increased thickness near their points.

Sharpening. Saws are *sharpened* by filing the teeth with a three-cornered file [**87**]. This has the same section as the tooth space, and thus files the front of one tooth and the back of the preceding one simultaneously. One, two, or three strokes of the file may be necessary to remove sufficient material to restore the keenness to the tooth point, and to make the entire depth of the gulleting of the tooth the same as it was originally. The file is not held at right angles with the blade, but is tilted to produce acute instead of square edges to the teeth. It follows the set, therefore, alternating with each tooth, so that all the teeth that lean to one side have acute points at their outer faces on that side, and all the others alternating have acute points on the other side. This may be seen in the end view [**86**], showing the set. These angles must also be uniform; and to simplify the work as much as possible, all the alternate teeth are done with the file leaning one way, and then the saw is turned round in the vice and the reverse teeth done. This transverse angle is greatest in saws with most set. Where there is no set, the edges are generally filed square.

It is necessary also that the points of the teeth should all be level. They are made so by topping them with a flat file [**84**] before sharpening. Sharpening is always done with the saw held teeth upwards in a long-jawed vice, the teeth projecting only slightly above the jaws. Very often a pair of wood jaws, or two strips of wood the full length of the saw, are clamped within any ordinary bench vice, the saw being enclosed between them [**84** and **87**].

Lining Out. Work is marked out by various devices. For cutting down boards, a chalked line is used [**88**], which is a strained cord held by a man and boy at opposite ends, or held at one end by a bradawl and pulled by a man at the other. Then, being strained up vertically at the centre, and allowed to snap back on the stuff, the chalk transferred from the line to the timber leaves a perfectly straight white mark for cutting by. For marking across boards, the try square and lead pencil are used [**90**]. Pencil lines are sometimes marked parallel with an edge by using the rule and forefingers as a gauge [**91**].

Sawing. With the exception of the two-handled cross-cut [**89**], all the saws cut during the forward thrusting stroke, and not when being drawn back. In starting a cut, little or no pressure is applied, but the saw is moved slightly backwards and forwards in very short strokes, guided by the thumb of the left hand [**93**], until the teeth have fairly entered the stuff. The full stroke is not given until the saw is well into its cut, and in no danger of slipping out. Then the left hand may be removed and used to steady the wood [**92**], or when that is not necessary, it may assist the right in working the saw [**94**]. The wood is held in the most convenient position for sawing, and means must be taken to balance or hold each portion so that it will remain in its relative position until the saw is completely through. Otherwise, the fall of one or both parts before the cut is completed will split the remaining portion away. Or if, in sawing across a board, the piece be supported near the ends, and is being sawn in the middle, the severed portion will tend to close and pinch the saw. The "cut" should, if possible, be strained slightly open, so that the saw will work easily, and in working across grain the sawing should finish as lightly as it commences, because even a slight breaking away of the fibres at a corner is often seriously detrimental.

The most convenient position for sawing boards is to lay them on stools or trestles [**92**, **93**, and **94**]. This raises them to a convenient height and leaves room below for the saw to work through them. Occasionally, only one saw stool, or a box, or any support about 2 ft. or more in height, is used, the board lying at an angle, with its farther end on the ground; but two supports, at a suitable distance apart, are best. Short pieces of wood are often held in the vice [**95**], but this is suitable only for cutting with the grain, or sawing out sweeps. A great deal of sawing is done on the bench, either against the bench hook [**96**], against the stop, or against dogs driven into the bench, but the tenon or other small saws are mostly used for this work. Fig. **97** shows sawing against a mitre block.

Sawing Straight. Considerable practice is necessary before anyone can saw to a line and cut squarely through the wood, the latter being

more difficult than the former. A straight line often proves more difficult to follow than a curved one, because in the latter case a narrow saw, the course of which can be instantly changed, is used, while if a hand saw inclines away from the line it can only be brought back gradually. A saw may be following a line, and yet be considerably to one side of it on the other side of the material—that is, the saw is not plumb. This is an error that a beginner is certain to make, and should pay especial attention to when sawing thick stuff. The tendency is generally to incline the handle end of the saw toward the side on which the person is standing. By giving it what seems a contrary slope, it will then generally be found to cut squarely, and after a little practice the operator's eye will tell him whether it is cutting square, or inclined to either side. Until the eye is sufficiently trained to do this, tests may be made, if necessary, with a square during the progress of a cut.

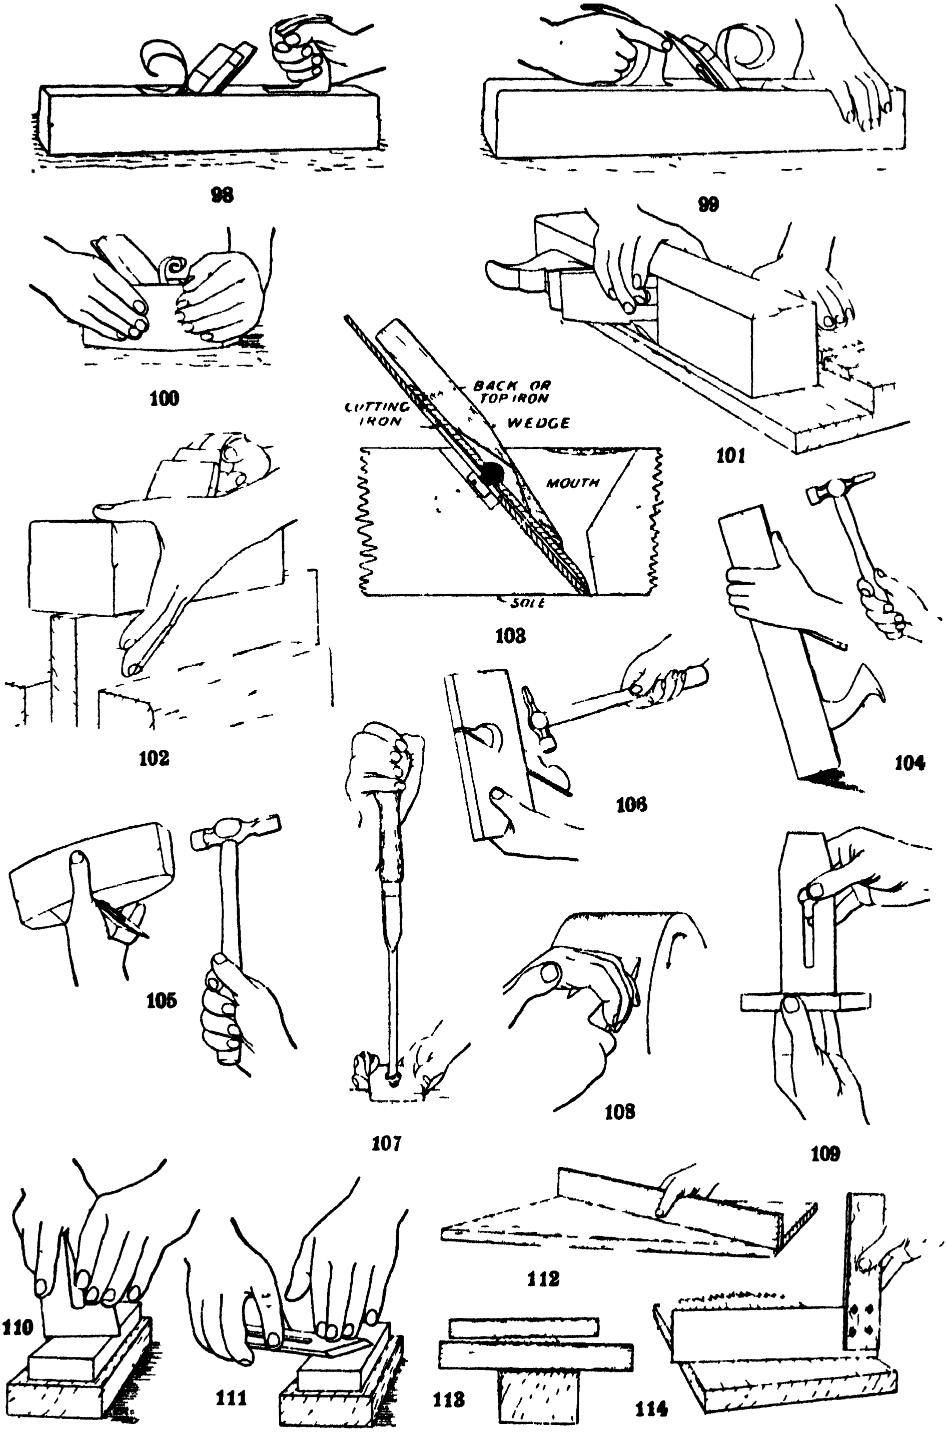
Straightening the Saw. If a saw is in the habit of running persistently to one side of a line it will generally be found to be due to a defect in the saw itself; either that the blade is twisted slightly, or the teeth have more set on one side than on the other. An untrue saw blade, or one in which the tension is unequal, is corrected by hammer blows; but if it be hammered elsewhere than in just the right places it may be made worse and bruised with hammer marks as well. Twists and lumps may be removed by laying the blade on a flat block of metal or hard wood, and hammering them down. Slack and tight places in the blade require skilful treatment with a hammer. The principle is that tight or strained places can be slackened by hammering, which spreads the metal in those parts and at the same time makes adjoining slack places uniform in tension with those which were tight. Places that are slack will, if the saw be held horizontally, fall, or can be easily pressed into a concavity, while the tight surrounding part remains level.

Planes. The three principal planes used by woodworkers are the *trying*, *jack*, and *smoothing* planes. These are always kept on the vice end of the bench, with their fore parts resting on a strip of wood which prevents the cutting edges from becoming damaged by contact with the bench. These planes and their uses have already been described in the chapter on tools [page 3385]. They are made both in wood and metal, the latter being preferable, but as they are more expensive they have not yet become so popular as wooden planes.

If the surface of a piece of timber has to be made merely smooth, regardless of accuracy, the smoothing plane is used, sometimes preceded by the jack plane when the surface is very rough or irregular. If it has to be planed truly—that is, with perfectly flat faces, square with each other—one face is first roughed down with the jack plane and then finished with the trying plane. Next, an edge is planed straight and square with the true or *trying* face. Then the gauge is brought into use, and the opposite edge gauged and planed parallel with the first. The thickness is now marked with a gauge, and the second face reduced almost to the gauged lines with the jack plane, and finished with the trying plane. The ends are then planed square with faces and edges. In very long pieces of wood, especially in planing long edges, a plane a few inches longer than the ordinary trying plane, called a *jointer*, is sometimes used. Two jack planes are also often employed, one for roughing down, and one set more finely for preparing for the trying plane.

The Art of Planing. The shavings are removed by grasping the handle with the right hand [98 and 99], and pushing the plane over the surface in as long strokes as the arm can conveniently make. At the end of the stroke the plane is raised sufficiently to finish the shaving, and the plane is then drawn back and another cut parallel with the first is taken, or a step forward is made and a continuous shaving taken. In planing a long edge for a glue joint, or in other important work with a trying plane, the tool is never raised, but a continuous shaving is cut along the entire length, the plane being stopped at the end of one stroke and moved carefully on again as the operator walks by the side of the board. That, of course, is in the finishing cuts. At the commencement there is always more to be planed from some parts than others. In using the jack plane either one or both hands are used according to circumstances [98]. In using the trying plane both hands are employed on the tool, the right grasping and pushing the handle, the left bearing on the fore part [99]. The smoothing plane is always grasped with both hands [100]. Sometimes the trying plane is used on a shooting board [101]. The wood is then held down by the left hand while the plane is slid on its side by the right. This is for planing edges, the alternative being to screw the wood in the vice [102].

End Grain. End grain is more troublesome to plane than longitudinal work, and it is always best, therefore, in squaring ends, to saw almost to the line, or to pare with a chisel so that the plane may be used only for finishing, and not for removing a quantity of material as it often is when working with the grain. Care must be taken also not to let the plane split the edge of the wood away at the end of a cut, on end grain. This may be prevented by bevelling the corner off with a chisel, so that the plane ceases to cut before the extreme weak edge is reached. With a little care the plane may then be used on the end grain without fear of breaking the farther edge away, and if it be necessary to plane the bevel out to leave a sharp corner, the plane must be turned and used in the opposite direction, so that the cutting always commences at the edge and stops before the cutter reaches the opposite edge. For squaring ends and cutting end grain, a mechanical trimmer is always used in preference to a plane, if possible. At the ends of planks, where the wood is often



PLANES AND THEIR USE

98. Using a jack plane **99.** Using a trying plane **100.** Using a smoothing plane **101.** Using a trying plane on a shooting board **102.** Planing an edge with wood in vice **103.** Section through a plane **104.** Loosening wedge and iron **105.** Loosening a smoothing plane wedge and iron **106.** Knocking back a rebate plane wedge **107.** Turning the screw of a double iron **108.** Grinding an iron **109.** Testing the curvature of the cutting edge **110.** Sharpening **111.** Removing the burr, or wire edge **112.** Testing a surface with a straightedge **113.** Testing with winding strips **114.** Testing planed surface with the edge of a square cracked and full of dirt, an inch or so is always sawn off and thrown away if the end has to be planed. Finishing to length is done on the same principle as the reduction in other directions, one end being first planed square with sides and edges, and then the required length marked, and a line squared across, and the material beyond this line removed.

Plane Irons. The irons or cutters of these three planes are usually what are known as *double irons*, one, the *iron* proper, being the cutter; and the other, called the *back iron*, being screwed to it in order to stiffen it and lessen the risk of its tearing up the grain. In jack planes, for coarse work, a single iron only is often employed, and in planes other than the three types we have been considering, a single iron is the rule. The back iron is screwed to the other about $\frac{1}{16}$ in. or $\frac{3}{32}$ in. back from the cutting edge and the double iron is then inserted and wedged in the same way as a single one would be [**103**]. For adjustment, the irons, after they are wedged, are tapped forward, or on either side, by a hammer, if the edge be out of square with the sole, or, if it project too much, the plane is given a blow on the fore part. This causes both iron and wedge to move back and consequently become loosened slightly, so that a tap on the wedge is then necessary to tighten it again. Striking the plane on the fore part is also the method adopted for getting the iron out to sharpen it [**104**]. The smoothing plane, being very short, can have its wedge loosened more readily by a blow on the back [**105**]. The beginner who is not skilful in using a hammer should be as careful as possible not to bruise the plane in doing this. In the trying and jack planes a good plan is to bore a hole about $\frac{7}{8}$ in. diameter and about $1\frac{1}{2}$ in. from the end of the planes, and, say, $1\frac{1}{2}$ in. deep, and to insert a hardwood plug with a rounding top standing about $\frac{3}{8}$ in. above the surface, and use this plug to hammer on The wedges of moulding and rebate planes are generally made of a shape that can be knocked back directly [**106**]. The cutters of iron planes of the large class are adjusted, and tightened and released, by screws, cams, or levers, so that hammers are not used on them.

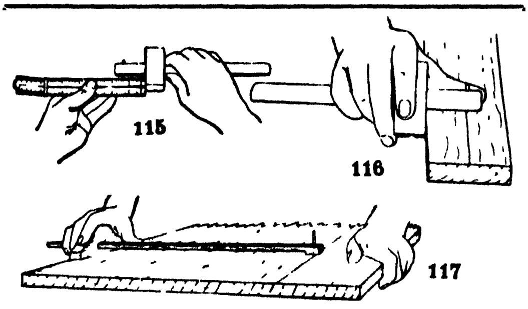
Sharpening Plane Irons. Plane irons are *ground* and *sharpened* in the same way as chisels, and to the same angles, but one important thing in the grinding and sharpening of the irons of the jack and smoothing planes which can be disregarded in chisels, is to impart a slight curve to the edge, so that when projecting below the sole of the plane they will cut a shaving slightly thicker in the middle than at the sides. At the extreme sides, in fact, the shaving must taper to nothing, and the corners of the iron must not touch the timber, otherwise they would leave unsightly ridges. In the trying plane iron, however, which is required for accurate work, the cutting edge must be as straight as possible consistent with the above-mentioned requirement. In the smoothing plane slightly more rounding is permissible, and in the jack plane, especially if used for very coarse work, a good deal of convexity, often $\frac{3}{32}$ in. or more, is given to the edge, because thick shavings can then be cut without difficulty. In a jack plane used for ordinary work the middle part of the cutting edge should project about $\frac{1}{16}$ in. below the sole when the corners are still within. Fig. **107** shows how the parts of a double iron are screwed and unscrewed when taken out for sharpening. Fig. **108** shows how an iron is held during grinding. In grinding and sharpening, the amount of curve present is tested by resting the edge vertically on a flat piece of wood and holding it up to the light to see exactly to what extent the corners are ground back [**109**]. A plane iron curved the opposite way, or hollow, will not work at all, as the shavings will corrugate and choke the plane mouth.

Regarding the angles for grinding and sharpening, planes for soft wood may have more acute cutting edges than those for hard wood. In all cases the angle should be as acute as will stand usage for a reasonable time without resharpening. The angles range from about 5 to 25 degrees with the sole of the plane, the iron itself being set in the plane at an angle of about 50 degrees. The ground or bevelled part of the cutter in this class of planes, and with only one or two unimportant exceptions in all planes, is downward [**103**]. Fig. **110** shows how an iron should be held during sharpening on an oilstone, and **111** shows how the burr should be rubbed from the face.

Choking of Shavings. This, as already mentioned, may be caused by an irregularly ground iron in which the corners project too much. It never occurs in coarse jack planes where the cutting edge is very rounding. It may also be caused by a very obtusely-ground iron, or by an untrue sole, or, in a few instances, in new planes, as a result of trying to plane a shaving thicker than will pass through the mouth easily. If it be due to the last-mentioned cause, the defect soon cures itself, because as the mouth wears back it widens, and the iron also is generally thicker at the end than further back, and so becomes thinner at the mouth as it wears. The width of the mouth can easily be increased with a chisel or file, but it should be touched only at the narrowest part. For doing fine work a narrow mouth is necessary, and when in a wood plane the mouth has greatly increased in width through the wearing back of the sole, workmen find it advisable to reduce it again by inserting a block of hard wood in the sole in front of the iron

Truing a Plane. The soles of all planes should be perfectly true. This is especially important in the case of the trying plane, which has to plane other surfaces true and has a large surface of its own which will get out of truth more readily than a small one. It is necessary therefore occasionally to *shoot* or plane it true. This is always done with the iron and wedge in place, but the cutting edge, of course, kept within the mouth, so that the body of the plane is in its normal state. The simplest and most expeditious way is to pass it over a finely-set jointing or planing machine if one be available, but if not, it is screwed in the vice, sole upwards, and thin shavings are taken off in the ordinary way with another trying plane. The surface has to be carefully tested with a straightedge and winding strips to ascertain whence to remove shavings. Soles are hardened and lubricated by the application of linseed or other oil which is allowed to soak into the wood. New planes are better, also, if they are protected from dirt by two or three coats of shellac varnish.

Testing Planed Surfaces. An experienced man sees a great deal with his eye that beginners have to find out by testing with instruments, and so the former will make a surface approximately true before he begins to test its truth. The degree of accuracy, however, must always be verified by instruments in all cases where accuracy is of importance. The chief instruments used are *straightedges*, *winding strips* and *squares* [112-114]. Straightedges are long strips of wood with edges perfectly straight, so that they can be used for testing other pieces. The piece of wood being operated on may be tested with them lengthwise, transversely, and across corners [112]. When the surface is nearly true, the straightedge is generally chalked, and the chalked edge is rubbed across the surface at various points, leaving marks of chalk on the high places that require planing down. For testing a board transversely, the edge of a steel bladed square is more convenient than a wood straightedge, because, being thin, the light can be seen under it where there are hollow places in the surface [114]. For testing long pieces lengthwise the eye alone is often sufficient, especially if the piece be so thin that it bends easily; but if not, a straightedge as long as the piece must be used. To test whether there is any twist or wind present on the surface, *winding strips* are employed [118], or if the piece of wood is of considerable width, a straightedge may be tried across the surface diagonally from corner to corner [112].



THE USE OF THE MARKING GAUGE
115. Setting a gauge 116. Gauging a line. 117. Gauging a line with a panel gauge

Testing with Winding Strips. In testing with these, the eye is really the judge, but the strips exaggerate the amount of twist so much that the eye requires no training to see it. Winding strips are simply two parallel straightedges which are placed on edge across the piece of wood to be tested, as shown in 118. The strips, being considerably longer than the width of the wood upon which they are placed, follow the inclination of the surface at each end and extend beyond the edges, so that when a glance of the eye is cast along from one end over the top edges of the strips, it is easy to see whether they are parallel, or whether one dips one way and the other the opposite way. They are then taken off and shavings are planed off the high corners of the surface until the strips show that the twist in the surface has been removed.

Planing True. In all pieces of wood that have to be accurately planed one of the surfaces must first be made true by tests of this kind. Nearly all boards are more or less curved transversely, and it is best when they have to be planed to a definite thickness to true the hollow side first, because if the edges are not planed under thickness it will then be certain that the middle part will hold up; and, because, if there is much to be planed off, it is best to take most off the rounding side to cause it to shrink more there and counteract the tendency to curve. When one surface has been planed true the square is used on an edge to get it exactly at right angles with the true surface, and a straightedge may be used to find when the edge is straight. Then gauges [115, 116, and 117] are used to mark lines parallel with these planed surfaces, and straightedge tests are no longer necessary except transversely on the opposite surface, the plane working to the gauged lines. In all work where planing and cutting with chisels are concerned, lines are, as a rule, gauged or scribed and not pencilled, because a pencil line is not accurate enough. Pencil lines are preferred for sawing by because they can be more easily seen from a distance and because sawing either presupposes rough work, or work that must have further lines marked afterwards for finishing to. In many cases finishing lines are scribed, and the saw kept well to one side of them.

Even if dimensions are unimportant, true surfaces and accurate angles are always essential in fitting work together. They make the chief difference between good work and bad, and are the main difficulty which the beginner must master.

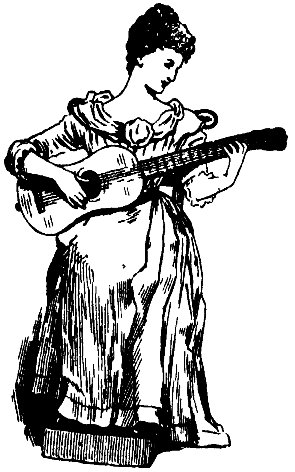
THE GUITAR AND ZITHER

How to Hold the Instruments. Tuning. Fingering. Positions. Scales. How the Finer Effects are Obtained

By ALGERNON ROSE

THE guitar has six strings, the top three being of gut, and the lower three of silk overspun with silver wire. According to their thickness so is the quality of the sound affected. The smallest gauge makes the tone sharp and brilliant, and the largest full and round. Medium sizes are best.

The pupil should be seated when playing. Place the right foot on a fairly high footstool. Rest the hollow, or curve, on the treble side of the instrument against the right knee. The bass side of the guitar should incline backward so as to be supported by the chest. Ladies rest the guitar in the lap. Spaniards play as often from the left knee as the right. When the instrument is played standing, to facilitate change of position in fingering, extend a ribbon from the peg provided for that purpose to the head of the guitar and pass this over the right shoulder. Place the right arm round the big end of the instrument, so as to hold it without the assistance of the left hand [1].



1. POSITION OF PLAYER

Dispose the right fingers perpendicularly over the strings. The first finger should be over the third string, the second finger over the second, and the third over the first. Elevate and curve the wrist. Keep the thumb away from the other fingers. They will thus be more independent when striking a chord. The usual place for the right hand is midway between the bridge and the soundhole When playing very softly, strike the strings immediately over. the hole. The thumb negotiates the three silver strings, or bass notes, E, A, D. Occasionally it is used for the third and second strings, G, B. To produce the best tone with the thumb, twang from left to right, and stop the next string. Avoid "wagging" the hand up and down.

Place the left thumb under the neck of the guitar between the first and second frets. This forms a fulcrum for the other fingers. Bring these round gracefully on to the fingerboard, right and left, above the thumb. Stop the notes not with the flat but with the tips of the fingers, firmly, close to the frets. Keep each finger down until the full value of a note has been sounded.

It is important for the student to study the course on Harmony [page 363], so as to understand how chords and arpeggios, appropriate to the guitar, should be built up, for all charm in playing vanishes if a wrong harmony is employed.

Tuning. The accordatura, or tuning, is simple. Tune the thickest string in unison with E (one ledger line below bass clef) on the piano. Having done this, place the second finger on the fifth fret of the string. Sound the note with the right hand and tune the next silver string, A, in unison with it. Then stop with the same finger the fifth fret of the second string, and tune the third to the note given. This will be D. Put down the finger on the same fret of the newly-tuned string. The note sounded will be G. Tune its neighbour in unison with it. Remember at this point to put the second finger on the fourth (not the fifth) fret of the fourth string. The result will be B, to which note tune the fifth string. Then put the second finger on the fifth fret of B. The note sounded will be E. Tune the sixth string in unison with it. If the right hand now strikes the strings one after another, they will sound in succession E, A, D, G, B, and E, the first four notes having fifths between them, the fourth and fifth strings sounding an interval of a fourth, and the fifth and sixth strings another interval of a fifth. This irregularity in the intervals between the strings enables the guitarist to get certain effects usually impossible on the violin.

But noted guitarists have not been satisfied with this inequality in the intervals. To get further effects, they have deliberately made the six strings disagree still more, in the same way that Paganini mistuned his violin in order to obtain unusual results and puzzle his brother fiddlers. A *scordatura,* as it is called, skilfully employed by a good guitarist enables him to get new effects. The beginner, however, will carefully tune in the orthodox fashion.

The Positions. Put the first finger on the first fret of the D string, and the second, third, and fourth fingers on the second, third, and fourth frets of the G, B, and D strings. The hand is now in the first position. It is in the second position, or the third, fourth, fifth, and so on to the twelfth, when the first finger is over the corresponding fret. In guitar music, 1, 2, 3 or 4 dots to the left of a note, or immediately under it, sometimes guide the player to the position for his left hand. An O over a note signifies an open string, or one which requires no stopping by any finger.

For the chromatic scale, begin on the lowest string, E. Keep the fingers off it. Strike with the right thumb. Put the first left finger down firmly on the first fret. Strike the string. This gives F, a semitone above. Put the second finger on the second fret. The note produced will be F♯. Put the third finger on the third fret. The sound is G. Now place the little finger as firmly as possible on the fourth fret. This will give G♯. Do the same thing again with the fifth string. The notes A, A♯, B, C, and C♯ will result. Continue on the fourth string. D, D♯, E, F, and F♯ will be obtained. Take the third string in the same way. Note that the little finger is not used with the third string. The sounds will be G, G♯, A, and A♯. Proceed to the second string. Again use all the four fingers. The effect will be B, C, C♯, D, and D♯. Lastly, go without interruption to the first string. Use all four fingers of the left hand. The sounds played will be E, F, F♯, G, and G♯.

Meanwhile, the left hand fingers used should be the first and second alternately—not the thumb. The left thumb is never employed to stop any of the strings. It is kept underneath the neck to enable the four fingers above to articulate the notes firmly and gracefully.

It is not advisable to make a pivot of the little finger of the right hand, as beginners are apt to do, by resting it on the soundboard. Keep the little finger up ; this allows the right hand to become light and lissom.

Having ascended the scale, go down the gamut in the same way. The pupil will now have executed the chromatic scale of 2½ octaves, and have learnt the fingering of each half note.

The Natural Scale. By omitting all the sharps, but keeping to the same fingering, proceed to practise the natural scale When this becomes easy, vary it by using the first instead of the second finger, and the second instead of the third, so as to get more tone, wherever (as on the fifth, fourth, and third strings) the first finger would otherwise play a sharp in the chromatic scale. The hand is thus shifted temporarily to the second position.

One of the greatest difficulties in guitar playing is usually regarded as the ability to finger all the scales and chords correctly in the different positions. Professor Prout, in Vol. I. of his "Orchestra," emphasises this But the great guitarist Duverhay points out in his "Method" that if the student studies well the natural scale of C major, and learns the fingering carefully, he can make the same fingering serve for all the other scales and chords by transposition. We give below the manner of fingering C. [Ex. 1.]

Remember always in scale playing, whether chromatic or diatonic, that whereas four fingers may be necessary for all the strings except the third, three suffice for the G, or middle string, because it is tuned a fourth below B, whilst all the others are in intervals of fifths.

The Shifts. If the first finger is used for the second fret, the hand is what is called in the second position, or shift. It is in the third, fourth, and so on, up to the fifth position, as the first finger stops the apposite fret.

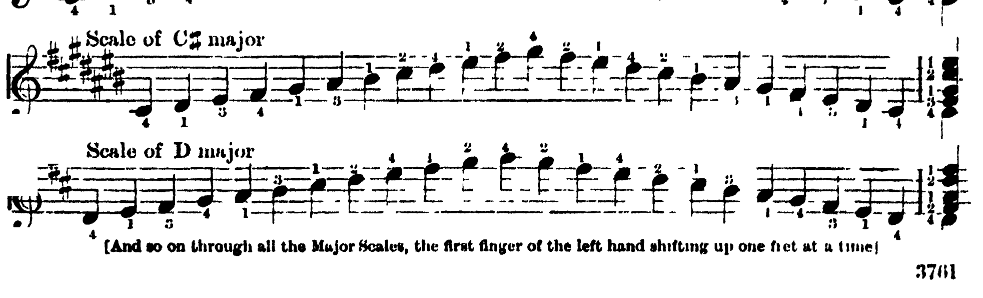
When the student has made acquaintance with these different positions, he will proceed to playing what is known as *barré*. Place the first finger of the left hand across the neck of the guitar, so as to stop more strings than one at a time. Strike the strings. It will be observed that those which are stopped are raised equally in pitch By this simple device many passages in guitar music, which would be otherwise difficult to execute, are made easy.

The effect known as Grand Barré is so-called when the first finger is laid across the fingerboard and the other three disengaged fingers are used to stop the strings as required, five or six strings being sounded as an arpeggio or chord. Little Barré is obtained by laying the first finger across merely a few strings, so as to stop a chord from the first to the fourth string. This plan of simplifying the playing is indicated as "2 P.B.," "3 P.B.," and so on.

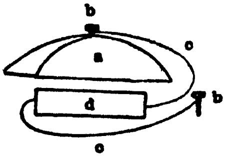
Capotasto. An easy method of raising the pitch of the guitar permanently at any given fret is to screw over the strings on to the fingerboard an artificial headstop. By this contrivance the pitch of all the strings is raised, and the clear effect of fresh open strings retained. This temporary nut is called the "*Capotasto*" or "Capodastro," its use being denoted by the words "con capotasto sulla 3 P,' 4 P, or whatever position is required [2]

The advantage of this will be evident when the player is asked to accompany a song in a higher key than that given in the music. With the capotasto he can play with ordinary fingering and

Ex. 1 **MAJOR SCALES**



[And so on through all the Major Scales, the first finger of the left hand shifting up one fret at a time] use the open strings, although the key has been changed. For duet playing the capotasto enables two guitars, one with and one without the artificial headstop, to play concerted music which usually would be rendered by a mandoline and guitar. Allusion to the capotasto has been made to emphasise the desirability, when playing barré, of the learner putting his first finger down with weight, so as to make it do temporarily what the capotasto does—*i.e.*, cause the tones of the strings to resemble as closely as possible those of open notes produced by the stress of a natural top-nut.



2 THE CAPOTASTO
a. Body *b.* Peg *c.* Peg-string *d.* Leather

When a note, or group of notes, ascending, is *glisséd*, pluck the first note with the right hand. The fingers of the left hand slide firmly to the succeeding note, and cause the sound to ascend as the vibration continues. When this "son porté," or "carried sound," is descending, after striking the first note, slide the finger in the opposite direction, taking care always to change the fingering correctly as each successive fret is reached.

In the slur the first note is struck by the right hand. The fingers of the left hand must stop those notes which succeed as strongly as possible, and "pull" them pizzicato fashion.

Harmonics. Harmonics are made by placing one of the fingers of the left hand very lightly over the fret, and playing with the thumb or the first finger of the right hand. The best natural harmonics are those of the third, fourth, fifth, seventh, ninth, and twelfth frets. Although the left hand stops the string gently, the right hand strikes forcibly and close to the bridge. Harmonics "à double doigter," or produced with two fingers, are made by stopping a note first in the usual way. At the same time, the right thumb touches the middle of the string lightly, whilst the first right finger strikes the string underneath. This produces a sound an octave higher than the natural tone of the string stopped.

A characteristic guitar effect is the *Twirl.* In this the thumb forms the centre of an imaginary circle, and the tips of the other fingers twirl round it so that the right hand makes a convolution by sweeping all the strings in succession above the rim of the rosette, or soundhole. If done properly in chord playing, the trick is delightful.

Another subtle conceit, or piquant effect in chord playing, *Les Ongles*, is made by running the finger nails of the right hand lightly across the strings from right to left.

The *Tambour*, or drum effect, is executed by raising the right hand a span over the soundboard, and dropping the side of the thumb with a free action from the wrist across the strings close to the bridge.

Again, for the effect known as *Corni*, strike energetically with the thumb and first finger, but with a closer action quite near the bridge. The effect is supposed to resemble the sounds of horns. "Corni" is also played by using the tips of the nails close to the bridge, or a single horn is imitated by all the notes of a phrase being sounded by the nail of the first finger on one of the silver strings.

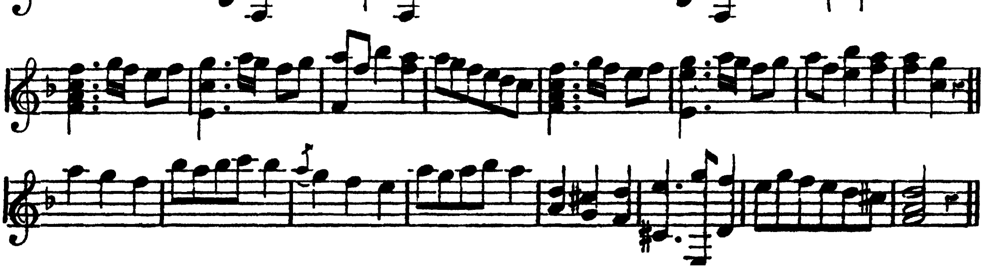
Son Étouffé is a sudden damping, or stifling, of chords when they are struck. It is done by the fingers being replaced immediately on the strings after striking them, or the sudden staccato is obtained by employing the whole of the right hand to damp the sound. This effect is marked ⊕.

Vibrato is not possible on the open strings. It is done by making each of the fingers of the left hand, after stopping a note, tremble firmly and evenly on the string. Practise making this motion slowly at first. A player capable of making a good vibrato, especially with his weaker fingers, produces a better quality of tone than an amateur less accomplished. Although, theoretically, a throbbing sound is opposed to the production of a pure and equal tone, it has a peculiar charm on the guitar, and good players who are able to make the notes pulsate can render entire passages unusually expressive.

The Tremolo. The tremolo is a rapid repetition of one or more notes struck alternately by the thumb and first finger of the right hand, the second and first finger, the thumb and second, the thumb, second, and first, or by varying the order of manipulation in other ways. Practise the different methods of fingering for the *Tremolo* systematically. The exercise adds to the suppleness of the right hand. It is as useful as is the practice of the vibrato for each of the left fingers.

Guitar concluded

Ex. 2 FANDANGO FOR GUITAR

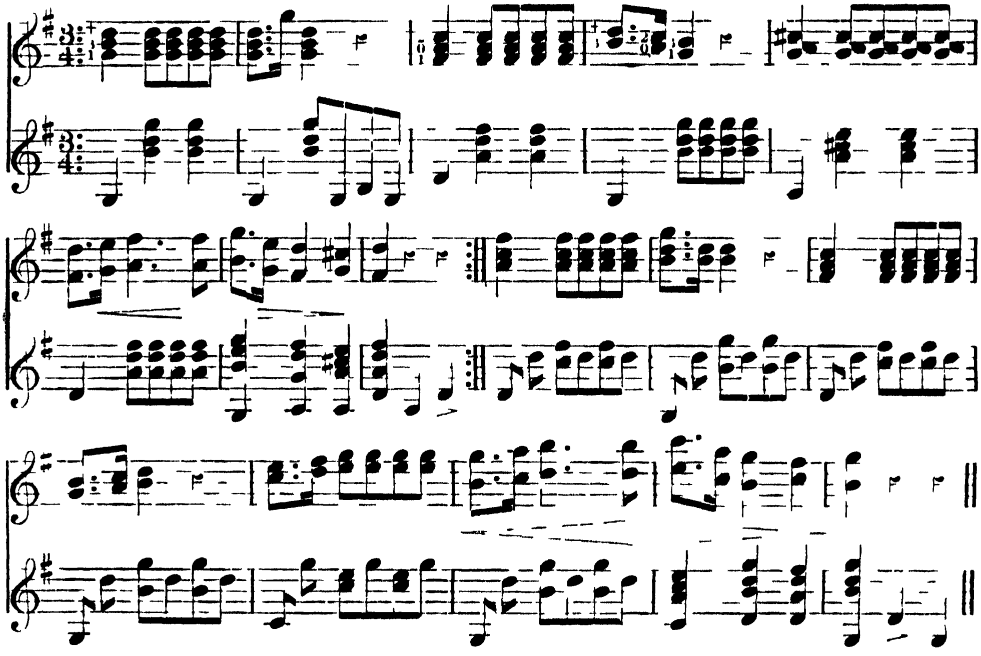


THE ZITHER

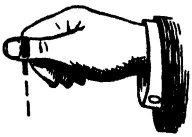
For zither notation two staves are employed. One is for the melody and the other for the accompaniment. Both are usually in the treble clef There are two methods of tuning—the first is that adopted in Vienna, and the second that in Germany. We will confine our attention to the now general German method

Tuning. The first string on the fingerboard nearest the player is of steel It is tuned to A, second space treble clef, as is also the second string, the object being to get reiterated effects from two strings in unison Brass wire is used for the third string This is tuned to D below first line The fourth string is of steel overspun with silver wire It is tuned to G below second ledger line The fifth is of brass overspun with copper, tuned to C below fourth ledger line

Ex 3 MINUET MOZART

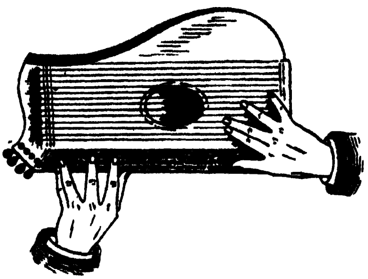


Next come the accompaniment strings Of these there are 13 The first, second, fourth, sixth, seventh, ninth, eleventh, and twelfth are of catgut, the third, fifth, eighth, tenth, and thirteenth being of silk covered with wire The contrasting substances of the strings are employed not merely as a help to the player, but have a peculiar effect on the individuality of the zither tone Beyond the 13 accompanying strings are the 13 bass strings These are all of silk, covered with wire and of a thicker gauge, so as to give the deeper sounds The diagram given shows the complete scale.



3 ZITHER RING

Position of the Player. Place the zither on a table of bare wood If the table rests firmly on the ground it magnifies the sound of the instrument The zither should be put obliquely with the fingerboard towards the player In playing, both thumbs are used, the only fingers unemployed being the fourth on both hands Place the thumb and three fingers of the left hand on the frets of the fingerboard In sounding a note be careful to incline the left fingers to the right inner side of each fret, otherwise the tone will not be good While the left fingers form the notes, the melody strings are plucked by the right thumb Over this is worn a clip of German silver ending in a prong, called a zither ring The upper portion of this prong forms a semicircular band of the thickness of an ordinary ring The clip goes over the base of the thumb-nail, the prong being underneath, and protruding to the left [3] When at rest, the position of the right thumb is for the plectrum to be over the middle melody string D The first right finger should rest on the second wire-covered accompaniment string, C, place the second finger on the third wire A, the third finger on the third bass string F, and allow the fourth finger to remain free It should follow the movement of the third, and not be rested on the tailboard—a bad habit contracted by careless players Keep the joints of the fingers straight It is the sides of the fingers and not the nails that have to come in contact with the strings Therefore do not appear to attempt to pick up the strings by curving the right fingers On the contrary, endeavour to press them [4] Thus, rest the third finger heavily on the F string Now, when the finger is removed, the act of its slipping off will cause the string to vibrate. The third finger should fall against the next string on the left, B♭, and impel it almost against its neighbour. But no sound other than the F will be heard. Finger pressure must be regulated according to the thickness of the string. For instance, it will not be necessary to use the same degree of force if the second right finger is pressed stiffly against the third accompanying wire, A, because that wire is of quicker utterance than the F.



4 FINGER POSITION

Having made this motion, try to play two strings at once with one finger. Rest the first finger firmly on the second wire, or fifth accompaniment string from the left C. Now pass it quickly from the C to the F, or the catgut string on its left, so as to sound both simultaneously. In doing so, the finger motion must finish on the third string, B♭, the digit resting firmly against it. A little thought will cause the pupil to realise that the arrangement of the accompanying strings admits of common chords and their inversions being played by two instead of three fingers. The pressure of one finger when passing to an adjacent string should be so rapid that the sounds of the two are merged. This would not be possible were the accompanying strings not tuned in fourths and fifths as they are.

In using the zither ring, play gently at first. Fulness of tone must be acquired evenly and gradually. It is easier to develop a *forte* by the slow and sure method than to begin carelessly and learn afterwards to play with delicacy.

Fingering. Fingering in zither music is indicated by a + for the thumb, 1 for the first finger, 2 and 3 for the second and third, and an 0 for an open string.

Before the fingers get accustomed to their duties and gradually harden, excessive practice will do more harm than good. Progress will be more rapid if the pupil practises for half an hour on the first day, and adds an extra quarter of an hour the second day, and so on up to a maximum of two hours, rather than if he tinkles upon the instrument during the whole of his evening leisure for the first two or three nights, and then lay the instrument aside in disgust.

Positions. There are six positions on the fingerboard in general use, besides three others more rarely employed.

For the first position, place the third finger of the right hand on the first or second fret, the second finger on the third or fourth fret, the first finger on the fifth or sixth fret, and the thumb on the seventh or eighth fret.

For the second position the third finger now comes on the third or fourth fret, the second finger on the fifth or sixth fret, the first finger on the seventh or eighth fret, and the thumb on the ninth or tenth fret.

For the third position, the third finger is placed on the fifth or sixth fret, the second finger on the seventh or eighth fret, the first finger on the ninth or tenth, and the thumb on the eleventh or twelfth.

Continue in the same way, moving every finger up one or two frets each time, so as to become accustomed to the fourth, fifth, and sixth positions. The player should make out a diagram, numbering and lettering the notes of each position. Get to know them automatically, so that any note indicated in the music may be produced with certainty. The less the fingers are shifted, the smoother will be the effect.

Double Notes. In playing double notes, hold the left hand obliquely towards the right. In the higher part of the scale, thirds are played by putting the left thumb on the first A string, and the second finger on the second A string. Practise sliding the fingers; do not lift them when passing from one fret to another. In playing sixths, the two A strings are not used together; the lower note required will be found on the string next to that which produces the higher note. Octaves, like thirds, are always played with the thumb and second finger. The ease with which a glissando, or sliding over intervening frets between two notes, is produced is one of the greatest charms of the zither. This effect, next to the *portamento* in singing, is indicated by a slur in the music. In making the slide, first put down the thumb deliberately. Then turn it over, so that the nail may touch the string. Do not hurry. After the ring on the right thumb has caused the string to vibrate, the sound will ascend or descend naturally according to the movement of the left finger, or fingers. Two notes linked together in the music by a slur must be played on the same string. Be careful not to remove the thumb after a glissando until the note has sounded its full value, or the charm will be destroyed.

When an open string is struck with the right thumb, and the interval to be slurred up is a big one, do not slide the whole length. It is better to make the glide only in the higher section of an interval in ascending or the lower section in descending. Take care to touch the string very lightly at first, and increase the pressure gradually. If the interval is a long one, the thumb ring must be used a second time to mark its conclusion.

The Shake. The shake is not so easy to execute on the zither as on the piano. When made closely and rapidly, its charm rewards the player for the time spent in practising it. Place the second finger on the note indicated in the music over which is printed the sign *tr*∿∿. Then put down the thumb on the next fret, or the next but one, as may be necessary for the trill. Press the tip of the first finger against the thumb to steady the latter. Let the thumb and second finger rise and fall alternately. Practise the shake slowly at first, evenly, and accelerate the speed gradually.

Vibrato. There are so many charming effects to be obtained out of this instrument that its admirers have not yet decided which is the most beautiful. But many of them maintain that the zenith of the zither's sublimity is only reached through the magnetic *vibrato* tone of which it is capable. Place one of the left fingers on the requisite note. Move the finger from left to right, backwards and forwards, from the tip. The motion must not be made from right to left. Avoid jerking the strings. The player who once contracts the bad habit of making the strings shake, will find it difficult later to cure himself of that defect. What is wanted is a sense of rapid but gentle pulsation—not a series of spasmodic jerks. The quicker the vibrato, if done in a smooth manner, the better will it sound. By its means the tone of any of the melody strings may be prolonged, the continuous trembling caused by the motion of the metal wire impinging on the metal frets seeming to reinforce the sound.

The sound of the strings is diminished when the word "*dolce*," or *pp*, is indicated in the music, by advancing the right hand over the circular hole in the sounding board. What is known as the ***harp effect*** is thereby obtained

Bell Notes. What are known as ***bell notes*** are of two kinds—natural and artificial. To produce the former, place the thumb lightly on the string above the required fret, exactly over it instead of a little to the right, as for notes which have to be stopped firmly. Sound the note with the right thumb by the "ring." Bell notes are also called ***flageolet tones***. They are harmonics, and sound an octave higher than written. Natural bell notes are produced by touching lightly the open strings at different points. The artificial harmonics are made by stopping certain frets and then touching very lightly a higher fret with a disengaged finger.

If the pupil has memorised the names of each of the accompaniment and bass strings so as to associate them instantly with the notes that represent them, he will be ready to practise what is known as a ***running accompaniment***. In this, each note is articulated separately, beginning on the lowest string. Major chords or arpeggios present little difficulty [Ex. 8]. Minor chords are easy to produce if the necessary third is supplied by the melody strings. The right hand then plays as if for the major chord, without using the second finger. Keep the right hand quiescent when playing full chords. Press slightly with the fingers. Withdraw them delicately. In staccato chords the fingers must be taken off instantly after making the sounds. Replace them immediately on the strings to damp the vibration.

FROM MINE TO MARKET

Surface Works. Winding Plant. Mine Ventilation and Lighting. Mine Gases. Screening, Washing and Crushing. Ore Roasting

Mine Tubs, or Corves. The system of haulage most suitable to the conditions of working having been selected, it remains to describe the vehicles employed to convey the materials from what is known as the *working face* to the bottom of the shaft. For this purpose stout iron carriages, or *tubs*, are employed, although wooden ones are still used in some of the Cornish mines and in several collieries. Numerous devices have been suggested for attaching the tubs to the rope, where rope haulage is employed. These usually take the form of a friction clutch, although in such cases the wear of the rope is apt to be considerable. The chief trouble arises, however, from the fact that the roads are apt to be dusty, and great difficulty is therefore experienced in keeping the axles and bearings free from dust and properly lubricated.

Winding. Methods of winding have necessarily to be modified by the various factors to be considered, such as depth of shaft, nature of materials, etc. In coal-mining practice the tubs are run into the cages previously described, and drawn to the surface by a rope which winds round the drum of the winding engine. A typical shaft, with cages, and the road leading from the working to the bottom is illustrated in 99.

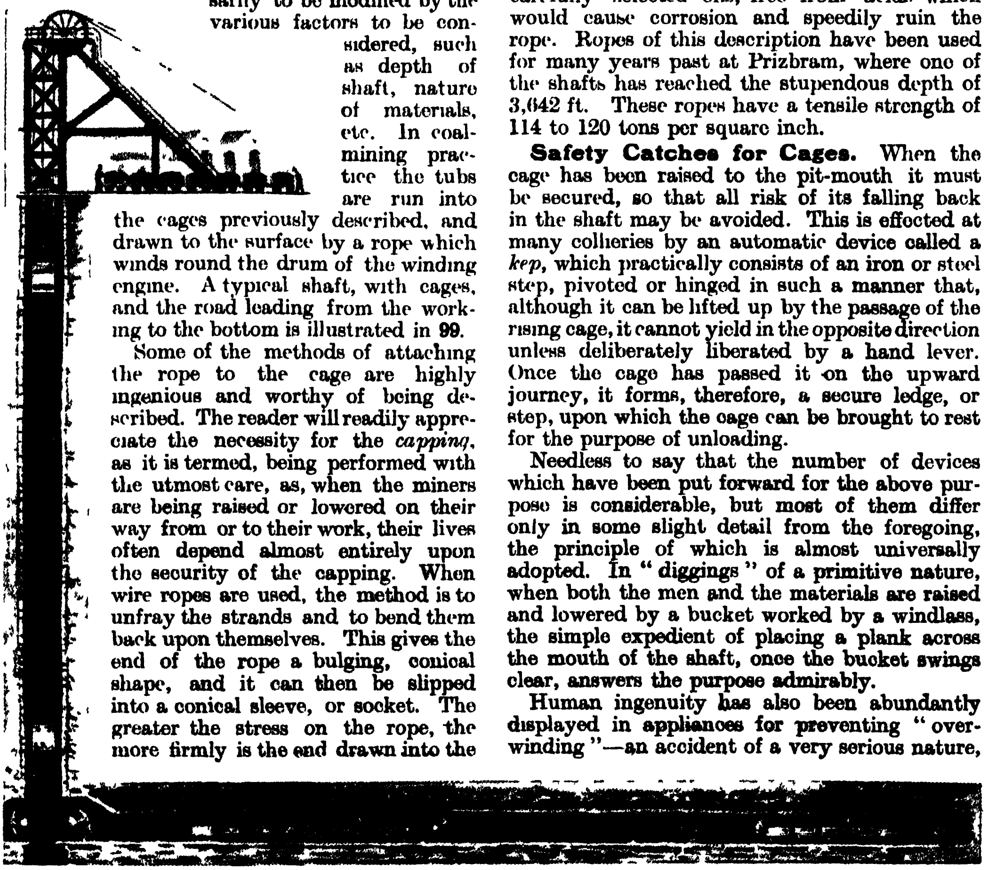
Some of the methods of attaching the rope to the cage are highly ingenious and worthy of being described. The reader will readily appreciate the necessity for the *capping*, as it is termed, being performed with the utmost care, as, when the miners are being raised or lowered on their way from or to their work, their lives often depend almost entirely upon the security of the capping. When wire ropes are used, the method is to unfray the strands and to bend them back upon themselves. This gives the end of the rope a bulging, conical shape, and it can then be slipped into a conical sleeve, or socket. The greater the stress on the rope, the more firmly is the end drawn into the socket, and this method of attachment has been found, generally speaking, very effective.

Just as the strength of a chain depends upon the strength of its weakest link, so, theoretically, the strength of a wire rope depends upon the strength of its weakest strand. In practice, however, the margin of strength—that is, the reserve resistance to breaking stresses over that which in practice the rope has habitually to endure—is such that it is permissible to have a few strands broken, provided the number does not exceed the percentage allowable for the particular type of rope used. The best ropes are of crucible steel wire, wound round a core of best manilla hemp, the winding being done in such a manner that the more tightly the rope is drawn, the more firmly do the strands of which it is composed interlock and become compacted. These ropes require liberal lubrication with carefully selected oils, free from acids which would cause corrosion and speedily ruin the rope. Ropes of this description have been used for many years past at Prizbram, where one of the shafts has reached the stupendous depth of 3,642 ft. These ropes have a tensile strength of 114 to 120 tons per square inch.

Safety Catches for Cages. When the cage has been raised to the pit-mouth it must be secured, so that all risk of its falling back in the shaft may be avoided. This is effected at many collieries by an automatic device called a *kep*, which practically consists of an iron or steel step, pivoted or hinged in such a manner that, although it can be lifted up by the passage of the rising cage, it cannot yield in the opposite direction unless deliberately liberated by a hand lever. Once the cage has passed it on the upward journey, it forms, therefore, a secure ledge, or step, upon which the cage can be brought to rest for the purpose of unloading.

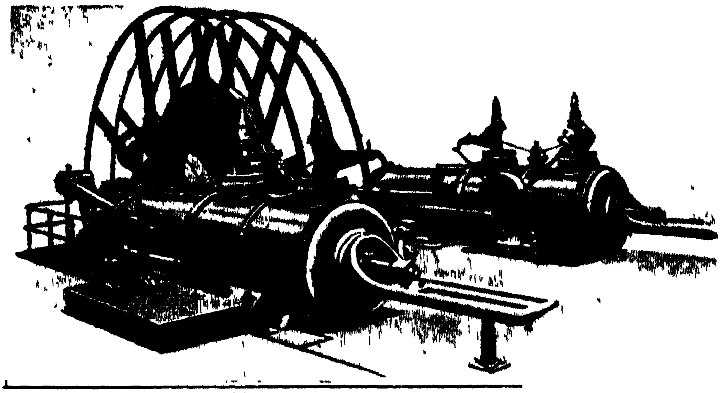
Needless to say that the number of devices which have been put forward for the above purpose is considerable, but most of them differ only in some slight detail from the foregoing, the principle of which is almost universally adopted. In "diggings" of a primitive nature, when both the men and the materials are raised and lowered by a bucket worked by a windlass, the simple expedient of placing a plank across the mouth of the shaft, once the bucket swings clear, answers the purpose admirably.

Human ingenuity has also been abundantly displayed in appliances for preventing "overwinding"—an accident of a very serious nature,



99. MINE SHAFT, HEAD GEAR AND GALLERY

as, in addition to the loss of life it may entail, the whole of the pit-frame may be almost irreparably damaged.



100. STEAM WINDING ENGINE

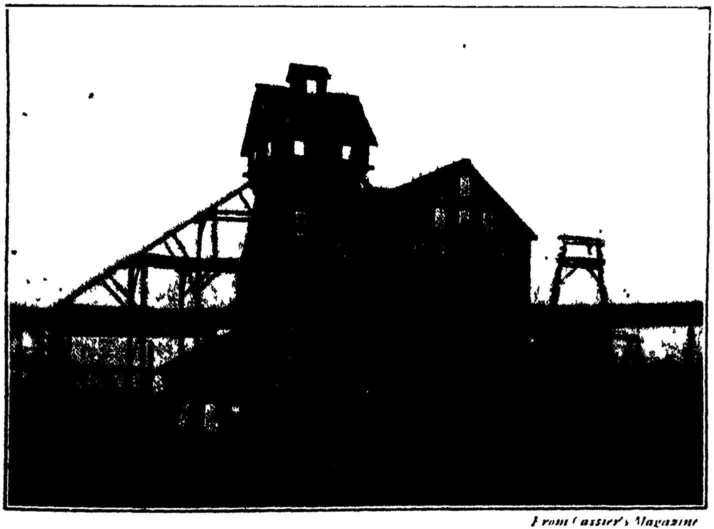
Winding Engines. A brief description of a large steam-engine recently exhibited at the International Exhibition at Liége will suffice to acquaint the reader with the size and power of the engines employed at the present time. The engine in question is shown in **100**. It has a drum 24 ft. in diameter, and is capable of raising nearly four tons of coal a distance of 1,300 yd. at a speed of 15 yd. to 20 yd. per second. With central condensation, and working under favourable circumstances, this engine will give results which, it is claimed, are not surpassed by those of any electrical installation extant. Of late years winding engines driven electrically have been adopted at most of the large collieries abroad, and are rapidly making progress in this country.

A point of great importance in winding is the position of the winding engine in relation to the pit-head gear. If too close, the inclination of the ropes may be such that the pull on the frame is too great, and it may be drawn backwards towards the engine. On the other hand, if the engine be too far away, the power is not applied to the best advantage, and serious waste ensues. The best authorities claim that the distance of the drum from the centre of the shaft should be from one, to one and a half times the height of the pit-head frame.

Pit-head Gear. Over the shaft is erected the pit-head gear and frame, which in its essentials practically amounts to a tripod, supporting at its apex the pulley over which the winding rope passes. Actually, the pit-head is a much more complicated device, and serves not only to support the pulley, but also to house tipples, chutes, and, at times, crushing plant to deal with the minerals raised. In **101** is shown the shaft rock house at the celebrated Tamarack copper-mine at Calumet, Michigan, U.S.A.

The cars have a capacity of about two and a half tons, and the rock is dumped into skips and raised to the surface, where there is a combined head-frame and crusher building in which the rock is crushed to a size of five or six inches. Fig **102** shows a typical pit-head frame at a large colliery, where the coal is raised and subsequently washed, screened, sorted, and run into waggons, which pass beneath the chutes with which it is provided.

Need for Ventilation. Proper ventilation is a matter of extreme importance in underground workings, particularly in coal mines, where the atmosphere is liable to become dangerously contaminated by noxious gases issuing from the coal-face and from blowers—that is, accumulations of fire-damp, under pressure.



From Cassier's Magazine

101. SHAFT ROCK HOUSE AT THE TAMARACK MINE, CALUMET, MICHIGAN

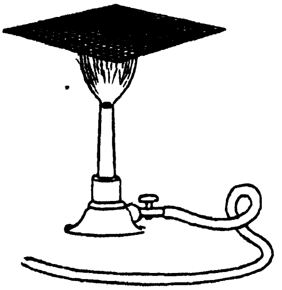
Gases in Mines. The principal gases found in mines are shown in the table on the next page which gives their chemical formulæ, popular names, and chief properties.

Black damp, or stythe, which is not enumerated in the table, as it is not a pure gas, but a mixture of gases, was formerly believed to consist of carbon dioxide. Recent researches have, however, shown it to contain 85 to 88 per cent. of nitrogen. It resembles carbon dioxide in its properties, and supports neither life nor combustion. Some of these gases are heavy and tend to collect in the lower workings of the mines. Others are lighter than air and collect near the roof. As these are generally explosive gases, their danger is increased, as they are more readily diffused. All the foregoing gases occur, more or less, in collieries, but they are also met with in metal mines and in nonmetallic mines other than coal mines. Thus, carbon dioxide is common in lead mines in Spain, France, and the United States. On the other hand, the gas sulphuretted hydrogen usually occurs in minute quantities only, in coal mines, where it is formed by the decomposition of pyrites in coal. In sulphur mines, on the other hand, it is frequently present in large quantities, and has been the cause of serious accidents in Sicily, and during the sinking of a shaft through the rock-salt beds of Strassfurt no less than fifteen fatal accidents occurred where persons were asphyxiated by sudden outbursts of the gas.

Chemical Name and Formula.	Popular Name.	Remarks.
Carbon monoxide, CO.	Carbonic oxide, or white damp	Very poisonous; explosive.
Carbon dioxide, CO_2.	Carbonic acid, or after damp, choke damp.	Poisonous, but non-explosive.
Methane, CH_4.	Marsh gas, carburetted hydrogen, or fire damp.	Highly inflammable.
Sulphuretted hydrogen, H_2S.	——	Highly inflammable and poisonous.
Nitrogen, N.	——	Inert.

102. COLLIERY PIT-HEAD GEAR

Dangerous Gases. Marsh gas and carbonic oxide are, however, the gases chiefly responsible for the disastrous explosions which occur from time to time, mostly in collieries. At the same time, the deaths which occur are usually due less to the explosions themselves than to the deadly *after damp* or *black damp* gases which are formed as the result of the explosion, and cause death by asphyxiation. Marsh gas has, however, been put to useful purposes before now, and, at the Eleonora pit, at Dombrau, in Austria, a large blower of the gas has been tapped and the gas employed to heat two steam boilers, with an annual saving of 600 tons of coal.



103. BUNSEN AND GAUZE, SHOWING PRINCIPLE OF DAVY SAFETY LAMP

While many mines are commendably free from gases, their presence in others is a standing menace to the miner. At the same time, it has been found that mine gases are not, by any means, the sole cause of explosions. The large amounts of coal dust present in the air of collieries also constitute a grave danger, and many explosions have been traced to this source.

In many collieries, water is sprinkled on the coal after it has been loaded into the tubs and the ways are carefully watered to help to allay the dust. But even this precaution may, in turn, constitute a fresh source of danger, as the warmth of the workings, combined with the moisture, is believed to create a highly favourable *nidus* for the propagation of the deadly *ankylostoma*, or miner's worm, the cause of a disease which has wrought much havoc in collieries in France, Germany and Belgium, but which, happily, has made very little progress in this country.

Ventilation in Mines and Collieries. The need of efficient ventilation will be obvious when it is remembered that, in addition to the necessity which exists for removing the dangerous gases naturally present in collieries and metal mines, the atmosphere is rendered foul by the fumes given off by blasting operations and "shot firing," and by the emanations from men and animals working in a confined space for long hours.

In quarries and opencast workings ventilation is, obviously, easily effected, but it is otherwise, with workings situated at great depths from the surface.

Ventilation is usually carried out by one of the three following methods: natural ventilation, furnace ventilation, and fan ventilation. Natural ventilation depends upon the presence of two shafts at least, of different depths, and

104. SURFACE WORKS, FERREIRA DEEP MINE, TRANSVAAL

containing, therefore, columns of air of different weights and pressures. Whenever these conditions are satisfied, the heavier column overbalances the lighter column and a system of air circulation is established. Natural ventilation is, however, subject to some uncertainty in operation, and to the great disadvantage that circumstances may, at times, lead to a total reversal of the direction of circulation, an occurrence which may be fraught with serious consequences. In practice, it is rarely depended upon alone, but is supplemented by a system of furnace ventilation, by which the air in what is called the *upcast* shaft is heated, and thereby rendered permanently lighter, thus ensuring a constant draught in the same direction. This system has, however, been almost entirely superseded by fan ventilation.

Ventilation by Fans. Ventilation by fans may be either by exhaustion or by compression—that is, the fan may be used to withdraw the foul air, or to drive in a supply of fresh air. In practice, fans are usually placed at the top of the up-cast shaft and used to exhaust the air by suction. These fans work on what is known as the centrifugal principle, and as they differ but little in essentials from those used to secure ventilation in large buildings, it will not be needful to do more than to point out that, naturally, they are much larger and more powerful. The chief types used are the "Guibal," "Waddle," "Schiele," "Cappell," "Walker," and "Rateau" fans. The speed at which such fans are run varies from 40 revolutions per minute to 500. They are, at the present day, frequently driven by electricity, and their diameter often exceeds 30 ft.

Lighting. The method of lighting mine workings is closely associated with the occurrence of fiery gases in mines, as, upon their absence depends the possibility of working with naked lights, while their presence necessitates the use of lamps specially designed to prevent the ignition of the explosive gases. Thus, in many parts of the world, and at many of the iron ore mines in this country, candles are used. They are stuck into a piece of clay which, by its plasticity, can very readily be put down anywhere convenient, adapting itself to the circumstances in a way which no more rigid form of holder could possibly do. At other mines oil lamps are freely used. For the most part, however, safety lamps have to be employed.

Theory of Safety Lamps. Before an explosive gas can be ignited it, or some part of it, must be raised to the requisite temperature, as otherwise the chemical forces upon which ignition depends do not come into play. It was found by Sir Humphry Davy that, if a piece of wire gauze be placed across a flame, the unconsumed gas issuing through the gauze cannot be ignited by the flame beneath, but requires an extraneous source of heat to ignite it. The illustration given [108] will make this clear. What really happens is that the strands of wire in the wire gauze are such excellent heat conductors that they carry off the heat of the flame too rapidly for it to be imparted to the gas on the other side to raise it to a temperature sufficient to ignite it. The Davy safety lamp, the prototype of numerous modifications since invented, depends upon this fact for its safety.

Preparation for the Market. While the operation of mining ends with the delivery of the minerals at the pit or shaft head, it is but seldom that such minerals can be directly employed in industry. In practice they have usually to be subjected to a series of operations which, as they are usually carried out at a mine or colliery from which the material has been won, may legitimately be regarded as the final stages of mining.

The chief reason for treating the minerals in the immediate vicinity of their source of extraction is to avoid the expense which would be entailed in transporting the dirt and dross with which they are almost inevitably associated —in other words, to obviate freight and carriage charges upon unremunerative tonnage. Even coal, which of all minerals is usually in the condition most suitable for immediate consumption, generally requires some degree of preparation before consignment to its destination.

105. HEAP ROASTING OF COPPER ORE *From Cassier's Magazine*

Screening Coal. With coal, the value of the marketable product depends largely upon size. On reaching the pit mouth it is therefore subjected to a series of operations which include screening, picking, sorting, and washing.

Screening is carried out by tipping the coal either on to inclined screens, set at an angle of about 30°, or into revolving or shaking screens. The size of mesh employed depends upon a variety of circumstances — for instance, the hardness of the coal, its ultimate uses, etc. At most large collieries *jigging* or shaking screens are employed, the movement imparted to such screens being comparatively gentle and regular so as to avoid breaking the coal too much in the process.

Coal Washing. Small coal intermixed with a large proportion of dirt is usually *washed*. In this process advantage is taken of the difference in density between the coal and its associated impurities. The principle employed is agitation with water, whereby the coal, being lighter, is carried away, while the heavier impurities collect at the bottom of the appliances used. There are a large number of coal washers on the market, the best known being the Murton, and the Wood and Burnett washers, which have movable troughs; the Luhrig, Coppée and Robinson washers, which depend upon the action of ascending currents of water; the Elliot washer, which is provided with movable scrapers operating in a fixed trough, and the Baum washer, which is practically a large vat into the water of which compressed air is admitted, causing considerable agitation of the water and effecting a very complete degree of separation by this means.

Coal washing effects a considerable reduction in the ash of the coal treated, and also serves to remove a proportion of the associated sulphur compounds which are a source of grave inconvenience in most of the subsequent uses to which the coal may be applied.

Gold Washing. It will have been seen that this process of washing tends to *concentrate* the material—that is, the finished product is richer in the required mineral than it was before. This principle is applied to an even greater extent in gold mining, particularly in alluvial workings where the prospector's pan, described on page 2380, is further developed into the *batea*, a conical vessel in which the heavier gold collects at the bottom, while the dirt flows out with the water at the top. At some gold mines, notably in Australia, the contents of a large pit are agitated with water by means of a series of revolving blades. This principle is also employed at the Kimberley diamond mines to separate the mud and clay from the gravel with which the diamonds are associated.

Crushing. While it is usually desired to keep coal in large lumps, it is sometimes crushed preparatory to coking in the coke ovens. The crushing of minerals finds its most interesting exemplification, however, at gold mines, where the gold is derived from quartz, which requires to be reduced to a fine powder preparatory to *leaching*—that is, treating with chemical solutions which dissolve out the gold, leaving the quartz behind.

On the Rand, the ore mined is a hard, splintery rock known as *banket*, or *almond rock*, a siliceous quartz conglomerate, consisting of bluish-grey quartz pebbles embedded in a quartzose matrix. This quartz has to be treated in stamp batteries, which consist of hammers shod with specially hard steel, such as chrome steel, or manganese steel. These hammers work vertically by means of a tappet, or collar, fixed near the top end of the rod to which the shoe is attached. This tappet is raised by a revolving lifter, furnished with a cam which, on rotating, engages with the lower surface of the tappet, raises it a few inches, and ultimately clears it, allowing it to fall. A number of these vertical hammers disposed side by side, having their tappets actuated by cams projecting from a common shaft which revolves continuously, constitute a stamp battery. The weight of each stamp—rod, head and shoe, and tappet—averages about half a ton, and the number of falls per minute, regulated by the hardness of the quartz, averages from 60 to 100 per minute.

Stamping is carried on either wet or dry. In the latter case the fine dust is liable to be carried about in all directions, and to become deposited on the working portions of the stamps with serious results, although the leaching is more rapidly effected with dry stamped ore. The usual practice in South Africa, New Zealand, America and Australia, is wet crushing. As its name implies, the ore is mixed with water in the mortar box, into which the stamp falls.

Leaching. Leaching is a process whereby the materials from which it is desired to extract some valuable constituent are treated, in a vat, with some liquid which dissolves the required constituent. Thus, in alkali manufacture, the salt "cake" is leached with water, which dissolves the soda salts, leaving the associated silicious matters, fuel, etc, untouched. In gold mining the fine ore from the stamps, which is known as *tailings*, is leached with a solution of cyanide of potassium, which dissolves the particles of gold—and silver, when this metal is present—and leaves the quartz slime behind after filtering. Fig. 104 shows the surface workings of the plant at Ferreira Deep, with the large tailings wheel on the right.

The dissolved gold is subsequently precipitated on zinc plates, or zinc turnings, zinc having a chemical affinity which causes it to withdraw gold from solution and to take its place. The zinc remaining is ultimately driven off by heat, leaving the gold, in the form of crude bullion, behind.

Roasting Ores ; Calcination. Some minerals, when delivered at the surface, are associated with substances which can be driven off by heat. In other cases, the application of heat may cause certain chemical reactions to occur which have the effect of rendering the mineral more readily reducible in the subsequent smelting operations to which it is usually subjected.

The ore may be roasted in heaps, or calcined in kilns. Sometimes the heat is derived from combustible materials associated with the ore as extracted, the combustion of which produces sufficient heat to effect the necessary changes in the mass. With other ores, fuel must be added before combustion can be effected. The best example of ores of the first class is afforded by blackband ironstone, which contains enough carbonaceous material to burn without any added material. In Scotland and in North Staffordshire, where this ore occurs, huge heaps may be seen roasting in the vicinity of the mines. Such ores may lose as much as 50 per cent. of their original weight, and the iron they contain will be in a more fully oxidised condition. Where the addition of fuel is necessary, the preparation of the ores is more economically carried out in kilns. In the Cleveland district, the kiln adopted is that of Gjers, the capacity being from 400 to 700 tons at a time, and even more. The waste heat from the blast furnaces is also employed for the purpose of calcining the ores. The ores of many other metals also require roasting preparatory to their use, while in the case of non-metallic minerals numerous examples might be adduced. Thus limestone, or calcium carbonate, is roasted in kilns to drive off the carbon dioxide, for the production of lime, and in cement manufacture. Fig. 105 shows the roasting of copper ores in heaps at Jerome, Arizona.

Weathering. In a number of instances materials require to be exposed to the action of atmospheric agents before they are fit for use. Into the process of weathering several factors enter. Thus, the mineral heaps become permeated with moisture in wet weather, and in the succeeding cold seasons the moisture freezes, and by its expansion induces disintegration of the masses.

The diamond-bearing rocks of the Kimberley district are weathered on a large scale, the rock being spread over areas extending thousands of acres. From time to time the masses are ploughed up and fresh portions exposed to the atmosphere, the weathering rendering the subsequent operations for the recovery of the diamonds much easier and cheaper. Clay also requires careful weathering and ripening, its physical properties being greatly improved, and its plasticity increased. It may incidentally be mentioned that the existence of clay itself depends upon the weathering, during long ages, of granite. The silicates of alumina, which enter into the composition of one of the chief constituents of granite, become separated from the quartz and mica with which they are associated, and being lighter, are deposited by the action of water in beds. The kaolin of Devonshire, from which the best descriptions of china and porcelain are made, has had its source in the cycle of operations included under the term weathering.

GEOGRAPHICAL DISTRIBUTION OF MINERALS

The following notes as to the distribution of the chief ores and minerals, arranged under the headings of the countries in which they occur, may prove of interest. It must be borne in mind, however, that the *venue* is frequently changed, and that the country which at one period is "booming" as, say, a gold country, may at almost any period be displaced by a "rush" to some other district from which prospectors may bring the news of important finds.

Great Britain and Ireland. Our own country owes its predominant commercial prosperity as much to its mineral wealth as to its geographical situation. Celebrated in the early dawn of its history as the source of tin ores, its coal, iron, copper, lead, zinc and salt mines have also contributed to its industrial development in later days. The Welsh steam coal is unexcelled for marine purposes. Unfortunately the iron ore mines upon which the prosperity of this country is largely dependent are approaching exhaustion, and the supplies for the ironworks have to be drawn from abroad, notably from Spain and from Sweden, supplemented by ores from the European mainland, from Greece, and even from Russia. Gold is found in North Wales, but in commercially insignificant quantities.

Other European Countries. France, Germany and Russia possess much mineral wealth, coal and iron predominating. Southern Russia and the hinterland between Europe and Asia is rich in petroleum, Baku being the centre of the oil industry. Sodium and potassium salts are found in Germany and Poland, while Austria-Hungary produces quicksilver, which is also found in Spain. Iron ore is found in Sweden, where it is smelted with charcoal, producing iron of great purity and excellence. Manganese ores are found in Russia, Greece and Turkey, while copper is mined in Spain and Portugal, and traces of ancient workings for the extraction of copper ores are found in Greece. Gold is found in Italy, the chief mineral wealth of which is, however, sulphur.

Asia. The mineral wealth of Asia is not fully known. Gold is found in Hindostan and elsewhere, while platinum is found in Siberia. Persia possesses coal and petroleum. China is a very rich country, and contains ores of nearly all the commercially valuable metals and minerals. Japan is rich in coal and iron. Diamonds, sapphires and rubies are found in Hindostan and in Upper Burmah. Petroleum is also found in Burmah, and in many of the larger islands of the Eastern Archipelago.

Africa. The gold mines of the Rand are justly celebrated; while the Niger States possess valuable deposits of alluvial gold which have not, as yet, been fully developed. Namaqualand is rich in copper ores, and Natal has abundant supplies of coal, a mineral in which the Transvaal is somewhat deficient. Diamonds are found at Kimberley and elsewhere. Algeria possesses mines of lead, zinc, antimony and copper.

America. Canada possesses an abundance of valuable minerals, including gold at Klondyke and in Nova Scotia and Columbia, silver, in the Lake Superior district, iron ores in various localities, coal, petroleum, and lastly, but not least, nickel, which is found at Sudbury, in Ontario. The mineral wealth of the United States is enormous. It is the chief iron ore producing country in the world, and its output of coal, petroleum and natural gas is likewise on a gigantic scale. The United States also produces a quantity of copper, lead and quicksilver, while gold is mined in Colorado, California, Nevada, Utah, Montana and Arizona. Silver is found in Colorado, and several of the other Western States, and copper abounds in the Lake Superior district. In South America the silver mines of Potosi are celebrated, while the nitrate beds of Chili are the most extensive in the world. Gold and diamonds are found in Brazil, and emeralds in Peru.

Australia and Oceania. Australia and Tasmania are rich in tin ores, while gold is found scattered throughout Australia, and in New Zealand. Coal is found in New South Wales. In Oceania the island of New Caledonia is justly celebrated for its mineral wealth, being rich in nickel, molybdenum, and chrome ores.

Ore Handling. Only a passing mention can be made of the marvellous advances which have taken place in the methods of transporting minerals. The most striking instances are the aerial ropeways by means of which enormous tonnages are cheaply and expeditiously conveyed from place to place, and the wonderful ore handling appliances in the Lake Superior district in America. There the ore is handled by gigantic machines, which feed it into the ore steamers which ply between the mines and the chief ore docks situated on the lakes. The capacity of these steamers is very great, and the limit would not, even yet, appear to have been reached, notwithstanding the fact that the Elbert H. Gary, a steamer belonging to the famous Steel Corporation, has recently broken all records by conveying a cargo of 12,328 tons of ore from Escanaba to South Chicago. For unloading these cargoes, Hulett automatic machines are installed, and one of these, at Lorrain, Ohio, recently achieved the wonderful task of unloading 681 tons in an hour. The speed and economy of these machines may be gauged by the fact that the cost of unloading has been reduced to 1 cent. (½d.) per ton. Indeed, the records of the Old World are fast being broken by those of the New World, and the student of mining fixes his eyes on the shores from which the Atlantic separates, in name only, the Mother Country, and views with admiration and surprise the striking progress which the adoption of scientific methods has enabled to be made in the Greater Britain beyond the seas, whose sons are the inheritors of the glorious mining traditions of the old country in that New Land whose resources so vastly surpass those of our own.

Bibliography. Students who wish to pursue the study of mining into greater detail than this course has provided will find no lack of reliable textbooks on the subject. Messrs. Charles Griffin & Co. publish several good handbooks, among which we may mention "Prospecting for Minerals," by S Herbert Cox, (5s.); "Ore and Stone Mining," by Sir C. le Neve Foster (34s.); "Elements of Mining and Quarrying," by the same author (7s. 6d.); "Coal Mining," by Herbert William Hughes (24s.); "Mine Surveying," by Bennett H. Brough (7s. 6d.); "Getting Gold," by J. C. F. Johnson (3s. 6d.); "Mine Accounts and Mine Bookkeeping," by James Gunson Lawn (10s. 6d.); and "The Investigation of Mine Air," by Sir Clement Foster (6s.). Books by other publishers include "British Mining," by R. Hunt (Lockwood. 42s.); "Economic Mining," by C. W. Lock (Spon. 21s.); "Colliery Working and Management" (Lockwood. 15s.); and "Rock Blasting," by G. G. André (Spon. 5s.).

VEHICLE CONSTRUCTION
continued from
page 3624

By H. J. BUTLER

IN the cycle factories of Coventry and Birmingham we have instances where the machine is built throughout, even including the tyres. now that various patents have lapsed; but usually, although completed machines leave the works, outside firms are depended on for such items as tubing, chains, balls, saddles, etc. Another class of factory is that where components or parts are made as well as completed frames. These are sold to dealers who assemble the different fittings together into the complete article. This *assembling* forms a large branch of the trade, and will be the form of manufacture most likely to interest the reader as being one he may himself adopt.

The Cycle and its Parts. Our bicycle of to-day consists of two wheels placed one before the other, mounted in a frame of steel tubing which carries the means for propulsion, seating, and steering. Three types of frame are illustrated—**60**, a road racing frame; **61**, lady's frame; and **62**, a tandem frame with rear seat for lady.

The frame consists of the following parts:

(*a*) The *top tube*. The horizontal member running from the seat to the steering.

(*b*) The *head*. The short member which receives the stem of the front forks.

(*c*) The *bottom tube*, running obliquely from the head to the bottom bracket.

(*d*) The *seat*, or *down tube*, running from the bottom bracket to the seat.

(*e*) The *back forks*, or *stays*, connecting the seat with the hind wheel hub.

(*f*) The *chain stays*, connecting the bottom bracket with the hind wheel hub.

(*g*) The *front forks*, the stem of which turns within the head tube (*b*).

The Frame of Ladies' Bicycles. The difference in dress necessitates a modification of the top tube [**61**]. This member, in the generality of machines, runs from the top of the head and sweeps downwards to a point just above the bottom bracket. Often it is connected by a stay to the bottom tube.

The Frame Lugs. The frame tubes are joined together by means of socket-shaped pieces called *lugs*, the junction being effected by brazing and internally strengthened by pieces called liners.

The lugs in a standard pattern frame are:

(*a*) The *top head lug*, joining the head and top tubes.

(*b*) The *bottom head lug*, joining the head and bottom tubes.

(*c*) The *seat lug*, joining the top and down tubes and provided with means of attaching the back forks, and split for adjusting the seat pillar which carries the saddle.

(*d*) The *bottom*, or *crank bracket*. This is provided with sockets for taking the down tube, bottom tube, and the two chain stays, as well as receiving the axle to which the pedals and their cranks are fastened.

(*e* and *f*) The two *chain stays* and the two *back forks* are generally connected together—sufficiently beyond the wheel to give a safe clearance—by a bridge in each case.

(*g*) The *back forks ends* may be brazed to the lower ends of the forks, but in many patterns both ends of the back forks are fixed by a bolt passing through them. A slot is provided for receiving the hind wheel axle.

(*h*) The two *front forks* are connected by a crown which also receives the fork stem.

In a flush-jointed frame the above lugs are placed inside the frame tubes instead of the usual practice of placing them outside. A lug usually connects the handlebars with the handlebar stem and another connects the two portions of the seat pillar.

The Head. The head tube receives within it the stem of the front forks, and, again, inside the front fork stem we place from above the stem of the handle bars. These two stems are held tightly together by a clip immediately above the top head lug. The clip is provided with a bolt and nut, while the fork stem is split for a couple of inches at the back to allow of adjustment. A nut is also provided to prevent vertical play. It is usual to provide a steering lock, whereby the turning of the front wheel is arrested This prevents damage when leaving the machine against a wall or curb.

There are numerous shapes of handlebars [**63**] brazed through the lug on top of the stem, and they are made to suit every taste. From the racing pattern, allowing of a low grasp placed forward, are intermediate patterns until we arrive at the full upturned lady's pattern which brings the hands above and behind the top of the head tube.

The Driving Gear. The modern bicycle is *rear-driven*—that is, the motion is transmitted through the hind wheel. By pressing down alternately on the pedals the cranks are rotated with their connecting axle which sets in motion the bracket chain wheel and, likewise, by means of the chain, the hub chain wheel.

The Cranks. The cranks receive at their lower ends the axle of the pedals. The latter may simply screw into the cranks. Care should be taken to see that a left and right handed thread is provided respectively, as although the pedals rotate round their own axle in the same direction, yet they are on opposite sides of the cranks, and the tendency will be, if opposite threads are not provided, for one of the pedals

to work loose. The inner end of the crank is swolled out and pierced to receive the crank axle. A common method of fixing is by a tapering cotter pin which drives into a similar shaped keyway. Both have a flat side to prevent working loose. The cotter pin is pulled up tight by a small nut.

The Throw of Cranks. The length from crank axle centre to pedal axle centre is called the *throw*. Usually 7 in. will be found suitable for a rider with normal length of leg. Increase of this means greater leverage, but the feet have to move through a larger circumference, thereby speed is lost. For tall riders using a high gear, 7½ in. is often used, and ladies find comfort when the throw is not more than 6½ in.

The Chain and Chain Wheels. The power is not merely transmitted from one chain wheel to the other, but by the relationship as regards the number of teeth on each wheel, the number of revolutions of the hind wheel are greater than the revolutions of the cranks. If there are 16 teeth on the bracket chain wheel and 8 on the hub chain wheel, the hind wheel will revolve twice as often as the cranks.

The Gear. The gear of a bicycle is calculated in inches, and represents the diameter of the wheel that would be necessary to ensure the same rate of speed if the cranks were connected directly to the driving wheel hub. Thus, if we have 16 teeth in front and 8 at the back, together with a 28 in. wheel, we call the gear "56 in.," which is arrived at by dividing the number of teeth on the hub chain wheel into the number on the bracket chain wheel and multiplying by the diameter of the driving wheel. By multiplying again by 3⅐ we get, approximately, the distance which the machine travels at one complete revolution of the cranks.

The Chain Line. It is absolutely necessary that the chain should run over the teeth on the chain wheels centrally, without any undue friction on either side. This is attained by a correct chain line, and is calculated at two points [see **64**].

1. From a line passing transversely through the centre of the back hub to a line passing through the centre of the chain wheel teeth.
2. From a line passing transversely through the centre of the crank bracket to the centre of the chain wheel teeth.

Both these measurements should be exactly the same, thereby ensuring that the two chain wheels will revolve exactly in the same line in the same way that the two road wheels should do. This chain line varies from 1⅜ in. in racers, to 1¾ in. in roadsters with gear cases.

The Bracket Chain Wheel. The chain wheel is usually fixed by screwing it on to the inside of the crank boss, and the outer ring carrying the teeth can be made detachable, so that the gear may be increased or decreased by adding another ring of teeth.

The Hub Chain Wheel. This is screwed on to the back hub and rotated with it in the patterns of the last few years, but now, owing to the almost universal adoption of the free wheel, it forms part of the free wheel hub, and by means of either roller friction or a pawl the hub can rotate while the chain, cranks, etc., are at rest. The hub chain wheel should be of a sufficient circumference to accommodate not fewer than eight teeth. The larger this wheel the further from the centre lies the chain, consequently meaning greater leverage; also, the chain is not unduly curved. But we must limit the size of this chain wheel, as the larger this wheel is, the larger must our bracket chain wheel be in order to obtain the same gear.

The Chain. The chain may either be a series of solid blocks connected to side links by means of pins allowing of free movement as the links run round the chain wheels, or the side links may be connected by pins which pass through rotating rollers. The first type of chain is known as the *block* chain, and now finds little favour; the second is the much used *roller* chain, in which we have the advantage of rolling over sliding friction. The links are formed into an endless chain, by means of a bolt and nut which takes the place of one of the pins.

Pitch of Chain. The pitch is measured from the centre of one pin to the centre of the next—usually it is ½ in.

Adjustment of the Chain. The chain when properly adjusted should show a very slight departure from the straight line. A loose chain may mount the chain wheel and cause disaster. The slot in the back fork ends allows of the hind wheel being pulled further away from the crank bracket. This is done by turning a nut at the end of the slot. Care must be taken to perform the operation equally on both fork ends, otherwise the alignment of the hind wheel may be destroyed.

Free Wheels. The roller type of free wheel is almost obsolete. When the chain ring is turning, a series of rollers are drawn by friction against the ring up inclined planes, and are jammed between the clutch and the ring, thus taking the hub, and consequently the road wheel with it. When free wheeling takes place, the rollers are released together with the contact between the chain ring and the free-wheel clutch.

In the ratchet free wheel the chain wheel is fitted internally as a ratchet wheel, while pawls are connected to the clutch. When the chain ring is revolving the pawls slip past, but when it is stopped either the pawls are free to drop by themselves, or they are forced home to their work by small coiled springs. These are various modifications of this main principle which are the subject of patents.

Pedal and Other Brakes. A back-pedalling brake is one in which retarding action is effected usually within the back hub by means of one cone wedging itself into another when pressure is exerted in the opposite direction to the usual pedalling force. Another variety of the same type of brake is in the form of a rim brake. This is brought into play by means of a tension rod connected with the crank bracket. Rim brakes are the type that have been adopted largely. Pressure is applied either by a system of levers and connecting rods, or by a Bowden wire, the power being applied by a small lever.

Variable Gears. Means are sometimes provided within the back hub whereby the gear may be altered at will. It is advantageous to lower the gearing when going up hill, and on a good level road one naturally wishes to increase the rate of speed. This may be effected when variable gear is fitted by merely pulling a lever and yet maintaining the same rate of crank rotation, although, of course, more power will be necessary for the higher gear. There are two and three-speed hubs, and usually on one gear (the high) the whole hub runs solid. The intermeshing of toothed wheels of varying numbers of teeth ensures different rates of speed in the same way as with the chain and its wheels. The modern gears are also fitted to allow of free wheeling.

The Tubing. The frame is composed of weldless steel tubing [65], which implies that it is not merely sheet metal welded to form a pipe, but is worked up from the solid. Usually the section of the tubing is circular [65 E], and varying in gauges according to the strength necessary, but the back forks and chain stays are usually of D section [65 C], while the front forks are oval [65 D]. Not only does the gauge vary, but in the same tube we may find the thickness increasing at the end. This is butted tubing, and when reinforced at both ends we have a *double-butted tube* [65 A], the type used in the best machines. Taper gauge tube [65 B] is often the material used in the front forks [66 and 67], the greatest strength being at the crown. Butted tubing obviates the necessity for using liners.

Wheels. The wheels consist of wire spokes inserted in metal or sometimes wooden rims, on which are placed the pneumatic tyres. Equal sized wheels allow of interchangeability of tyres, which is an advantage, as the wear on the back tyre is greater. Therefore, after a bicycle has run a considerable distance, the tyres may be exchanged. Wheels of 28 in. diameter are usual.

Spokes. Spokes are generally tangential to the hub, the direct-spoked wheel being out of date. Spokes may be the same gauge throughout or single and double butted. They are made stouter at the ends where the strength is necessary; the centre is lighter, and gives less air resistance. The spoke is prevented from passing through the hub flange by its head, and is attached, and its tension is regulated, by the thread and nipple and washer at the rim.

Rims. Steel rims are either hollow or solid, and are adapted for the different brands of tyres. A rim joint, when placed exactly opposite the tyre valve, can be made to balance it, and such a rim can be manufactured without heat.

Tyres. The pneumatic tyre consists of three portions: (*a*) The inner tube, made of rubber, lightly vulcanised and provided with a valve

whereby the tyre may be inflated and retain the air pumped in—this valve passes through the other portions of the tyre and the rim ; (*b*) the fabric on which (*c*) the outer vulcanised cover is mounted. These last two portions are solutioned together. Single-tube tyres have no distinct inner tube.

The tread of the outer cover varies from the mere strip of the racing tyre to the heavy tread of the roadster. Tyres may be retained by wires or by a beaded edge.

Building the Wheels. The number of spokes in a rear wheel is usually 40, while 32 suffices for the front wheel. There are mechanical contrivances for spacing the spoke holes in a rim, or they may be taken off from a spacing board or from an old wheel. The holes are then drilled, the delicate rim being properly supported, and the burr round the holes removed with a half-round file. The spokes are cut off to correct length. This is found by laying the rim on a level surface, and supporting the hub in its centre at its proper height, and then taking the required length.

Spacing the Front Spokes. The spokes are built into the wheel in the following manner. For a 32-spoke wheel mark two holes in the rim, leaving nine apart. Thread the ends of four spokes, and try them in position. Screw up the nipples till the hub is held exactly in the centre of the rim. Here we shall be able to see if we have measured with precision, for the spoke should not project beyond the rim ; also, if threaded for the proper length, no threads will show beyond the nipple. If any alteration is necessary, we shall be able to make it in the remaining spokes Sixteen spokes proceed from one side of the hub to the rim. At the rim the spoke heads are alternately inside and outside the hub flange. An equal number proceeds from the other flange in like manner, both sets spacing themselves on the rim alternately. After the first four spokes have been inserted, another four are fixed, leaving the same space apart as before, and so on till the wheel is built.

Spacing the Hind Spokes. The 40 spokes for this wheel are first spaced by placing two spokes in the hub flange six holes apart, one with head inside and the other outside ; the spokes are crossed, and reach the rim one hole apart. Miss two holes in the hub flange below each of the first spokes, and repeat the operation as before. The fifth spoke leaves the hub with one hole between it and the next, and runs in the same direction as the spoke from which it was spaced on the hub, and proceeds to the rim, entering the same three holes from its fellow. Complete the whole of one side first by putting 10 spokes in one direction. The remaining eight spokes running from the same hub flange are placed in the opposite direction, and crossed as before mentioned. The other hub flange, with its 16 spokes, is similarly treated.

Wheel Truth. The wheels are trued by the careful tightening or slackening of the nipples. Not only have we to see that the rim is equidistant all round its circumference from the centre, but that its two faces lie in parallel planes. To cure a defect in circularity the spoke at the fault and directly opposite is adjusted.

Frame Building. We shall suppose that an outline drawing of the frame has been made, preferably on a sheet of metal, so as to test the true relationship of the parts while hot, and in order that we may know the exact length of the tubes before brazing in the lugs.

The Components. Before constructing the frame we shall need, beside our lengths of tubing, a set of components which are as follows:

1. The front wheel hub.
2. The back wheel hub, with chain-wheel.
3. The crank bracket, with cranks, axle and chain-wheel.
4. The head tube, with its top and bottom lugs and ball races; front fork crown, lamp bracket, etc.
5. Pair of pedals.
6. Chain stay bridge.
7. Chain stay ends.
8. Back fork bridge.
9. Back fork eyes.
10. Seat lug.

These and the other numerous parts of a modern bicycle are illustrated in **69** and **70**. We have selected the parts of a Rudge-Whitworth bicycle as typical.

Chain Stays. The chain stays are cut to length, so that with the short bridge tubes (those running from the bridge to the crank bracket) and the bridge in position we shall have not less than ¾ in. between the tyre and the inside of the bridge, the back wheel spindle being at the commencement of the slot. The chain stay ends are brazed to the chain stays, and the short bridge tubes are brazed to the bridge lugs.

Back Forks. The seat lug, or back fork eyes are then fitted to the back forks, and brazed.

The chain stays, with their brazed-in ends are tried to the back wheel and spindle to see that the stay end faces are parallel, and that the stay lines correctly each side of the wheel. But only the *trying* should be conducted with the wheel in position, as any attempt to adjust any error will injure the parts. The necessary alterations should be made at the bench, and it is a safe rule to remember that a tube must be gripped or a blow given by something softer in nature than the part undergoing the operation. Tube clamps are therefore constructed of hard wood, and a wooden mallet must be used in most cases.

Fitting up the Frame. The bottom head lug has the head and bottom tubes fitted to it, and as the bottom tube butts right on to the head tube inside the lug, a piece must be hollowed out to allow of the two tubes being brought close together. We next place in position the top head lug and into it fit the top tube, hollowing out the latter in the same manner as the bottom tube. Knock on the crank bracket, and into it the seat tube; lastly, fit the seat lug in position, hollowing out having been performed at the end of the top tube, where it touches the seat tube and the end of the bottom tube to miss the end of the seat tube. Therefore both bottom and top tubes are hollowed at each end.

The Use of the Mandrel. If a tube be too small for its lug we force the tube gradually on to a mandrel held in the vice. The tube should be revolved as it is knocked forwards in order that the enlargement required may be performed equally all round. A caulking chisel is also used to ensure that the lug shall fit absolutely all round its tube.

Brazing. Being quite sure that the frame follows accurately the drawing as regards every measurement, and that the various angles formed by the tubes with one another are as drawn, we may proceed to braze the frame together. Brazing is a process effected by means of an internal charge of brass or spelter and borax. During the heating, brazing pegs are inserted at the joints. Parts, such as threads, where it is necessary that the brazing mixture should not run, are coated with blacklead. Care must be taken not to burn or overheat the tube. Where the tube has not an outlet, a tiny hole must be punched to allow of the escape of heated air. Brazing is also effected by steeping the specially prepared frame in a vat of molten brass.

Completing the Chain Stays. The bridge with its short tubes and the two stays with their ends are first fitted and then brazed together with the back wheel spindle in position to give them their proper relationship, after which they are united to the proper lugs on the bottom or crank bracket. While brazing the stays into the crank bracket we must tie the frame from the spindle to the seat lug. If the back stays are of the detachable variety, it will be convenient to bolt one in position.

Testing the Chain Line. Clean out the crank bracket, and place the cups and spindle in position, and fit on the bracket chain wheel. Then, place the hind wheel in position with its chain wheel, and place a straightedge along the faces of each of the chain wheels.

Building the Front Forks. The fork ends may be either slotted or drilled for the front wheel spindle; the former method is best, as it prevents *springing* in the spindle. Clean out the slots or holes and braze on the ends. Having allowed for the ⅜ in. clearance, as in the chain stays, for the wheel, braze on the fork crown. The fork stem is then brazed to the crown. Care should be taken that each fork blade is exactly the same length, that the side clearance from the rim is the same, and that it unites with the stem exactly as marked out on the drawing. The side and front view of a complete pair of front forks is shown in 66 and 67.

Handlebars. The handlebars may be fitted to the handlebar stem by a lap joint or a lug. The lap joint is merely wrapped round the centre of the bar and brazed; but with the lug we have a strong and neat fixing such as is used in the frame proper.

The Seat Pillar. The seat pillar has an alternative fixing, as the handlebars, and we must be careful to see that it forms a similar angle to that formed by the top and down tubes.

Testing the Frame. Too much attention cannot be given to making absolutely sure that the frame is true. It must follow the drawing in every detail, all lengths, overall length and angles being as set out. The wheels are correct before mounting in the frame; and we must test our work to see that they are centrally placed. Another important matter is that the centre line of each of the tubes lies in the same plane. A straightedge placed on the face of the bottom bracket at one end should be parallel to the edge of the tube up which it is placed, the space between the straightedge and tube being tried by a pair of inside callipers. After the testing has been completed and the frame found correct, it is filed up and cleaned with emery.

Plating and Enamelling. The parts usually plated are the handlebars, seat-pillar, front fork crown, fork tips, chain wheel, cranks, pedals, spokes, wheel rims, and all nuts. Plated parts are finished with the polisher's bob, so that except in corners where the bob could not reach we need not trouble about much high finish

Enamelled parts must be carefully finished with emery, and the better the surface the better finish will the enameller be enabled to produce. Being quite sure that the parts are free from grease, the tubes are given a coat of enamel, either by dipping or by hand. The surplus having been removed, the frame is hung up in an oven and subjected to a temperature of about 350° for a couple of hours. This coat is flatted with pumice dust and the enamelling and heating repeated A third coat gives a better finish.

Assembling the Finished Parts. We first proceed to fit up the bottom bracket, taking care to protect the freshly-enamelled frame. When the cones, balls and axle are in position we proceed to fit on the cranks, driving up the cotter pins securing them with the nut provided for the purpose. The head is then fitted up with the balls in their respective races, and the handlebar clip, lamp-bracket, and lock nut placed in position. The wheels are then put in, care being taken before final adjustment to see that they track. A properly fitting chain allows about ¼ in. play of the cranks. Then we fix on the mudguards and brake, of whatever pattern used, the seat pillar with its saddle, and, lastly, the gear case if used; and if a lady's machine, a dress guard.

Bearings. One of the most important factors in deciding the sweet running of a cycle is the design of the bearings and their lubrication. A bearing is to be found wherever movement occurs, such as the wheel, crank and pedal axles, and for many years past they are and have been—ball bearings.

Ball Bearings. A ball bearing consists of a series of steel balls working in a race, which is formed between a cone on the one hand and an encircling cup on the other. In a plain bearing these two surfaces would work directly on one another ; but in ball bearings we have the friction transferred to the small points on the surface of the balls, and rolling friction substituted for sliding friction.

Types of Bearings. Bearings may be classified according to their type or method of adjustment. The balls of the bearings work between a cone, fixed generally to the axle, and a cup screwing into a corresponding part of the machine. In the crank bracket the cone is affixed to the crank axle and revolves with it, while the cup is screwed into the shell of the bracket and remains stationary. In the wheels this is reversed ; the axle and cones are fixed and the two cups revolve.

Adjustment Variations. Bearings are either cone or disc adjusting. In a cone variety hub the cups are fixed into the case of the hub. One cone is attached permanently to the hub axle, while that on the other side is threaded on so that it is capable of adjustment and at the same time allows of the passage of the balls to and from the ball race when required.

Fitting Up a Ball Bearing. It will be readily understood that by sliding the axle in the hub and by unscrewing the movable cone, the balls may be slipped in. In putting the bearing together the side with the fixed cone would be inserted first. Then, after holding that up to its place and turning the wheel over, the other side is found with the movable cone projecting out ready for the balls, after the insertion of which the cone is screwed up into position.

Disc Adjustment. In the disc adjustment bearing or cup adjustment, as it is sometimes called, we have a fixed cone on each end of the axle. The cups screw bodily into the case of the bearing.

Width of Bearings. In the cone type of bearing the cones are outside the cups, while in the disc type the cones are inside. It is well to point out that the distance between the ball races, and consequently the width apart of the bearings, should be as wide as possible to resist the one-sided strain that we get in the chain-driven bicycle. The disc adjusting type gives a slightly greater width of bearing, and where it is used in the bottom bracket, it is a good plan if the bracket chain wheel can be dished inwards towards the centre, thus bringing the strain more central—nearer the ideal position of the driving chain.

Accessories. By accessories we include such items as the saddle and tool bag, lamp, bell or horn, tools such as spanners, oil-can, inflator, luggage carrier, repairing outfit, trouser and toe-clips.

Saddle. There are many forms of saddles, and they are made to suit any purse. A good saddle should be made from selected leather, be adjusted to allow the cyclist to rest on the broad part and reach the handlebars and pedals without any suspicion of stretching. It should be mounted on springs that with their elasticity will prevent bouncing on the one hand and a hard seat on the other. The peak is merely to retain the rider from getting away from his proper seating, and is not meant to receive any great strain. There are special forms of saddles for racing men which give great freedom of action, and the most fastidious can choose various types of hygienic saddles. Means are provided for taking up the slack, should the saddle through exposure and heavy usage warrant it, and the judicious application of occasional dressing will all help to lengthen the life of that part of the machine which, with the tyres, gives comfort to the cyclist as he rides.

Lamps. Most cyclists use the oil lamp, but acetylene gas gives a far more powerful light. Candle lamps are also manufactured. To burn well, a lamp should be kept thoroughly clean. This is especially the case in a gas lamp. A cheap lamp is no economy, for a light is a legal necessity at night, so we must pay a fair price if we are to expect a lamp that will keep alight in the roughest weather and always to be depended on.

The Tricycle. The tricycle is a slower and heavier machine but free from side slip. The one essential difference, apart from the number of wheels, is the presence of the balance or differential gear on the hind axle, which allows of the outer wheel revolving at a greater speed than the inner one, a necessity when rounding a curve.

The Modern Use of the Tricycle. The tricycle is now chiefly used as a carrier [68], having a box of varying descriptions mounted in the frame. The box may be on the front axle with the handlebar fixed to the top back rail of the body, or on the hind axle, when the steering is usually effected by stirrup handles. In a *bicycle carrier* small boxes are fitted each side of the hind wheel.

Tandems. The tandem frame [62] is constructed practically under the same conditions as the bicycle frame, and is arranged for a lady either front or behind, or with both seats for men. The tubing used is of a heavier gauge, and we have another set of chain and back stays, down and top tubes, to provide as well as the extra handlebar and stem, seat-pillar, bracket, chain wheel and chain. Other multiseated types are used for path pacing, but are being discontinued owing to the advent of the motor bicycle.

COMPARATIVE LITERATURE

A Note on Comparative Literature. American Writers. Ancient and Foreign Classics for English Readers. Books that Must, May, and Need Not be Read

By J. A. HAMMERTON

WHAT is technically known as "comparative literature" is a vitalising factor in international goodwill and the fellowship of nations.

To know only the literature of our own country is no small thing, but we must know also something of the other literatures, else we are in much the same position as the man who has travelled throughout these green islands of our race and has never set foot on foreign soil. He is the least competent person to tell us of his own land, lacking as he does all standards of comparison. The reader who knows only his national literature is not quite so insular, since he has at least spent time in the company of writers who, for the most part, reflect a universality of culture; but it behoves the serious student to acquire some knowledge of foreign literature, preferably in the original, even if his linguistic attainments be limited to one foreign language—French or German. There is, however, an abundance of good translations.

Thus, many of the best novels of recent years have come to us from France, Germany, Russia, and Italy. Some of the soundest criticisms of English literature are the work of French writers. In the study of comparative literature, the French are undeniably in advance of ourselves; and a short time ago a most useful treatise on the subject was written by M. Frédéric Loliée. This has been translated by Mr. Douglas Power, M.A., and published under the title of "A Short History of Comparative Literature from the Earliest Times to the Present Day" (Hodder & Stoughton. 6s.). There can be no doubt, of course, that it is best to read a foreign book in the language in which it was originally written; but the reader's knowledge of that language must be a competent knowledge. Where this is lacking, competent translators are the more desirable from every point of view. The English Bible is a translation, so we may well accept Homer at second hand.

AMERICAN LITERATURE

Although it is true in the main that American literature is only a province of English literature, we have not dealt with American writers in our preceding studies, reserving them for separate notice. Apart from the influences of environment, the sources of American literature may be truthfully described as English and German. In America, of recent years there has been a much greater study of the Greek and Roman classics, while Transatlantic scholarship is rivalling that of England, particularly in regard to the literature of the Elizabethan period. We must now pass in review the names of those American authors with whose work every English reader should be acquainted.

Poetry. In poetry, the outstanding names are those of WILLIAM CULLEN BRYANT (b. 1794; d. 1878); RALPH WALDO EMERSON (b. 1803; d. 1882); HENRY WADSWORTH LONGFELLOW (b. 1807; d. 1882); JOHN GREENLEAF WHITTIER (b. 1807; d. 1892); EDGAR ALLEN POE (b. 1809; d. 1849); OLIVER WENDELL HOLMES (b. 1809; d. 1894); WALT WHITMAN (b. 1819; d. 1892); JAMES RUSSELL LOWELL (b. 1819; d. 1891); CHARLES GODFREY LELAND (b. 1824; d. 1903); RICHARD HENRY STODDARD (b. 1825; d. 1903); BAYARD TAYLOR (b. 1825; d. 1878); FRANCIS BRET HARTE (b. 1839; d. 1902); JAMES WHITCOMB RILEY (b. 1853); and CINCINNATUS HINER MILLER ("Joaquin Miller") (b. 1841). A number of these poets are no less, and some are more, distinguished as prose writers.

Prose Fiction. American prose is characterised by much didacticism; its earliest examples bear the impress of Steele and Addison and the Puritan divines. In its later phases it has, however, lacked neither fancy nor humour, the humour being especially racy of the soil. Perhaps no name more representative of American letters could be mentioned than that of "Mark Twain," SAMUEL LANGHORNE CLEMENS (b. 1835), who is essentially a humorist, with a vein of seriousness cropping out at times above the surface of his humour. The short story has been brought nearer to perfection in America than it has in England. Taking the writers of fiction in chronological order, the following may be accepted as representative: JAMES FENIMORE COOPER (b. 1789; d. 1851), author of "The Last of the Mohicans" and other tales of Red Indian life; NATHANIEL HAWTHORNE (b. 1804; d. 1864), author of "The Scarlet Letter"; OLIVER WENDELL HOLMES, author of "Elsie Venner"; EDGAR ALLEN POE, an absolute master of the short story; HARRIET BEECHER STOWE (b. 1811; d. 1896), author of "Uncle Tom's Cabin"; FRANCIS RICHARD STOCKTON (b. 1832; d. 1902), author of "Rudder Grange"; THOMAS BAILEY ALDRICH (b. 1836), whose "Queen of Sheba" is one of the greatest of short stories; WILLIAM DEAN HOWELLS (b. 1837), who shares with HENRY JAMES (b. 1843) the honour of being at the head of living American novelists, much as Meredith and Hardy are prominent in England; GEORGE WASHINGTON CABLE (b. 1844), the author of "Old Creole Days"; JOEL CHANDLER HARRIS ("Uncle Remus") (b. 1848); FRANCIS MARION CRAWFORD (b. 1854), who, though born in Italy, and devoting his talents to the description of Italian life, may be ranked as an American; HAROLD FREDERIC (b. 1856; d. 1898); GERTRUDE

ATHERTON; and EDITH WHARTON (b. 1862), whose "Valley of Decision" and "House of Mirth" are among the best examples of the novel, while her tale "The Descent of Man" shows her to be one of the best of short story writers now living.

Criticism and Philosophy. Of American essayists, critics, and philosophers, much might be written, especially of BENJAMIN FRANKLIN (b. 1706; d. 1790); WASHINGTON IRVING (b. 1783; d. 1859); RALPH WALDO EMERSON; JAMES RUSSELL LOWELL; OLIVER WENDELL HOLMES; and HENRY DAVID THOREAU (b. 1817; d. 1862). Of more recent writers, in addition to W. D. HOWELLS and HENRY JAMES, may be cited EDWARD EVERETT HALE (b. 1822); THOMAS WENTWORTH HIGGINSON (b. 1823); CHARLES ELIOT NORTON (b. 1827); WILLIAM JAMES ROLFE (b. 1827); WILLIAM WINTER (b. 1836); HAMILTON WRIGHT MABIE (b. 1846); and AGNES REPPLIER (b. 1851).

Science and History. In the world of science the name of the Swiss naturalist, JEAN LOUIS RUDOLPHE AGASSIZ (b. 1807; d. 1873), may be claimed as American. American historians of note include GEORGE BANCROFT (b. 1800; d. 1891); JOHN LOTHROP MOTLEY (b. 1814; d. 1877); WILLIAM HICKLING PRESCOTT (b. 1796; d 1859); and GEORGE TICKNOR (b. 1791; d. 1871), whose "History of Spanish Literature" is one of the best works on that difficult subject. Some acquaintance with the works of every writer named is desirable in anyone who would be considered "well read."

ANCIENT CLASSICS

Greek Literature. An excellent little primer on the "History of Greek Literature" is that by Sir Richard Jebb (Macmillan. 1s.). The study will be the more profitable if it is made supplementary to a study of the history of Greece, for which purpose we would commend W. Smith's "Student's Manual of Greek History" (Murray. 7s. 6d.). One further point has to be borne in mind, and that is the importance of a knowledge of mythology. This in itself is a wide subject, but some acquaintance with it is a primary essential for all who wish to understand the language of the classics, modern as well as ancient. There is a useful little handbook of mythology by Thomas Bullfinch (Routledge. 1s.).

The student's next concern will be with particular authors: Homer, the father of the epic; Hesiod, poet of men as Homer was poet of the gods; Theocritus, the writer of idylls; Pindar, the lyric poet; Æschylus, Sophocles, Euripides, the writers of tragedies; Aristophanes, the writer of comedies; Plato and Aristotle, the philosophers; Xenophon, Plutarch, Thucydides, and Herodotus, the historians; Demosthenes, the orator; Lucian, the satirist; and others. We know of no better introductions to the study of these masters than the "Ancient Classics for English Readers" (Blackwood. 28 vols., 2s. 6d. each). Of the "Iliad" and the "Odyssey" of Homer, Chapman's versions still maintain a general excellence despite many rivals; and one may here commend Gladstone's primer on Homer (Macmillan. 1s.). For texts and translations of the other writers we must refer the student to the catalogues of Messrs. Frowde, Clay, Macmillan, and Bell.

Latin Literature. We know of no better introduction to the study of Latin literature than the manual by Professor J. W. Mackail (Murray. 3s. 6d.). But A. S. Wilkins's little primer (Macmillan. 1s.) and Smith's "Student's Rome" (Murray. 7s. 6d.) will prove most helpful. To come to particular works: the philosophical poetry of Lucretius; the lyrics of Catullus; the orations of Cicero; the epic strains of Virgil; the odes and satires of Horace; the voluminous verse of Ovid; the histories of Cæsar, Livy, Tacitus, Sallust and Suetonius; the satires of Persius, Juvenal, and Apuleius; the philosophical writings and plays of the younger Seneca; the comedies of Plautus; the natural history of the elder Pliny; the epistles of the younger Pliny; the epigrams of Martial; the rhetoric of Quintilian; the writings of Tertullian, the first of the Latin Fathers—these, one and all, may well claim patient study. Apart from the catalogues of the educational publishers already mentioned, J. E. B. Mayor's "Bibliographic Clue to Latin Literature" will be found of material assistance to the student, whether the quest be a sound text or a competent translation.

FOREIGN CLASSICS

Italy. After a good grounding in the literature of Greece and Rome, the student will turn naturally to the literature of modern Italy, beginning with Dante, whose "Divine Comedy," written at the opening of the fourteenth century, links the ancient with the modern world, and marks the beginning of what is called the Renaissance. As a nucleus of this study, Richard Garnett's "History of Italian Literature" (Heinemann. 6s.) and Lewis Einstein's "The Italian Renaissance in England" (Macmillan) could not be improved upon, and much help through the tangled maze of an important period of European development will be derived from the abstract of John Addington Symonds's colossal history of "The Renaissance in Italy," written by Alfred Pearson (Smith, Elder. 7s. 6d.). One may trace the line of Italian literary development from Dante through the poetry of Petrarch, Ariosto, Guarini, Tasso, Marini, Alfieri, Monti, Manzoni, Leopardi, Metastasio, Carducci, and Rossetti; the tales and novels of Boccaccio, Bandello, Manzoni, Gabriele d'Annunzio, Verga, Fogazzaro, and Mathilde Serao; and the prose of Machiavelli, Guicciardini, Castiglione, Benvenuto Cellini, Bruno, Leopardi, Silvio Pellico, and Villari.

France. French literature is, from a strictly literary standpoint, of the first importance. One can have no more reliable guide in this study than Professor Dowden's handbook (Heinemann. 6s.) or Professor Saintsbury's "Short History of French Literature" (Clarendon Press. 10s. 6d.). Leaving "the shores of old romance" sacred to such works as the "Chanson de Roland" and the "Roman de la Rose," we may briefly indicate the vast stores of literary wealth in the language of our nearest neighbours by mentioning the histories of Froissart, De Comines, Thierry, Guizot, Thiers, Michelet, and de Tocqueville; the poetry of Villon, Ronsard, Malherbe, Lafontaine, Boileau, André Chenier, Lamartine, Béranger, Hugo, Alfred de Musset, Leconte de Lisle, Beaudelaire, Théophile Gautier, Sully Prudhomme, and François Coppée; the wit of Rabelais, Voltaire, la Rochefoucauld, Chamfort, Marot, and Montesquieu; the philosophy of Montaigne, Descartes, Beyle ("Stendhal"), Rousseau, Condillac and Condorcet; the plays of Corneille, Racine, Molière, Scarron, Crébillon, Beaumarchais, Sardou, Hervieu and Maeterlinck; the thoughts of Pascal and Joubert; the novels and tales of Marguerite de Valois, Le Sage, Voltaire, Hugo, Bourget, Balzac, Boisgobey, Prévost, Dumas, Flaubert, Daudet, Zola, Merimée, Maupassant, the brothers De Goncourt, Murger, Georges Sand, Eugene Sue, Erckmann-Chatrian, Jules Verne, Pierre Loti, René Bazin, and "Gyp"; the letters of Mme. de Sévigné, Mme. de Stael, Mlle. de Lespinasse, and De Sénancour; the fables of Perrault and Lafontaine; the writings of Renan; the sermons of Bossuet, Fénelon, and Massillon; the oratory of Mirabeau; the acute critical work of Sainte-Beuve, Boileau, Diderot, Taine, Faguet, Jusserand, and Brunetière. To the reader with a knowledge of the French language we would commend "Blackie's Little French Classics," in which the cream of the literature is reprinted and carefully annotated.

Germany. German literature is another vitally important section of European letters. It has had a profound effect on both English and American thought. It is rich in romance, poetry, history, philosophy, religion, fiction, and works for the young. The English student is advised to begin his study of the subject with two works by Professor Charles H. Herford—"Studies in the Literary Relations of England and Germany" (Cambridge University Press. 9s.); and "A Short History of German Literature" (Heinemann. 6s.). First come the tales of the Nibelungs and the songs of the Mastersingers, which form such an important groundwork for modern German music, and especially the music of Richard Wagner. Next in importance from a chronological standpoint come the sermons and other compositions in prose and verse of Luther, Zwingli, and their fellow reformers. From this standpoint may be followed the course of German philosophy in the writings of Leibnitz, Kant, Fichte, Schelling, Hegel, Herbart, Schopenhauer, Von Hartmann, and Nietzsche; the evolution of poetry and the drama in the works of Klopstock, Lessing, Wieland, Herder, Schiller, Goethe, Bürger, Kleist, Körner, Arndt, Rückert, Uhland, Heine, Wagner, Kotzebue, De la Motte Fouqué, Chamisso, Sudermann, Hauptmann; the theological writings of Reinhard, Schleiermacher, Neander, Strauss, Dollinger, Ritschl, Wellhausen, and Haeckel; the historical studies of Gervinus, Ranke, Niebuhr, Boeckh, and Mommsen; the novels and tales of Goethe, Tieck, Novalis, Hoffmann, Jean Paul Richter, Auerbach, Gustave Freytag, Fritz Reuter, and Gottfried Keller. The philological and scientific writings of German origin are far too numerous even for the barest mention.

Spain. The literature of Spain is the theme of a well-written monograph by J. Fitzmaurice Kelly (Heinemann. 6s.) After consideration of the "Chronicle of the Cid," the oldest epic in a Romance language, and the romances of chivalry, such as the "Amadis de Gaula," the names that the English student can least afford to pass over are those of Montemayor, Cervantes, Lope de Vega, Mendoza, Herrera, Calderon, Camoens, Gongora, Juan Valera, and Palacio Valdés. It is in particular with reference to the history of the drama that Spanish literature is worthy of study. That its influence on English letters has been considerable may be gleaned from F. W. Chandler's "The Picaresque Novel in Spain" and J. G. Underhill's "Spanish Literature in the England of the Tudors" (Macmillan).

Russia. Russian literature, as represented in the work of Gogol, Poushkin, Oneguin, Lermontoff, Dostoievsky, Turgenieff, Tolstoy, and Gorky, has exercised considerable influence on European literature generally. Charles E. Turner's "Russian Literature" and "Modern Russian Novelists" and Waliszewsky's "Russian Literature" may be consulted.

Scandinavia. Scandinavia is also playing a great part in the formation of modern literature. The dramas of Henrik Ibsen and the novels and plays of Björnson Björnstjerne represent Norway's contribution. Denmark can boast the powerful literary criticisms of George Brandes; and Holland the penetrating novels of Maarten Maartens.

WHAT TO READ

Books that Must be Read. The student who has companied with us thus far is already acquainted with the books which we consider must be read by all who desire to have a substantial knowledge of English literature. Here we purpose offering no more than a few concluding hints.

The obvious reply to the question, "What are the books that must be read?" is, "The Best Books." But "the best books" for one are not "the best books" for another. Remember "the personal equation" of which we spoke at page 105. In the voice of many counsellors there is wisdom; but this wisdom has to be distilled by the person who hopes to profit from it.

This is but one of many reasons why we consider the lists of "the best books" that have been drawn up from time to time by well-known men are positively harmful if taken as of universal application. At the same time it is quite obvious that, as Ruskin once wrote, "a well-trained gentleman should know the literature of his own country and half a dozen classics thoroughly." The rest may wait on inclination. We are at least on firm ground in saying that the study of literature for educational purposes is likely to be of the greatest value if it is based on a knowledge of literary history. The course, then, which we advise the student to pursue is to acquire a good "grounding" in general history, and then to study a good handbook to literary history such as the Lectures of Frederick Schlegel (a translation of which is to be found in "Bohn's Library") or the "Short History of Comparative Literature," by Frédéric Loliée, already mentioned. Of the other literary histories which he will find suggestive, first place may be claimed for Taine's "History of English Literature" (translated by H. Van Laun, and published by Chatto & Windus in four volumes, at 2s. net).

The books in English that must be read by everyone should include the Bible; Chaucer's "Canterbury Tales;" Spenser's "Faëry Queen;" the whole of Shakespeare; Milton's "Paradise Lost," "Comus," and the shorter poems; Bunyan's "Pilgrim's Progress;" Swift's "Gulliver's Travels;" Defoe's "Robinson Crusoe" and "Moll Flanders;" Goldsmith's "Vicar of Wakefield" and his two comedies; Sheridan's plays; Byron's "Childe Harold;" the greater part of Scott's poems, Wordsworth, Keats, Burns, Gray, Tennyson, Browning and Swinburne; Lewes's "History of Philosophy;" Gibbon's "Decline and Fall of the Roman Empire;" Bacon's "New Atlantis," "Novum Organum," and "Essays;" the Essays of Addison, Macaulay, Lamb and Hazlitt; Green's "Short History of England;" Carlyle's "Past and Present" and "The French Revolution;" Mill's "Political Economy;" Boswell's "Life of Johnson;" the novels of Fielding, Scott, Kingsley, Thackeray, Dickens, George Eliot, several of Trollope, Meredith and Hardy; and in foreign literature Homer, Plutarch, Virgil, Horace, Dante, Rabelais, Cervantes, Molière, Montaigne, Goethe, Schiller, Voltaire, Hugo and Balzac.

Books that May be Read. Here we pass to less certain ground, but we may claim that throughout our studies considerable care has been taken to specify, as their names have occurred, the works of many great writers which might be left entirely to the inclination of the general reader, though imperative to the student. For instance, we would have every "well-read" man know all the best plays of the Elizabethan dramatists, as these are to be found in the "Mermaid Series;" but we are far from saying that this is not optional to the general reader, though it is imperative to the student. So with such classics as "The Wealth of Nations" and "The Origin of Species." The gist of Adam Smith's philosophy and of Darwin's science is absorbed in one's general reading; by which we mean that both of these writers have so influenced their contemporaries and their successors that few intelligent people of the present day are ignorant of their teachings, even though they may not have read their works. This is no excuse for neglecting either; but the man who has not read "Hamlet" or "Paradise Lost," let us say, has an unfurnished chamber in his mind, and this could not with equal force be charged against him who had not read "The Wealth of Nations" or "The Origin of Species." Beyond the minimum of "Books that must be read," which we have ventured to suggest above, the reader may be left to rove at will among the treasures of our literature, applying such knowledge as we trust he has acquired in these studies.

Books that Need Not be Read. We have indicated above that we do not believe in any "best hundred books." A hundred books that have a universal appeal could not possibly be named by the most ingenious and omnivorous reader that ever attempted the task. At least forty of Lord Avebury's hundred might be left unread, and there are not more than ten books of Lord Acton's hundred that anyone but a leisured and polyglot monk need trouble to open. We have already named many books which need not be read, and, what is more to the purpose, we have agreed upon certain methods of testing a book which should enable each of us for himself to decide what not to read. Few books are so bad as not to generate one new thought in the mind of the reader; but so long as we can turn in a moment to any work which the verdict of time has placed among the great books of the world, we must not palter with the "unplaced" modern writer, unless we have for ourselves discovered that he has something to tell us for which we are the better, or which we want to know. Above all, while we have tastes in certain directions, let us develop these. Thus, if we delight in history, do not let us waste one moment with Maine's "Ancient Law" merely because Lord Acton thought that one of the hundred best books. Let us get through with Gibbon—a glorious task—although Lord Acton found no place for "The Decline and Fall" in his amazing list. Finally, in history and science no book need be read whose author is known to be untrustworthy; in philosophy none that has not been accepted by the mass of thinkers; in religion, none whose author has not been noted for sincerity, and who could not have said with Whitman:

> "Camerado, this is no book,
> Who touches this touches a man;'

in biography, no book that is not the work of a writer noted for his care no less than his sympathy and literary grace; in poetry, none that has not touched the heart of a generation, or awakened the enthusiasm of the most cultured; in fiction, nothing that is not in the estimation of honest criticism informed with real character, fidelity to life, and charm of style, no matter how widely it may have been sold or is selling. All such excluded, there will still remain a sufficient number of great and enduring works of literature to occupy the most insatiable reader throughout a fairly long life!

PERSONAL PRONOUNS—continued

Conjunctive Forms. The forms *me*, *a me*, *te*, *a te*, *noi*, *a noi*, etc., are used when emphasis is laid on the pronouns; but when the pronoun is of secondary importance in the sentence, which is nearly always the case, the following forms must be used:

mi	for	*me*, *a me*, me, to me
ti	„	*te*, *a te*, thee, to thee
ci	„	*noi*, *a noi*, us, to us
vi	„	*voi*, *a voi*, you, to you
si	„	*sè*, *a sè*, himself, to himself, etc.
gli	„	*a lui*, *a esso*, to him (to it)
le	„	*a lei*, *a essa*, to her (to it)
loro	„	*a loro*, to them
lo	„	*lui*, *esso*, him (it)
la	„	*lei*, *essa*, her (it)
li	„	*loro*, *essi*, them
le	„	*loro*, *esse*, them

The student should here observe the forms: *ne* (some, any) = of him, of it, from it, etc. *ci*, *vi* (there) = in it, in them, etc.

Note. The forms *mi*, *ti*, *vi*, *lo*, *la* may be written *m'*, *t'*, *v' l'*, *l'* before any vowel; *ci* may be written *c'* only before *e* and *i*. The above forms of pronoun are, as a rule, placed before the verb, except *loro*, which is generally placed after it. In compound tenses they precede the auxiliary, and in negative sentences they are placed between the negative and the verb. Exceptions to this rule will be given below.

Examples:

1. *Io ti vedo*, I see thee.
2. *Io ti parlo*, I speak to thee.
3. *V'inviterò*, I shall invite you.
4. *Vi darò*, I will give (to) you.
5. *Ci mostràrono*, they showed (to) us.
6. *C' è*, *non c' è*, there is, there is not.
7. *Ne ho gran rispetto*, I have a great respect for him.
8. *L' avete comprato?* Have you bought it?
9. *Li avete venduti?* Have you sold them?
10. *Non le abbiamo vedute*, We have not seen them.
11. *Ho parlato loro*, I have spoken to them.
12. *Gli ho parlato*, I have spoken to him.

Note. *Gli* may be used also for *loro*: *Gli hanno dato un buon esèmpio*, They have set him (or them) a good example.

Observe from the above examples (8, 9, 10) that the past participle agrees with the object when the object is placed before the verb. A past participle that precedes the object is invariable. Example: *Avete spedito le lettere? Sì, le ho spedite.*

Exercise XXV.

1. Li incontreremo. 2. Ci daranno. 3. Gli mandàrono. 4. Che cosa (*what*) vi ha detto? 5. Che cosa gli avete risposto? 6. Dove sono i fiori che abbiamo raccolti? 7. Li ho messi nell'acqua. 8. Appena (*as soon as*) lo vedrò, gli parlerò di te. 9. L'ho veduto dalla finestra e l'ho chiamato ad alta voce due volte, ma non mi ha sentito. 10. La Maria ci disse che sarebbe andata in Italia quest'anno. 11. Essi hanno comprato un mùcchio di libri; li hanno letti e riletti, ma son sicuro che non ne hanno capito niente.

Exercise XXVI.

1. Quanto (*how much*) avete pagato codesti guanti? 2. Li ho pagati un po' caro, ma sono di una qualità eccellente. 3. Li avete trovati in casa? 4. Lei sì, ma non lui. 5. Quando mi darete quello che m'avete tante volte promesso? 6. Se mi date dei giocàttoli io sarò buono. 7. Avete più carta da lèttere? Voglio (*I wish*) scrivere al mio libraio che mi mandi i libri che gli ho ordinati. 8. Mi dispiace (*I am sorry*), non ne ho più; vi ho dato tutta la carta che mi restava. 9. Non fa niente, gli scriverò più tardi.

VERBS—continued

Second Conjugation. Infinitive in *ēre* (long) or *ĕre* (short). Examples: *temère*, to fear; *crèdere*, to believe. We shall here give the full conjugation of the verb *crèdere* only, as a model for the verbs of the second conjugation, since the only difference consists in the length of the infinitive. This difference, however, is very important, and care should be taken to distinguish whether the accent falls on the *penultimate* (on the termination) or on the *antepenultimate* (on the stem). Those who know Latin will notice that some verbs have displaced their accent in passing from one language into the other. Example: Latin *cadĕre*, Italian *cadère* (to fall). We shall here always indicate where the accent falls.

Crèdere, to believe

INDICATIVE MOOD

Present

I believe, etc.	We believe, etc.
credo	*crediamo*
credi	*credete*
crede	*crèdono*

Past Indefinite

I have believed, etc.	We have believed, etc.
ho creduto	*abbiamo creduto*
hai creduto	*avete creduto*
ha creduto	*hanno creduto*

Imperfect

I believed, etc.	We believed, etc.
credevo	*credevamo*
credevi	*credevate*
credeva	*credèvano*

First Pluperfect

I had believed, etc.	We had believed, etc.
avevo creduto	*avevamo creduto*
avevi creduto	*avevate creduto*
aveva creduto	*avévano creduto*

Past Definite

I believed, etc.	We believed, etc.
credèi, -etti	*credemmo*
credesti	*credeste*
credè, -ette	*credèrono, -èttero*

Second Pluperfect

I had believed, etc.	We had believed, etc.
ebbi creduto	*avemmo creduto*
avesti creduto	*aveste creduto*
ebbe creduto	*èbbero creduto*

Future

I shall believe, etc.	We shall believe, etc.
crederò	*crederemo*
crederai	*crederete*
crederá	*crederanno*

Future Perfect

I shall have believed, etc.	We shall have believed, etc.
avrò creduto	*avremo creduto*
avrai creduto	*avrete creduto*
avrà creduto	*avranno creduto*

IMPERATIVE MOOD

Present

Believe, etc.	Let us believe, etc.
—	*crediamo*
credi	*credete*
creda	*crèdano*

SUBJUNCTIVE MOOD

Present

That I believe, etc.	That we believe, etc.
creda	*crediamo*
creda	*crediate*
creda	*crèdano*

Perfect

That I have believed, etc.	That we have believed, etc.
àbbia creduto	*abbiamo creduto*
àbbia creduto	*abbiate creduto*
àbbia creduto	*àbbiano creduto.*

Imperfect

If I believed, etc.	If we believed, etc.
credessi	*credèssimo*
credessi	*credeste*
credesse	*credèssero*

Pluperfect

If I had believed, etc.	If we had believed, etc.
avessi creduto	*avèssimo creduto*
avessi creduto	*aveste creduto*
avesse creduto	*avèssero creduto*

CONDITIONAL MOOD

Present

I should believe, etc.	We should believe, etc.
crederei	*crederemmo*
crederesti	*credereste*
crederebbe	*crederèbbero*

Perfect

I should have believed, etc.	We should have believed, etc.
avrei creduto	*avremmo creduto*
avresti creduto	*avreste creduto*
avrebbe creduto	*avrèbbero creduto*

INFINITIVE MOOD

Present

crèdere, to believe.

Perfect

avèr creduto, to have believed.

Gerund

Present—credendo, believing
Perfect—avendo creduto, having believed

Participle

Present—credente, -i, believing
Perfect—creduto, -a, -i, -e, believed

EXERCISE XXVII.

1. Riceveremo. 2. Avete bevuto? 3. Se noi perdèssimo. 4. Temèvano. 5. Non avrèbbero creduto. 6. Avreste venduto? 7. Venderemmo. 8. Vendemmo. 9. Ha (egli) ricevuto? 10. Io non ho ancora ricevuto, ma riceverò. 11. Egli è sempre senza danaro, eppure ne riceve sempre. 12. Quanto credete che egli àbbia ricevuto ultimamente? 13. Ricevette cinquanta lire la settimana scorsa, ma ne riceverà altrettante domani. 14. Vendemmo il nostro giardino e venderemo pure la casa. 15. Non posso crèdere ch'egli non àbbia ricevuto il nostro invito. 16. Andiamo, se no perderemo il nostro tempo inutilmente. 17. Se non stiamo attenti, ho paura che perderemo quello che (what) abbiamo già guadagnato. 18. Le foglie incominciano a cadère. 19. Quei valorosi combattèrono tutti fino alla morte.

Third Conjugation. Infinitive in *-ire.* The verbs of the third conjugation may be divided into three classes:

1. Verbs in which the terminations are added directly to the stem in all tenses, as: *vestire,* to dress; *partire,* to start. [See page 3210.] The verbs belonging to this class are very few.

2. Verbs which, in the singular and in the third person plural of the present of the indicative, imperative, and subjunctive, insert the syllable *isc* between the stem and the terminations, as: *capire,* to understand; present indicative, *cap-isc-o.*

3. Verbs which can be conjugated either with or without the addition of the syllable *isc,* as: *nutrire,* to feed; present indicative, *nutro* and *nutrisco.*

Vestire, to dress

INDICATIVE MOOD

Present

I dress, etc.	We dress, etc.
vesto	*vestiamo*
vesti	*vestite*
veste	*vèstono*

Past Indefinite

I have dressed, etc.	We have dressed, etc.
ho vestito	*abbiamo vestito*
hai vestito	*avete vestito*
ha vestito	*hanno vestito*

Imperfect

I dressed, etc.	We dressed, etc.
vestivo	*vestivamo*
vestivi	*vestivate*
vestiva	*vestìvano*

First Pluperfect

I had dressed, etc	We had dressed, etc.
avevo vestito	*avevamo vestito*
avevi vestito	*avevate vestito*
aveva vestito	*avèvano vestito*

Past Definite

I dressed, etc.	We dressed, etc.
vestii	*vestimmo*
vestisti	*vestiste*
vestì	*vestìrono*

Second Pluperfect

I had dressed, etc.	We had dressed, etc.
ebbi vestito	*avemmo vestito*
avesti vestito	*aveste vestito*
ebbe vestito	*èbbero vestito*

Future

I shall dress, etc.	We shall dress, etc.
vestirò	*vestiremo*
vestirai	*vestirete*
vestirà	*vestiranno*

Future Perfect

I shall have dressed, etc.	We shall have dressed, etc.
avrò vestito	*avremo vestito*
avrai vestito	*avrete vestito*
avrà vestito	*avranno vestito*

IMPERATIVE MOOD

Present

Dress, etc.	Let us dress, etc.
—	*vestiamo*
vesti	*vestite*
vesta	*vèstano*

SUBJUNCTIVE MOOD

Present

That I dress, etc.	That we dress, etc.
vesta	*vestiamo*
vesta	*vestiate*
vesta	*vèstano*

Perfect

That I have dressed, etc.	That we have dressed, etc.
àbbia vestito	*abbiamo vestito*
àbbia vestito	*abbiate vestito*
àbbia vestito	*àbbiano vestito*

Imperfect

If I dressed, etc.	If we dressed, etc.
vestissi	*vestìssimo*
vestissi	*vestiste*
vestisse	*vestìssero*

Pluperfect

If I had dressed, etc.	If we had dressed, etc.
avessi vestito	*avèssimo vestito*
avessi vestito	*aveste vestito*
avesse vestito	*avèssero vestito*

CONDITIONAL MOOD

Present

I should dress, etc.	We should dress, etc.
vestirei	*vestiremmo*
vestiresti	*vestireste*
vestirebbe	*vestirèbbero*

Perfect

I should have dressed, etc.	We should have dressed, etc.
avrei vestito	*avremmo vestito*
avresti vestito	*avreste vestito*
avrebbe vestito	*avrèbbero vestito*

INFINITIVE MOOD

Present

vestire, to dress

Perfect

avèr vestito, to have dressed

Gerund

Present—vestendo, dressing
Perfect—avendo vestito, having dressed

Participle

Present—vestente, -i, dressing
Perfect—vestito, -a, -i, -e, dressed

EXERCISE XXVIII.

1. Partiremo. 2. Se fòssimo partiti. 3. Non aprite. 4. Sentite. 5. Se avèssero seguito. 6. Soffrirèbbero. 7. Quella pòvera donna soffrì tanto quando il figliuolo partì. 8. Se i bottegai ci servìssero male avremmo ragione di andare a spèndere altrove. 9. Aprite la finestra, fa troppo caldo. 10. Partirei domani se avessi finito i miei affari. 11. Questi fanciulli dòrmono troppo. 12. Appena vìdero il perìcolo fuggìrono tutti e lo lasciàrono solo. 13. Quante volte li abbiamo uditi dire che erano stanchi di studiare! 14. Venite con me. 15. Fuggite la compagnìa dei cattivi, e seguite l'esèmpio dei buoni.

KEY TO EXERCISE XXIII.

1. We have worked more than you. 2. The letter has been written by me and not by him. 3. If you accompany me, I will accompany you. 4. They always think quite the contrary of what they say. 5. They think they are behaving well, and instead they are behaving very ill. 6. We never have anything; they keep all for themselves. 7. She is very kind, but not he. 8. When we have been in need, they have always done much for us. 9. Thou thinkest always of thyself, and never thinkest of others. 10. A gentleman has asked for you.

KEY TO EXERCISE XXIV.

1. Dove andate? Se aspettate ancòra un poco verrò con voi. 2. Siete venuto in tempo noi parlavamo appunto di voi. 3. Credevamo che fosse lui, non lei. 4. Bisognerebbe imparare a far tutto da sè. 5. Abbiamo scritto sì a lui che a lei diverse volte, ma essi non hanno mai risposto alle nostre lèttere. 6. Chi ha rotto quel vaso? 7. Io no, è cascato da sè. 8. A chi avete consegnato il pacco, a lui o a lei? 9. A nessuno dei due, perchè essi non èrano in casa. 10. Non so capire perchè àbbia fatto a me una tale proposta.

VERBS—continued

Finir, to finish

Second Conjugation. PRINCIPAL PARTS: *Finir, finissant, fini, je finis, je finie.*

INDICATIVE

SIMPLE TENSES	COMPOUND TENSES
Present	*Past Indefinite*
I finish, am finishing, etc.	I have finished, etc.
je finis	*j'ai fini*
tu finis	*tu as fini*
il, elle finit	*il, elle a fini*
nous finissons	*nous avons fini*
vous finissez	*vous avez fini*
ils, elles finissent	*ils, elles ont fini*
Imperfect	*Pluperfect*
I was finishing, used to finish, etc.	I had finished, etc.
je finissais	*j'avais fini*
tu finissais	*tu avais fini*
il, elle finissait	*il, elle avait fini*
nous finissions	*nous avions fini*
vous finissiez	*vous aviez fini*
ils, elles finissaient	*ils, elles avaient fini*
Past Definite	*Past Anterior*
I finished, etc.	I had finished, etc.
je finis	*j'eus fini*
tu finis	*tu eus fini*
il, elle finit	*il, elle eut fini*
nous finîmes	*nous eûmes fini.*
vous finîtes	*vous eûtes fini*
ils, elles finirent	*ils, elles eurent fini*
Future	*Future Anterior*
I shall finish, etc.	I shall have finished, etc.
je finirai	*j'aurai fini*
tu finiras	*tu auras fini*
il, elle finira	*il, elle aura fini*
nous finirons	*nous aurons fini*
vous finirez	*vous aurez fini*
ils, elles finiront	*ils, elles auront fini*

CONDITIONAL

Present	*Past*
I would finish, etc.	I would have finished, etc.
je finirais	*j'aurais fini*
tu finirais	*tu aurais fini*
il, elle finirait	*il, elle aurait fini*
nous finirions	*nous aurions fini*
vous finiriez	*vous auriez fini*
ils, elles finiraient	*ils, elles auraient fini*

IMPERATIVE

Present

finis,	finish (thou)
qu'il finisse,	let him finish
qu'elle finisse,	let her finish
finissons,	let us finish
finissez,	finish (ye)
qu'ils finissent,	let them (m.) finish
qu'elles finissent,	let them (f.) finish

SUBJUNCTIVE

Present	*Past*
That I may finish, etc.	That I may have finished, etc.
que je finisse	*que j'aie fini*
que tu finisses	*que tu aies fini*
qu'il, qu'elle finisse	*qu'il, qu'elle ait fini*
que nous finissions	*que nous ayons fini*
que vous finissiez	*que vous ayez fini*
qu'ils, qu'elles finissent	*qu'ils, qu'elles aient fini*
Imperfect	*Pluperfect*
That I might finish, etc.	That I might have finished, etc.
que je finisse	*que j'eusse fini*
que tu finisses	*que tu eusses fini*
qu'il, qu'elle finît	*qu'il, qu'elle eût fini*
que nous finissions	*que nous eussions fini*
que vous finissiez	*que vous eussiez fini*
qu'ils, qu'elles finissent	*qu'ils, qu'elles eussent fini*

INFINITIVE

Present

finir, to finish

Past

avoir fini, to have finished

PARTICIPLE

Present

finissant, finishing

Past

fini, -e, finished

ayant fini, having finished

REMARKS. The negative, the interrogative, and the negative-interrogative forms being the same for all conjugations, it is not necessary to repeat them.

It is to be noted that all regular verbs of the second conjugation have the additional syllable *iss* in the present participle and in all the parts formed from it.

The verb *bénir,* to bless, has two forms of the past participle: *béni, bénie* and *bénit, bénite.* The latter of these is applied exclusively to that which is blessed or consecrated by a religious ceremony.

The verb *fleurir*, to blossom and to flourish, has two forms of the present participle, and of the imperfect indicative, which is formed from it: *fleurissant*, *fleurissais* and *florissant*, *florissais*. The second of these forms is used exclusively in the sense of to flourish, meaning to be prosperous.

The verb *haïr*, to hate, drops the diæresis in the three persons singular of the present indicative: *je hais*, *tu hais*, *il hait*; and in the second person singular of the imperative: *hais*. It is the only verb that does not take a circumflex accent in the first and second persons plural of the past definite and the third singular of the imperfect subjunctive: *nous haïmes*, *vous haïtes*, *qu'il haït*

Exercise XXVI.

1. When I was a child I was very bashful (*honteux*); I used to blush (*rougir*) up to the (*jusqu'aux*) eyes when anyone spoke to me

2. The earth is never ungrateful (*ingrat*); it feeds (*nourrir*) with (*de*) its fruits all those who cultivate it.

3. It is not age, it is grief (*le chagrin*) that has made his hair white (*blanchir*).

4. If you do not choose (*choisir*) a good spot (*un endroit*) to lay (*établir*) the foundation (*les fondations*) of the house, you will be obliged to pull it down (*démolir*).

5. The shame of that action reflects (*réfléchir*) on all those who have participated (*participer à*) in it.

6. Amongst the trees, almond-trees (*amandier*) blossom (the) first, and medlars (*néflier*) last.

7. After so many calamities (*calamité*) it is astonishing (*étonnant*) that this country should be (pres. subj.) so flourishing to-day.

8. The arms which have been blessed by (*par*) the Church are not always blessed by (*de*) heaven on the battlefield.

9. There are men by (of) whom it is glorious to be hated.

10. We (one) do not always hate those whom we render unhappy.

11. Good books cure (*guérir*) the diseases (*la maladie*) of the mind (*esprit*, m).

12. A free (*libre*) people (*peuple*) obeys (*obéir*), but it does not serve (*sert*).

Key to Exercise XXV.

1. Plus il avançait en âge, plus il avançait en sagesse.

2. La manière dont les Romains prononçaient le latin était très différente de celle dont nous le prononçons aujourd'hui.

3. Il partagea sa fortune entre ses trois enfants.

4. Selon un proverbe français, l'appétit vient en mangeant.

5. Il appelle sur son bienfaiteur les bénédictions du ciel.

6. On dit d'un homme qui dissipe sa fortune, qu'il jette son argent par la fenêtre.

7. Cette lettre nous annonce une bonne nouvelle.

8. La leçon commence à la page soixante-dix.

9. Envoyez cette pendule chez l'horloger pour qu'il l'arrange.

10. Je gagerais volontiers cent francs que ce n'est pas lui qui remportera le prix.

11. En mil six cent soixante, Charles II. fut rappelé au trône.

12. Ce poisson est trop petit; rejetez-le dans l'eau.

13. Quand les pêcheurs seront en pleine mer, ils jetteront leurs filets.

14. Ceux qui emploient mal leur temps sont les premiers à se plaindre de sa brièveté.

15. La lumière emploie de sept à huit minutes à nous venir du soleil.

16. Nous pardonnons souvent à ceux qui nous ennuient; mais nous pardonnons rarement à ceux que nous ennuyons.

17. Nous avons acheté la victoire au prix de nos meilleurs soldats.

18. Ce qu'on achète en détail est plus cher que ce qu'on achète en gros.

19. Il a gelé toute la nuit; s'il gèle encore demain, nous pourrons peut-être patiner samedi.

20. Dieu a tiré le ciel et la terre du néant; il les a créés par sa parole.

21. Agréez, Monsieur, mes salutations respectueuses—formule qu'on emploie souvent en terminant une lettre.

22. On est quelquefois obligé de céder aux circonstances.

23. Ce n'est pas lui qui possède sa fortune, c'est sa fortune qui le possède.

24. Tout chemin mène à Rome, dit le proverbe.

By P. G. Konody and Dr. Osten

VERBS—continued

LXXVI. Copulative Verbs. The verbs ſein, werden, bleiben (to remain), heißen (to call, name), ſcheinen (to seem, appear), dünken (to seem, appear) form the connecting link between two nominatives—that of the subject, and that of the complement: Er (nominative) iſt, wird, bleibt, ſcheint, dünkt (mir) ein Betrüger (nominative), he is, is getting, remains, seems (to be) a cheat.

LXXVII. As in the case of the copulative verbs several verbs may be connected with two accusatives, that of the object and that of the noun in apposition with it. Such verbs are: heißen, to call; rühmen, preiſen, to praise; ſchelten, to scold; ſchimpfen, to abuse; taufen, to name; nennen, to name. Man hieß ihn (accusative) einen Helden (accusative), They called him a hero; er nannte ihn einen Verläumder, He called him a slanderer. Rühmen and preiſen are often used with the conjunction als (in the capacity of): Der Direktor rühmte, pries ihn (accusative) als (conjunction) einen verläßlichen Beamten (accusative), The director praised him as a reliable employee. When brought into the passive voice, the two accusatives are changed into nominatives: Er (nominative) wurde ein

Held (nominative) geheißen; er wurde ein Verläumder genannt; er wurde vom Direktor als ein verläßlicher Beamter gerühmt.

LXXVIII. Verbs Governing the Accusative and Infinitive: ſehen, to see; hören, to hear; fühlen, to feel; finden, to find; lehren, to teach; laſſen, to let; machen, to make; heißen, to command, etc. Ich ſah ihn (accusative) fallen (infinitive), I saw him fall; Ich hörte das Mädchen ſingen, I heard the girl sing; Ich fühlte mein Herz klopfen, I felt my heart beat; Ich fand ihn gut ausſehen, I found him looking well, etc. If the dependent infinitive is a copulative verb, the two obligatory nominatives [see LXXVI.] are changed into accusatives. Thus, if laſſen stands with the infinitive of the copulative verb ſein, the subject of the latter and the following noun are changed into the accusative: Er läßt den Zufall (accusative) ſeinen Führer (accusative) ſein, He lets chance be his guide. Sentences with a proper object in the accusative (that is to say with transitive verbs) naturally have two accusatives—one of the object dependent on the governing transitive verb, and one of the object dependent on the infinitive. The sentence: Ich ſah, wie der Vogel (subject nominative) ſeine Flügel (object accusative) ausbreitete, I saw how the bird spread his wings, is changed into: Ich ſah den Vogel (accusative) ſeine Flügel (accusative) ausbreiten (infinitive), I saw the bird spread its wings. Ich hörte, wie der Künſtler ein Lied ſang, I heard how the artist sang a song; and: Ich hörte den Künſtler ein Lied ſingen, I heard the artist sing a song.

LXXIX. Displacement of the Verb in Independent Sentences. If an independent sentence is introduced by an adverb or an adverbial noun, the verb has to precede the subject, and has to occupy the same position as in the independent question: Ich bin hier (adverb of place), and: Hier bin ich. Es gibt keine Wirkung ohne Urſache, There is no effect without cause, and: Ohne Urſache gibt es keine Wirkung

LXXX. Verbs with Accusative and Genitive. Many verbs with an "object of the person" (transitives and reflectives) require a complement "of matter" in the genitive. Example: entheben, to exempt from, to dismiss from; Er enthob ihn (personal object) ſeiner Verpflichtung (genitive), He released him from his obligation. Verbs requiring such complementary genitives are: anklagen, beſchuldigen, bezichtigen, zeihen, to accuse; überführen, to convict; entbinden, entledigen, to release from, to deliver; entkleiden, to divest; erinnern, to remind; frei'ſprechen, to acquit; verſichern, to assure, etc.: Die Geſchworenen ſprachen den An'geklagte (accusative) des Verbrechens (genitive) frei, The jury acquitted the defendant [of the crime]; Der An'kläger beſchuldigte ihn (accusative) der ſchrecklichen Tat (genitive), The prosecutor accused him of the monstrous deed; Ich entbinde dich deines Verſprechens, I release you from your promise.

The following reflective verbs require also the genitive of matter with the accusative of the person: (ſich einer Sache) annehmen, to interest oneself in . . .; bedienen, to help oneself; bemächtigen, to seize; entſinnen, to remember; freuen, to rejoice in; rühmen, to glory in; ſchämen, to be ashamed of; erbarmen, to take pity on, etc.: Ich nahm mich (accusative) ſeiner (genitive) an (separable prefix), I took interest in him; Du bedienteſt dich meines Einfluſſes, You made use of my influence; Der Feind bemächtigte ſich der Feſtung, The enemy seized the fortress; Wir entſinnen uns des Fremden, We remember the stranger; Ihr freut euch des Lebens, You rejoice in life; ſie rühmen ſich ihrer Tat, They glory in their deed.

LXXXI. Interjections. These words are outside the syntactic structure of the sentence, and therefore do not generally govern other nouns, though they may require dependent cases or certain prepositions, such as auf, über (on): Pfui über (4) dich! Shame on you! Schande auf (4) ihn! Disgrace on him! Dependent clauses can also be added to interjections: Pfui, ſchäme dich, daß du ſo unwahr biſt! Fie! Be ashamed to be so untruthful!

LXXXII. Omission and Displacement of the Auxiliary Verb. To achieve increased vivacity and force, the finite auxiliary verb may sometimes be dropped from the end of a subordinate clause: Wir beſtiegen, nachdem wir das Haus verlaſſen [hatten], den Wagen, We got into the carriage after having left the house; Der Richter fiel ihm, bevor er geendet [hatte], ins Wort, The judge interrupted him before he had finished.

1. Omissions of finite auxiliary verbs occur frequently for the sake of euphony, to avoid the clashing of forms sounded alike: Der Brief, der geſtern früh abgegangen [iſt], iſt erſt heute Abends eingelangt, The letter which was despatched yesterday morning, has only arrived to-night; der Mann, der es euch geſagt [hat], hat ſich mit euch einen Scherz gemacht, The man who told you of it has made fun of you.

2. The displacement of the auxiliary verb werden occurs when the same forms would follow each other directly; for instance, in: Ich hoffe, daß der junge Mann und das Mädchen ein glückliches Paar werden werden, I hope that the young man and the girl will become a happy couple; one of the two „werden" must be displaced, so that the sentence would read: Ich hoffe, daß der junge Mann und das Mädchen werden ein glückliches Paar werden. Sometimes an adverb is repeated for similar reasons: Sobald die Früchte reif werden werden, werden wir ſie abnehmen, As soon as the fruit becomes ripe, we shall gather it, is changed into: Sobald die Früchte werden reif werden, ſobald (repeated) werden wir ſie abnehmen.

LXXXIII. Elliptic Sentences. Force, vivacity, and conciseness are sometimes brought about in German by the omission of the predicate, if the meaning of the curtailed sentence is not impaired by this proceeding, or if the missing words can easily be understood: [Sei] Willkommen! Be welcome! Woher [kommt Ihr] des Weges? Whence do you come? Keine Roſe [gibt es or iſt] ohne Dornen, There is no rose without thorns. This elliptic form frequently occurs in proverbs and proverbial sayings.

LXXXIV. Tenses in Dependent Clauses. In German the rules which govern the tenses in principal sentences and dependent clauses are not very strict. If the principal sentence contains a verb in the present, perfect, or future, any of the six tenses may at times be employed in the dependent clause. But it is safest to make the tense of the dependent clause agree with that of the principal sentence, especially if the verb of the dependent clause is in the subjunctive mood.

EXAMINATION PAPER XX.

1. What are copulative verbs, and which verbs belong to this group?
2. If the complement used with a copulative verb is a substantive, in what case must it stand?
3. What verbs are used with two accusatives, and into which case are these accusatives changed, if the sentence is transposed into the passive voice?
4. Which verbs govern the accusative with the infinitive?
5. What is the result, if this infinitive is a copulative verb?
6. How many accusatives are under these circumstances used with the transitive verb?
7. In what manner are the words displaced if an independent sentence is introduced by an adverb or an adverbial noun?
8. Which verbs require a complementary genitive with the object of the person?
9. Which prepositions are required by certain interjections?
10. For what reason are the finite verbs sometimes omitted, and which class of verb can thus be dropped?
11. When is it necessary to displace an auxiliary verb, and which auxiliary verb is subject to this displacement?
12. What omissions occur in elliptic sentences, and when is such a curtailment admissible?
13. Is it necessary to make the tense of the dependent clause agree with that of the principal sentence?
14. Under what circumstances is it preferable to make them agree?

CONVERSATIONAL EXERCISES

III. In the Street

Which is my best way to King Street?	Wie gehe ich am beſten in die Königsſtraße?
Straight on to the church, and then the fourth turning on the right.	Gerade bis zur Kirche, und dann die vierte Straße rechts.
Thank you very much.	Ich danke beſtens, or, Beſten Dank.
Would you kindly tell me where the cathedral is?	Können Sie mir gefälligſt ſagen, wo die Kathedrale iſt?
At the end of the next turning on the left.	Am Ende der nächſten Straße links.
How far is it to the Zoological Gardens?	Wie weit iſt es zum Zoologiſchen Garten?
Scarcely five minutes.	Kaum fünf Minuten.
Oh, it is very far from here.	O, es iſt ſehr weit von hier.
Is there any 'bus or tram going there?	Gibt es einen Stellwagen oder eine Pferdebahn dahin?
Oh yes, you can get there by 'bus.	O ja, Sie können mit dem Omnibus hinkommen.
Which is the High Street, please?	Bitte, welche iſt die Hauptſtraße?
The long street opposite the church.	Die lange Straße gegenüber der Kirche.
Would you kindly tell me where there is a tobacconist?	Könnten Sie mir gütigſt ſagen, wo hier ein Tabakladen iſt?
How do I get to the Rome Hotel, please?	Wie komme ich zum Hotel Rom, bitte?
Round the corner, and then the second on the right.	Um die Ecke, und dann die zweite Straße rechts.
I want to go to the museum; which is the shortest way?	Ich will nach dem Muſeum; welches iſt der kürzeſte Weg?
Could you tell me the time?	Könnten Sie mir ſagen, wie ſpät (wie viel Uhr) es iſt?
Half-past five.	Halb ſechs Uhr.
May I trouble you for a light?	Darf ich Sie um Feuer bitten?

IV. In the Shop

Do you keep picture postcards?	Haben Sie Anſichtskarten?
Here, if you please.	Hier, bitte.
I want some with the museum, the church, the Royal Palace.	Ich möchte welche mit dem Muſeum, der Kirche, dem Königlichen Schloſſe darauf.
How much is a dozen?	Was koſtet das Dutzend?
One mark twenty pfennigs.	Eine Mark zwanzig Pſennige.
Here are ten marks. Will you, please, give me the change in one-mark pieces?	Hier ſind zehn Mark. Geben Sie mir, bitte, den Reſt in Markſtücken.
I want a hat.	Ich brauche einen Hut.
Of what kind? A top hat, a felt hat, or one of straw?	Welcher Art? Einen Cylinder, einen Filzhut, oder einen aus Stroh?
A soft grey felt hat.	Einen weichen grauen Filzhut.
This one is too big for me.	Deiſer iſt mir zu groß.
Here is a smaller one. This one fits well.	Hier iſt ein kleinerer. Dieſer ſitzt gut.
What is the price? Nine marks.	Was koſtet er? Neun Mark.
Can you send it to me at the hotel?	Können Sie ihn mir ins Hotel ſchicken?
I'll put down the address.	Ich will die Adreſſe aufſchreiben.

How much is the umbrella in your shop-window?	Was koſtet der Regenſchirm in Ihrem Ausʼlagefenſter?
Which one do you mean?	Welchen meinen Sie?
The black one with the silver handle.	Den ſchwarzen mit dem ſilbernen Griff.
Eighteen marks.	Achtzehn Mark.
That is too dear; haven't you got a cheaper one?	Das iſt mir zu teuer; haben Sie nicht einen billigeren?
Oh yes, but not of such good silk.	O ja, aber nicht aus ſo feiner Seide.
I should like to change English money for German.	Ich möchte gerne engliſches Geld gegen deutſches einwechſeln.
Is it gold or paper?	Iſt es Gold oder Papier?
I have some sovereigns and five-pound notes.	Ich habe einige Sovereigns und Funf Pfund-Noten.
How much of each?	Wie viel von jeder Sorte?
Ten pounds in gold and fifteen in notes.	Zehn Pfund in Gold und fünfzehn in Noten.
How many marks do you reckon to the pound?	Mit wie viel Mark berechnen Sie das Pfund?
Nineteen marks 75 pfennigs.	Mit 19 Mark 75 Pfennige.
Don't you want some small change as well?	Brauchen Sie nicht auch einiges Kleingeld?
Will you kindly change marks for English money?	Wollen Sie mir gefälligſt Mark in engliſches Geld umwechſeln?
How much do you reckon a pound sterling?	Wie berechnen Sie das Pfund Sterling?
We charge 20 marks for one pound.	Wir berechnen 20 Mark für ein Pfund.
I have 420 marks, that would be £21.	Ich habe 420 Mark, das würde alſo £21 ausmachen
Can I have £1 in silver?	Kann ich ein Pfund in Silber haben?
Do you want half-crowns, or shillings also?	Wünſchen Sie halbe Kronen oder auch Schillinge?

Continued

SPANISH

Continued from page 3497

By Amalia de Alberti & H. S. Duncan

BEFORE proceeding further with the study of the verbs, it may be well to pause for one lesson the more thoroughly to comprehend certain important points which affect one's knowledge of what may be termed the living language of Spain; points which have perhaps not been sufficiently insisted upon in previous lessons. In all languages there is, of course, the literary and the commercial use of words, and while a student who has had his attention concentrated on one or other of these uses, but not equally on both, may truly have acquired a good working knowledge of the foreign tongue, he is in danger of lacking the readiness of application which comes from knowing the varying values of words and modes of composition. We have so far endeavoured chiefly to give in our vocabularies and our exercises such examples as might be considered of "literary" rather than "commercial" use, holding that the knowledge of any language for its own sake should always take precedence over its application to the uses of the market-place. But at this stage it is well that our consideration of Spanish should proceed with increasing regard to the work of, say, a Spanish merchant's office in one of our great cities, or clerical work in one of the Spanish-speaking countries of the old or new world. This also should be mentioned at this point: that in certain of the passages which we have transcribed from standard Spanish authors, words occasionally, though rarely, occur which in more recent years have become somewhat archaic, just as in English speech words are constantly undergoing modification. It should also be noted that the Spanish authors of the past, though the most entertaining and instructive to read, not only make use of certain archaic words, but also of phrases, which, while the student should be familiar with them, are not to be reproduced by him in writing the language. He must avoid such forms as

Destas for *de estas*
Dellos ,, *de ellos*, etc.

All such cases, so far as our readings in this course are affected, are covered by the words and phrases in the following brief vocabulary:

Vocabulary	Vocabulario
The grandfather	El abuelo
The grandmother	La abuela
A share	Una accion
The farmer	El agricultor
Sea water	Agua de mar
The flag	La bandera
A trunk	Un baúl
The library	La bibliotéca
The country	El campo
A desk	Una carpeta
A surgeon	Un cirujano
A merchant	Un comerciante
Inasmuch as	Como quiera que
Destination	Destino
To contend	Disputar
An endorsement	Un endoso
A sculptor	Un escultor
The stars	Las estrellas
To exaggerate	Exagerar
Field flowers	Flores silvestres
A picklock	Una ganzúa
A gipsy	Un gitano
A guarantee	Una garantia
A throat	Una garganta
A sentry-box	Una garita
The gamekeeper	El guarda
Until	Hasta
Heliotrope	Heliotropo
A man of knowledge	Un hombre instruido
Incredible	Increible
A shawl	Un mantón

A doctor	Un médico
Foreign country	Pais extranjero
Picturesque	Pintoresco
A porthole	Una portilla de luz
The cousin	El primo (*fem.*, la prima)
The sunset	La puesta del sol
The hand-bag	El saco de mano
A joint-stock company	Una sociedad en comandita
A slash	Un tajo
The grocer	El especiero
Draper's shop	Tienda ó almacen de tejidos
The uncle	El tio
The aunt	La tia
Wholesale	La venta al por mayor

MISCELLANEOUS PHRASES	FRASES SUELTAS
Let us count our money	Contémos nuestro dinero
To go to the confectioner's to eat pastry, take ices, and drink lemonade	Ir á la confiteria para comer pasteles, tomar helados, y beber limonada
We were fortunate to obtain a private audience of the Pope	Fuimos afortunados en obtener una audiencia privada del Papa
I am glad to come home	Me alegro de volver á casa
The bookkeeper is making up the accounts for the end of the year	El tenedor de libros está haciendo las cuentas de fin de año
This gentleman has a letter of credit upon our house	Este caballero tiene una carta de crédito contra nuestra casa

Importance of Accents. Insignificant as these may appear to a beginner they are really of vital importance, as the omission or misuse of them may entirely alter the tense or person of a verb, confuse verbs with substantives, and one substantive with another.

EXAMPLES. *Yo amo,* I love; *él amó,* he loved; *el amo,* the master or owner

Yo hablé, I spoke; *hable Vd,* speak you; *que yo hable* (subj.), that I may speak (imp); or, let me speak.

El Papa, the Pope; *el papá,* the father.

These examples might be multiplied indefinitely; but they will suffice to demonstrate the importance of thoroughly mastering the use and position of the accent.

Article, Gender and Number. For the present purpose these three may be considered together in their relation to one another. Special care must be taken to make the articles and adjectives agree in gender and number with the substantives and pronouns to which they relate. Verbs must also agree with these as regards number, and likewise in gender, where the past participle is employed adjectively. The rules already given should be carefully studied.

EXAMPLES. *El Emperador Nerón fué cruelísimo,* The Emperor Nero was most cruel.

Esa muchacha es amabilísima, That girl is most amiable.

Tengo una hermosa biblioteca y algunos libros espléndidos, I have a beautiful library and some splendid books.

El mar está placido, The sea is calm.

Las señoras están sentadas en el salon, The ladies are seated in the drawing-room.

La moral de las naciones difiere, The morals of nations differ.

Las casas que tengo compradas no me gustan, The houses which I have bought do not please me.

It might be noted here that a number of words change their meaning entirely according to the gender of the article employed.

EXAMPLES. *El capital* (capital, money); *la capital* (capital of a country); *el corte* (cut); *la corte* (the Court); *el órden* (order, sequence); *la órden* (order, command, mandate); *el papá,* the father; *la papa,* the potato.

Dates, Days, Months. The first of a month is variously called *el primero del mes, el primer dia* or *el dia primero.*

Note that the final *o* in *primero* and *tercero* is dropped when used before a masculine noun.

The days are written with a small letter and, like the dates of the month, are preceded by the article *el.* The months are spelt with a capital: *El domingo, el* 11 *de Septiembre, el mes de Agosto.*

Euphony. This is also a very important point in speaking and writing Spanish elegantly, but fortunately the rule is easily acquired.

Before words beginning with *i* or the unaspirated *h* followed by *i,* be careful to use *é* for "and" instead of the usual *y* (*ee-griega*) Similarly, before words beginning with *o* it is usual to use *ú* for "or" thus:

Ese hombre es cobarde é ingrato, That man is cowardly and ungrateful.

Los caballeros é hidalgos, Gentlemen and noblemen.

Salvo error ú omision, Errors and omissions excepted.

Feminine words beginning with *a* on which the stress falls take the masculine article:

El alma, the soul; *el agua,* the water; *el ama,* the mistress.

Errata. We take this opportunity of printing the following important corrections of a series of errors which unfortunately we were unable to correct in all the copies containing page 2917.

PERSONAL PRONOUNS (Accusative)

Le quiero, I like him
La quiero, I like her
Les quiero, I like them
Las quiero, I like them (f.)

PERSONAL PRONOUNS (Dative)

Le hablé, I spoke to him *or* her
Le dí, I gave him, *or* to him *or* her
Le compré, I bought him, *or* for him *or* her
Le quité, I took from him, *or* her
Les envié, I sent them, *or* to them, *or* to you
Le hablé á él, I spoke to him
Le hablé á ella, I spoke to her
Me dijo algo, lo cual no escuché, He said something to me to which I did not listen [page 3207]

Hemos matado al ladron, We have killed the thief [page 3350]

HISTORY OF ART
continued from page 3678

By P. G. KONODY

RENAISSANCE painting, like architecture and sculpture, was born in Florence, and its cradle is the Brancacci Chapel in S. Maria Novella, with the frescoes of Masaccio, which have been the source from which many succeeding generations of artists drew their inspiration. It was the tendency of the Renaissance to give its due to the human body, to deliver it from the tyranny of the spirit, and Masaccio (A.D. 1401 to 1428) was the first of the painters to represent the nude living and in all its beauty and strength, as in the "Expulsion" and the "Baptism." He also departed from the generally prevailing practice of arranging the figures of his compositions in one row, in the manner of the ancient relief, or of placing them one above the other in diminishing size. His figures occupy their right places in the receding planes of the landscape and live in the surrounding atmosphere. They are full of dignity and expression, whilst the folds of their draperies have the amplitude of the best classic models. Altogether, his work marks an immense step forward in the direction first indicated by Giotto.

Filippo Lippi. His artistic heritage was divided among many of his followers, chief among whom is Fra Filippo Lippi, the worldly friar, whose love of life and beauty found expression in many exquisite easel pictures and in the fine frescoes at Prato and Spoleto Cathedrals. The emotions expressed by him are not purely spiritual, like those of Fra Angelico, but intensely human A healthy, robust type of peasantry served for his models; and his sense of beauty and loveliness and pleasure in the joys of the world is reflected by the gay splendour of his palette. Domenico Veneziano, who is credited with the introduction of oil-painting in Italy, was, above all, a master of technique, a naturalistic painter whose chief concern was the pictorial rendering of movement and expression. Paolo Uccello was a scientist, chiefly absorbed in the investigation of the laws of perspective, and an excellent painter of horses, dogs, birds, and other animals His colour was frequently quite arbitrary, and used almost in the manner of the mediæval illuminators. The National Gallery possesses an interesting battle picture from his brush, illustrating how the field of painting had widened since its liberation from the exclusive rule of the Church.

Representations of Contemporary Life. Under the cloak of scriptural illustration, Benozzo Gozzoli (A.D. 1420 to 1498), a follower of Fra Angelico, dealt in his extensive series of frescoes in the Pisan Campo Santo with general scenes of contemporary life, in which the customs, costumes, and types of his day are recorded with vivacious charm and great truth to Nature. [See page 725.] His frescoes at the Riccardo Palace represent a scene of gorgeous pageantry of fifteenth century Florence. Among those who were strongly influenced by Masaccio, the sculptors Verrocchio and Pollajuolo take a high place in the art of their time, though only few of their pictures have come down to us.

The Art of Botticelli. The Renaissance leaning towards classic learning found its supreme expression in Fra Filippo's pupil, Sandro Botticelli, one of the most personal and fascinating of the world's great masters. His strength lay in the marvellously expressive use of decorative line, the like of which can only be found in the art of Japan. He used colour not so much to deceive the eye into belief of the plastic reality of things as to strengthen the effect of the line. The rhythmic movement of the human figure in dance, the fluttering of drapery or of flowing locks in the wind, cannot be expressed more happily than in his "Allegory of Spring" [71] and "Venus Rising from the Sea." For his compositions he was more concerned with producing a beautiful decorative pattern than with making the figures live in their surroundings, which are frequently quite conventional. Botticelli was profoundly steeped in the "New Learning" of the period, and his pictures often show a curious blending of the Pagan and the Christian spirit. His "Madonna" [page 869] and his "Venus" present very much the same type of face—melancholy, timid, pure, scarcely beautiful, but intensely fascinating.

Filippino Lippi. Botticelli became in his turn the master of the latter's son, Filippino Lippi (A.D. 1457 to 1504), who combined many of his master's qualities with a sense of dainty beauty in expression and rich colour. In his earliest important work, the completion of the frescoes begun by Masaccio in S. Maria Novella, he tried with remarkable success to adapt himself to the manner of his great precursor; but in his later frescoes in the Strozzi Chapel he introduced such a florid mass of "Renaissance" detail, classic architectural motives with a tendency to over-decoration, Roman armour and trophies and instruments, that one is apt to overlook the really remarkable expressiveness in the varied gestures and movement of the figures. His most charming qualities appear quite unadulterated in such easel pictures as his "St. Bernhard," in the Badia in Florence [72], and the "Madonna with SS. Jerome and Dominic," at the National Gallery.

Pietro della Francesca (A D. 1415 to 1495), of Borgo S. Sepolcro, in Tuscany, stands between the Florentine and the Umbrian schools. The transparent golden tone in which his landscape

71. ALLEGORY OF SPRING, BY BOTTICELLI

and figures are bathed in the earliest approach to the modern conception of painting open-air sunlight. He, too, was a master of perspective and foreshortening, and was endowed with a rare sense of pure beauty. One of his finest works, the "Baptism of Christ," is to be seen at the National Gallery. His pupil, Luca Signorelli, of Cortona, the author of a great series of frescoes at Orvieto Cathedral, may perhaps best be described as a painter of human limbs and of muscular activity. He delighted in illustrating scenes in which he could introduce seething, passionate crowds of unclothed humanity in every possible stage of violent movement; but he was not a painter of the "nude" in the modern sense—that is, an artist who will paint the figure for its beauty of form and surface texture. For that his drawing was too hard, his colour too dry; and the charm of the female form escaped his perception.

The Umbrian School. Umbrian painting was an offshoot of the Sienese school, modified by Florentine teaching. It never attained artistic independence, and was always more or less tied to the illustrative tendency. The Umbrians were more concerned with tenderness of sentiment and intensity of religious expression than with form and line and movement for their own sake. A long succession of minor artists, who need not here be enumerated, culminates in Pietro Perugino, the most typical, as he was the most accomplished master of the school. His scriptural pictures—and he painted few, if any, others—are peaceful, serene, detached from this world [73]. He painted the life of the soul and not of the body; and the lovely Umbrian landscapes in which his figures are set, landscapes that open up the whole depth of space, range after range of billowing hills under a limpid blue sky, only enhance the effect of pure spirituality. As a master of space composition he was only surpassed by his great pupil Raphael.

To the same school belongs Pinturicchio, one of the most productive fresco painters of the fifteenth century. The decoration of the Borgia apartments at the Vatican in Rome, and of the library of Siena Cathedral, are his chief works—masterly space compositions which, however, in their excessive love of splendour, of sumptuous gold, ultramarine and red, overstep the natural limitations of decorative wall paintings.

Influence of the Paduan School. Meanwhile, the Renaissance movement had made equal progress in Northern Italy. In Padua, Squarcione, a painter who had travelled in Greece and brought back with him a fine collection of antique sculptures, was the founder of a school based on the study of these antiques. His great pupil Mantegna (A.D. 1431 to 1506) was entirely imbued with the classic spirit, and treated his paintings in a noble, sculpturesque style which has much in common with relief work. His "Triumph of Cæsar," now at Hampton Court Palace, shows the extent of his classical and antiquarian knowledge and his masterly draughtsmanship, though his frescoes in the Gonzaga Palace at Mantua, which have for their subject scenes of contemporary life, show even better the power of his brush. The Paduan school exercised considerable influence over Milanese and Venetian art in the fifteenth century, particularly over Bramantino in Milan, and the Vivarini in Venice, though Venetian painting was soon directed into other channels.

The Splendour of Venice. The powerful mercantile Republic of Venice was never the soil for humanism that Florence had been. Accustomed to gorgeous pageants, pomp and ceremony, and luxurious life, and living in an atmosphere that cannot but develop a keen sense of beautiful mellow colour, these wealthy traders required an art that should be neither academic nor didactic, an art that should not reflect classic knowledge or stimulate thought, but an art that should reflect the splendour of their daily surroundings and appeal direct to the senses through the musical quality of colour. In Florentine painting colour had always been subordinate to line; the Venetians were the first school of real colourists—painters who thought in colour, not in line; who studied the colour appearance of Nature, and rendered the true appearance of things in pigment—true painters, in fact, in the modern sense of the word. The introduction of oil-painting by Antonello da Messina was of inestimable advantage to the achievement of this new ideal in painting.

The Bellinis. The brothers Giovanni and Gentile Bellini show already the germ of the Venetian tendencies which were to culminate in Titian and Tintoretto. Gentile revelled in historical processional pictures of Venetian life, a type of work in which Vittore Carpaccio achieved the greatest fame. Giovanni Bellini's paintings have a noble, classic dignity of style, an almost monumental character. He strove for the typical rather than the individual. His colour is rich and harmonious, though not as sensuous as that of the later masters. Two other masters of the earlier Venetian school must here be mentioned—Carlo Crivelli, a pupil of the elder Vivarini, and strongly influenced by Mantegna; and Cima da Conegliano, whose altar-pieces are full of character and glowing colour. Crivelli, whose love of carefully executed detail rivals the early Flemish masters, is magnificently represented at the National Gallery.

Towards the end of the fifteenth century there was scarcely a city in Italy that was not a centre of some important school, and could not boast of some masters of more than local reputation. When the sixteenth century dawned, painting, though still frequently employed for the decoration of architecture, had to a great extent become an end in itself, independent of the other arts.

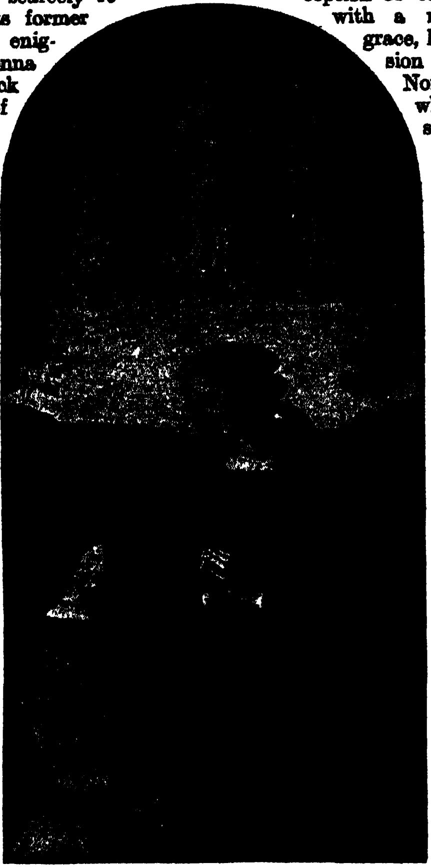
Lionardo and Raphael. Leaving Venice and returning to Florence and Central Italy, we come to the man who inaugurated the greatest period in Italian art—the period when supreme technical mastery went hand in hand with ideal beauty and classic perfection. This man was Lionardo da Vinci, that universal genius who could master and achieve greatness in every phase of intellectual and artistic activity. Raphael was an eclectic who, gifted by nature with a rare capacity for assimilating all that was most admirable in the art of those that had gone before him, consciously combined these qualities in works that have for centuries been held up as the acme of perfection, and have, through academic teaching which encourages the cold, soulless imitation of all that is purely formal, exercised a deterrent influence on the evolution of art. Lionardo, too, had assimilated the accumulated experience of two centuries of painting, but with him this process was unconscious, and though the perfection of his work sounds a unique personal note, there was nothing his brush could not express—emotion or serenity, character or pure beauty, strength or tenderness. He was a master of line and of colour, of movement and expression. Volumes have been

Anderson

72 APPEARANCE OF THE VIRGIN MARY TO ST. BERNHARD, BY FILIPPINO LIPPI

written about the deep significance of every figure in his "Last Supper" fresco, in Milan, now a complete wreck, which scarcely reflects a dim shadow of its former glory. And the mysterious enigmatic smile of the "Monna Lisa" has become the stock phrase of a generation of art writers [76].

Called to the Court of the Sforza in Milan, Lionardo became the head of an important school, from which issued such masters as Luini, Beltraffio, Gaudenzio Ferrari, and the Sienese painter Sodoma. Lionardo himself produced but few finished works, and forms in this respect a marked contrast to his great rival Michelangelo, whose work is truly titanic in character and in extent. His ceiling of the Sistine Chapel alone would be no inconsiderable result [74] of a life's work. We have already dealt with the master's sculpture. In painting he shows the same powerful grasp of the human form, the same passionately heightened vitality, the same grandeur of design. But he was not a colourist in the sense of the Venetians, or of Lionardo. His genius was more sculptural than pictorial. His strong personality attracted many followers, of whom Sebastiano del Piombo achieved great fame, and even Raphael at one period fell under his spell.



Mansell

73. THE VIRGIN ADORING, BY PERUGINO (National Gallery, London)

"The Perfect Painter." Of the other Florentines of the period, Fra Bartolommeo and Andrea del Sarto enjoy the widest fame. The former, a follower of Savonarola's, eschewed all worldliness in his art, and painted in his early period many serious and solemn altar-pieces of great beauty and harmoniously blended, mellow colour, though later in life he attempted more ambitious works of pompous character, but without much significance. Andrea del Sarto, who earned the epithet of "the perfect painter," approached the Venetians in his conception of colour. Perfect in drawing, with a rare sense of beauty and grace, he lacked power of expression and depth of feeling. In Northern Italy, Correggio, whose chief works are to be seen in Parma, is the most typical master of the late Renaissance. An artist of great nervous sensibility, he had little concern with nobility of form and carefully-measured rhythm of line. His art is intensely emotional; the expression of his "Madonna," as of his "Magdalen" and his "Io," is almost ecstatic in its intensity of delight or grief. His real medium is light and shade rather than colour and line, and he almost rivals Rembrandt in his rendering of chiaroscuro.

74. PORTION OF THE CREATION OF MAN, BY MICHELANGELO (Sistine Chapel, Vatican, Rome)

Raphael marks the turning-point of Italian art—Venice always excepted—which after his death degenerates into eclectic mannerism on the one hand and crude naturalism on the other. Of Raphael's pupils, Giulio Romano and Perino del Vaga continued for a while his tradition, but towards the end of the century Bologna took the lead. The Caracci and Guido Reni and Sassoferrato and other eclectics are, however, scarcely worthy of a place in a short survey of the world's art, except to typify the shallow depth to which painting had sunk after its glorious efflorescence at the beginning of the century. The naturalists flourished especially in Naples, where Ribera painted numerous scenes of torture and other horrors with bold use of contrasts of light and shade.

Giorgione. In Venice the sixteenth century is inaugurated by three glorious masters—Giorgione, Palma, and Titian. Of the first of them only few pictures can be identified with certainty, but they suffice to secure him a position among the elect. He knew how to express the emotion of the figures in the surrounding landscape; he was the first, in fact, that did not paint the background merely to fill in a pleasing manner the space between and behind the figures, but made the figures live in their surroundings. He was an idealist whose art was the fruit of his imagination.

75. THREE SISTERS, BY PALMA VECCHIO *Tamme*
(Dresden Gallery)

Palma. Palma, who owed much to Giorgione's example, was intoxicated with the sensuous beauty of Venice and of her daughters, and revelled in painting the luxurious charm of their rounded forms and golden hair [75].

Titian. Titian stands for the highest achievement of Venetian art. He was, perhaps, the greatest colourist the world has ever seen, and could do justice to every task by which a painter may be confronted. That he could express in terms of colour the most exalted emotions of the human soul is proved by such works as his "Assumption," at the Venice Academy [see page 181]. In space composition he rivalled the greatest Tuscans. The sumptuous glow of his colour is only rivalled by the rhythm of his linear composition, and in portraiture he ranks with Velasquez and Rembrandt.

76. MONNA LISA, BY LIONARDO DA VINCI
(The Louvre, Paris)

Tintoretto and Paolo Veronese. While in the later part of the sixteenth century the rest of Italy was given over to uninspired eclecticism, Tintoretto and Paolo Veronese worthily upheld the great tradition of Venetian painting. The former, who had chosen the motto, "The design of Michelangelo, the colour of Titian," was endowed with a fecund imagination, was a complete master of the human form, and of all effects of light, and a gigantic worker, who devoted himself with preference to decorative tasks on a monumental scale. His principal works were executed for the Doge's Palace and the Scuola di San Rocco, in Venice. Paolo Veronese, one of the greatest masters of composition and a sumptuous colourist, was above all the painter of Venetian festive life. His subjects, true enough, are chosen from Scripture, but the scenes are invariably clad in the gorgeous costume of sixteenth century Venice, which they bring vividly before our eyes. He loved the beautiful surface appearance of things, and did not trouble much about their inner meaning. [See Plate facing 3793.]

Canaletto. Tintoretto and Veronese are followed by many florid imitators, but the end of the seventeenth century produced a new "genre," of which the elder Canaletto is the chief representative. He was a purely objective painter of the architectural features of this floating city of palaces, which he recorded with great love of detail, without losing sight of the effect of massed light and shade. Francesco Guardi chose similar motifs for his pictures, but treated them in a less topographical spirit. His brush is more liquid and broad, his tone silvery and creamy, his atmosphere truer than Canaletto's.

Tiepolo. The last of the masters of Venice was Tiepolo (1696-1770), who catered for the craving of his time for florid splendour—a great colourist, who modelled himself on his greater precursors of the sixteenth century, but totally lacking in ideas and expressiveness. He devoted himself chiefly to decorative paintings for ceilings and walls, and died in Spain, whither he had been summoned as painter to the Court of Madrid.

Continued from page 3720

THE VITAL NEED OF PURE AIR

Pure Air is Essential to Health. Sources of Impurity in the Atmosphere. Rain, Sunshine, and Wind as Purifiers. Poisonous Air in our Homes

By Dr. A. T. SCHOFIELD

INORGANIC particles form the third class of impurities in air and include lead, arsenic, zinc, copper, brass, sand, chalk, phosphate of lime, clay, coal, rust, dust of glass, and in special trades dust from saw grinders, cutters, miners, potters, watchmakers and paint workers.

The Evil of Dust. Dust is a great evil as well as a nuisance. It has lately increased greatly in our country roads owing to motor traffic, and has become such a danger and annoyance that it must certainly be lessened, partly by improved structure of vehicles, and partly by a more dustless construction of roads. In towns it has changed in character with the introduction of wood pavements, the ground-up fibres of which make an irritating dust when dry, and a most tenacious mud when wet.

Dust is of three principal varieties—nutritious, harmless and hurtful. Amongst nutritious dusts are those of bakeries, bone mills, and wood turneries. It is said that wood dust actually fattens. Amongst dusts that are, on the whole, harmless, we are glad to reckon coal. Were this not so, life in cities would be very fatal. Anyone who has seen the appearance after death of a Londoner's lungs and a countryman's cannot but be struck with the great difference. The Londoner's lungs are of a greenish black, and are full of grit everywhere, apparently choked with it, and yet the man lives and dies without his respiration suffering; but those of the countryman are a fresh pink, and quite clean. The reason coal dust does not injure and tear the lungs is because the corners of the little particles are not sharp, but rounded. London air is not, therefore, primarily unhealthy on account of the coal dust it contains, but on account of the organic poisons with which it is laden.

Many Kinds of Dust. Hurtful dusts are of several classes—vegetable, mineral, chemical and animal. There are in the first place those that are *vegetable irritants*, which are of no great account unless constantly breathed for a prolonged period. Such is the dust from wool, hair, silk, cotton, flax, hemp and jute mills.

We then get *mineral irritants*, such as dust from stone, glass and sand, and also from metals—steel, iron, and tin dusts, which are very irritating. The peculiar danger of knife grinders' dust is that the trade is conducted in draughty buildings, predisposing to colds and chills, and the dust itself constantly inhaled is a mixture of stone grit and steel dust. These irritating dusts are liable to set up some form of consumption.

It is found that coal-miners have least respiratory diseases, thus showing that coal dust is harmless; while tin-miners are the worst sufferers from lung diseases, which are four times as numerous among them as among coal-miners. Next, we get potters and file makers and cutters, three times as numerous; and then quarrymen and wool and cotton factory hands, twice as numerous. There are, besides, poisonous chemical dusts, such as bleaching powder, bichromate of potash, white lead, phosphorus, and arsenical wall-papers. Besides phthisis, lead dust produces colic; the dust of copper and brass, etc., produces ague, and that of phosphorus causes diseases of the jawbone.

Lastly, and most pernicious of all, there are all sorts of septic animal dusts from hospitals and diseased persons, from manure works, from hides, and from all decomposing animal refuse. Some of the worst of these are the numerous dried particles of expectoration from diseased people, and it is in consequence of this that vigorous efforts are being put forth to make expectoration in public places an offence.

The immediate vicinity of graveyards, brickfields, and infectious hospitals has sometimes a bad effect on health by causing impurities in the air; also the proximity of chemical works and offensive trades.

Breathing as a Source of Impurity. We will now look briefly at the leading sources of these impurities, which are respiration, combustion, stagnation, trades, towns, marshes and invalids.

Of all these sources, respiration—or, rather, expiration—is the chief. In *expiration* each person, if at rest, gives out about ·6 cubic feet of CO_2 per hour, or 16 cubic ft. of CO_2 per day. If the person be at work, much more CO_2 is given out, as the amount rises in proportion to the amount of work done. In hard work it will rise to as much as 1·5 cubic ft. per hour. The expired air, being also laden with moisture, saturates the air with water vapour.

But, besides this, the expired breath is laden with effete animal refuse, and it is *this*, with CO_2, that makes it so pernicious. We have, therefore, three changes in it produced by respiration—it becomes laden with CO_2, with water, and with animal refuse.

It is computed that 2,000 people in one hour produce carbonic acid gas containing 1 cwt. of pure carbon and about 17 gallons of water. The animal matter given off is so poisonous that, if this breath be condensed on the wall of a close room in the form of drops of water, one single drop of the fluid will poison a rabbit.

The skin of the body also expires, or perspires, and from this source also a vast mass of impurities enters the air.

Various Causes of Impure Air. Combustion is another cause of impurity. The burning of gas, lights, and coal fires produces carbonic acid and other gases. But we must note that carbonic acid gas produced in this way is very different from that produced by expiration, for it is free from all poisonous organic particles.

Stagnant air has a diminution of oxygen and an increase of CO_2, and in fogs a great deal of solid matter is suspended.

Trades give off innumerable particles and poisonous gases, and need not be enumerated.

Towns are another source of impurities on account of the crowded life and the indoor existence. In a room there are ten times as many bacteria in the air as there are in town air; and in town air there are ten times as many bacteria as there are in country air.

In addition there is household dust of every sort, and street dust laden with particles of manure.

Poisonous exhalations emanate from marshes, which are also the birth-place of insects that cause malaria.

Invalids are ever giving off exhalations of a specially poisonous nature, while in all infectious diseases the air is laden with contagious particles.

The Health Value of Rain. Agents which cleanse the air from these defilements are rain, ventilation (external and internal), prevention of smoke, plants, sunshine and wind.

Rain is a great purifier of air; how great, but few realise. Perhaps one of the best ways to prove this is to go out with a white waistcoat on a dry day and on a wet day. If rain be prevented from falling on the waistcoat, it will keep quite clean on a wet day Another test is the difference in the taste of the air after rain, for air breathed through the mouth has a decided taste. If we examine rain-water, we shall find it filled with impurities which it has washed down from the air.

In the best systems of ventilation of churches and other large buildings, one of the processes is to wash all the air that is admitted by imitation rain (water running down a fine string screen), thus ensuring its purity. It is therefore fortunate for us in one way that this is such a rainy climate, for there is no doubt that from this cause town air is much purer than it would otherwise be.

A combination of rain and electricity, as in a thunderstorm, not only purifies the air, but refreshes it by storing it with ozone. The air in towns, therefore, is at its best and purest after such a cleansing storm.

Air in Towns. *External ventilation* consists in the ventilation of towns by the abolition of courts, cul-de-sacs and narrow streets. To secure the best air in a town, it should have plenty of parks, and streets 36 ft. wide, with footpaths 24 ft., making at least 60 ft. between the houses, but no back-to-back houses and no places without a through draught. We must remember that the air when it first reaches a town is country air. It is a curious fact that in so many of our towns the west end is the fashionable quarter, and on investigation it is found that this is connected with the question of external ventilation, for in towns where the west end is the fashionable suburb the prevailing wind comes from the west. It is evident, therefore, that those who dwell in this locality get the purest air, for they get it just fresh from the country, whereas those in the east only get it when it has passed over the whole city. *Internal ventilation*, or ventilation proper, is the other aspect of the subject.

The prevention and consumption of smoke are both of great importance, and not only make a town cleaner and brighter, but, through more perfect combustion and decreased use of raw coal, prevent many deleterious products, especially sulphur fumes, from entering the air. It is comparatively an easy matter to prevent smoke in factories; the difficulty is to do away with it in private houses. The remedy will probably come from the supply of electricity at so cheap a rate that heating will be largely done by its means.

Nature's Purifying Agents. Plants, of course, absorb CO_2, and give out oxygen, so that, theoretically, sufficient plants to absorb the CO_2 given out by a man should keep the air perfectly pure. Anyhow, there is no doubt that trees in the parks and in the streets of a city are of great use, and assist in purifying the air.

The sun is a mighty purifier. Not only by its heat and its light, but by the chemical action of its actinic rays, it rapidly burns up and destroys the germs that swarm in the air. It does another thing. It makes the dirt visible, and a person who walks through a sunbeam, where the air, thick with dust of all kinds, can be plainly seen, distinctly hesitates before he breathes such a thick and nasty compound.

The last purifier of which we have to speak is wind. We must, however, point out that it is also a great introducer of impurities as well as a remover of them by assisting ventilation. When all the road-sweepings are blown up in clouds, and all the dust whirls round in eddies, the wind is scarcely acting as a purifier. The steady breezes, which, without so much as raising the dust, cause the air to move rapidly. do much good. Air frequently by this aid travels 10 to 14 miles an hour If you stand in Oxford Street, with such a west wind blowing, the air you breathe is hardly town air at all, for it was over Wimbledon and Barnes Commons a few minutes before, and the town air is quickly blown out to be purified in the country. Wind, therefore, is of the greatest value, for nothing can be worse than stagnant air.

Air Indoors. Some idea will have been formed by now how far we are from breathing pure air out-of-doors, in towns, at any rate; but all this is as nothing compared to the quality of the air indoors, on which we have not yet touched.

There is one country in the world in a high state of civilisation where the question of ventilation is of no importance, and that is Japan. Here, owing to the paper walls of the houses and rooms, and their extraordinary mobility, the air indoors and out-of-doors is more easily kept alike than anywhere else; and it is quite possible that in our intimate associations with

Japan we may find some principles that could be adopted with advantage even here.

Of course, our great difficulty in England is not only the solidity of our houses, but the inclemency and changeableness of our climate, in which nearly every attempt at ventilation causes a horrid draught.

Ventilation is, of course, the science of effectually changing the air indoors *without draught*, and it is a science of the greatest importance to the health and well-being of this country.

Out-of-doors the air is generally in more or less rapid movement, and thus, even in the heart of London, fresh breezes from the country, travelling at from 10 to 15 miles an hour, frequently come from the fields and flowers, and the air is being continually changed. The largest crowd cannot make the air close, and it is only when it is allowed to stagnate that it becomes injurious. Hence the danger of courts and alleys which have only one entrance, the building of which is now wisely forbidden. No; the evil really lies in the extraordinary folly we display in our dwellings, where, as a rule, with every arrangement for comfort and even luxury, none is definitely made indoors for securing pure air for the breath of life.

Poisonous Cottages in Fine Air. It is certainly startling to find what numbers of people are thus poisoned in the finest air in the world. In the country, and in Scotland especially, the death rate from consumption is very high amongst the women in proportion to the men; and this is undoubtedly due to the indoor life of the former as compared with the latter, for any greater contrast between the air of a Highland moor and that of a Highland cottage it would be hard to conceive. It is for a similar reason that so many people derive small benefit from their seaside change. They spend half their time—their nights, at any rate—in such small, stufty, over-crowded and poisonous rooms, with windows that do not open at the top, that the good of the fresh breezes of the day is quite undone.

In the Hebrides, consumption is almost unknown, for the cabins there, built of unhewn stones, allow an abundance of fresh air to enter, while a great square hole, 18 in. in diameter, in the roof, carries off all the foul air. On a large estate on the mainland, where this primitive state of things was with the best intentions done away with, and the rough shanties were replaced with neat cottages, whose walls and roofs were hermetically sealed with plaster and whitewash, and whose windows and doors were close-fitting, the mortality speedily increased, in spite of the greater comfort thus afforded.

Air in Hospitals. Yea s ago, in the Franco-Prussian War, numbers of the wounded soldiers were placed in draughty barns, the hospitals being over-crowded. Cold and comfortless as these barns were, those who were in them got well more quickly than those who were in hospital, simply because they had more fresh air; and similar experiences have repeatedly occurred in other wars. It cannot be too much insisted on that close air is as poison to the sick.

With regard to the necessity of providing pure air in our houses, there is another thought which will bear repeating. As to our food, we can go about and select it when and where we will, and eat it at certain times; as to our clothes, we can choose them where and when we will with equal ease; but as to the breath of life, we are compelled by an inexorable law of Nature to draw in whatever air we happen to be standing in, about 17 times every minute of our lives, day and night, without ceasing, or about 9,000,000 times every year, whether it be pure or poisonous. What an amazing importance, then, attaches to this one question of ventilation!

Gradual Poisoning by Vitiated Air. Another fact also shows the vital importance of thoroughly understanding this subject. The poison of carbonic acid gas is like those poisons (arsenic, etc.) selected by scientific murderers for their victims, in that it is insidious and gradual in its action. By constant habit, greater and greater quantities of it can be taken, profoundly injuring the whole system, though not absolutely destroying life. There are many rooms in which we live, and especially in which we sleep, which get in such a state that a person introduced into them from the open air is nearly stifled.

The reader will soon demonstrate this if, some morning, he will get up and dress and go straight out-of-doors for a few minutes, shutting up the unventilated bed-room, and then return and shut himself up in it and try to breathe.

It must never, however, be imagined that because we can get accustomed to poison, *it does us no injury*. The contrary is the case, and chronic slow poisoning is the worst.

The constant breathing of impure air produces blood-poisoning of the most profound description, known as anæmia. In this terrible disease, all colour goes from the face, and even from the lips and gums; the breath is short, the blood itself watery, and the whole system a prey to other passing diseases.

The Vital Need of Our Lives. It cannot be too widely known that we owe our lives to the power the fresh air has of entering a room and the foul air of leaving it. If a man enters a large dining-room and seals up door, window and chimney, he can exist one hour on the air it contains and no longer; then he will die. His life does not depend on the size of the room, but on its ventilation, and this people so often forget.

Ventilation, then, is the process of introducing into our rooms pure air for inspiration and getting rid of the impure air of expiration freely and without draughts.

One very great difficulty exists with regard to all ventilation, and especially amongst that class whose health is really their wealth and capital, those who earn their daily bread by hard work in towns. We must remember that fresh air is cold, and that impure air, as it is breathed out of our lungs, is warm, nearly blood heat, or 98°, and it is this fact which constitutes the fundamental difficulty in ventilation.

The Royal Commission of 1885 on the Housing of the Working Classes wisely recognises this, and says: "It must never be forgotten that the human body has a desire and a need for warmth, and that fresh air, which is so necessary to the health of a well-nurtured body, chills the half-starved, ill-clad frames of men and women whose homes have been described."

Fresh Air Costs Money! The simple truth is this. The poor find out that by far the cheapest way of warming a room is by their own breath, and they therefore stuff up every crack and crevice, close door and window, and crowd closely together, rigorously keeping out that on which their very life depends—pure air. And were it not for the chimneys in most rooms, deaths directly from this cause would be far more common than they are. Even at sea, some of the foulest air in the world is to be found in the seamen's cabins in the forecastle, which are warmed by the same poisonous means. The difference between pure warm air and foul warm air cannot be too strongly insisted on, and the fatal effects of living or sleeping in close rooms, warmed by the heat of one's own poisonous breath, too plainly pointed out. It is a matter of pounds, shillings, and pence, and the pity is that those who need this pure air most are those who have least of these three things to spare. If the room is to be kept fresh and pure, more coals must be burnt, or more clothes worn, or both.

It is curious, seeing the enormous importance of this subject, that it has not yet been found possibie to apply to the dwellings of the poor any simple way of warming the fresh air as it enters a room. Some of the rich who can afford it adopt a Galton grate, which does this by admitting the fresh air at its sides; but we still think that in the vast blocks of model dwellings rising all over London some way might be found of economically laying on warm fresh air to a flat from a central furnace.

In schools a wholesome horror of rebreathed air should be vigorously inculcated, and its deadly effect shown by experiment, so that when the children grow up, nothing will tempt them to live in close rooms and breathe foul air. Carbonic acid gas, produced by the various functions of life in our bodies, and breathed out with every breath, is a powerful brain and nerve poison. Its effects are intensified when combined with the germs in expired air.

Effects of Poisoned Air. It is this, too, and not always the sermon, that makes people so sleepy in churches and chapels. It is this, and not the lesson, that makes children so listless and fidgety in ill-ventilated schools. It is this, and not hard work, that makes people so dull and heavy when they wake in the morning. It is this, and not mere temper, that makes the wife or the work-girl who has been working in a close room all day so irritable. The need for ventilation is so pressing, as we have shown, that efforts will never cease to come nearer and nearer to an ideal. That ideal is to make indoor air in the country as pure as outdoor air.

It must be remembered that that is the problem—since the foulest outdoor air is purer than the best indoor; and the evil of cities is not the air of their streets, but the indoor lives of their inhabitants. Now, the air out-of-doors contains ·04 per cent. of CO_2, and it has long been found that to attain this standard of purity indoors is practically impossible. By common consent, therefore, the standard of pure indoor air has been made to differ from outdoor; for the former has been raised to ·06 per cent. CO_2, while the latter is ·04 per cent. CO_2. Perfect ventilation may therefore be defined roughly as the science of keeping indoor air below ·06 per cent. CO_2 without causing a perceptible draught.

If indoor air on the average had to be kept actually as pure as outdoor air, about 100,000 cubic ft. per hour should be supplied, which means a movement of 17 ft. per second; but in this climate any movement of the air of over 6 ft. per second produces a draught, and the air must be changed without draught, which shows the necessity of the compromise.

An Analysis of London Air. Outdoor air in the New Cut has 4 parts CO_2 in 10,000.

The following are specimens of indoor air:

Ventilated and fresh ..	6	parts CO_2	in 10,000
Rather close	8	„	„
Close	10	„	„
Very close	13	„	„
Close bed-room	15	„	„
Foul by smell	17	„	„
Pit of crowded theatre	20	„	„
Box of crowded theatre	30	„	„
Crowded school-room ..	37	„	„

The Metropolitan Railway in some parts has 15 parts CO_2 in 10,000.

These results are produced in various ways, of which a rough outline has been previously given, but it may be considered a little further here.

The following are the amounts of CO_2 given off and air used per hour by—

MAN	Cubic feet CO_2	Cubic feet air	WOMAN	Cubic feet CO_2	Cubic feet air.	CHILD	Cubic feet CO_2	Cubic feet air
	Per hour.	Per hour.		Per hour.	Per hour.		Per hour.	Per hour.
Repose ..	·6	3,000	Repose ..	4	2,000	Repose .	·3	1,500
Work ..	1·1	4,500	Work .	·6	3,000	Work or play	·5	2,250
Hard Work	1·6	9,000	Hard Work	1·2	6,000	Hard work or play	1·1	4,500

Now, *the maximum addition to outdoor air for pure* indoor air is ·2 CO_2 per 1,000 ft. If a man gives out ·6 CO_2 per hour, and only ·2 CO_2 can be put into each 1,000 ft., it is evident that he must have 3,000 cubic ft. *outdoor air per hour* supplied to him to put it in. This is the foundation-stone of all ventilation.

Combustion is the next impurity to consider. Two gas burners produce 6·0 cubic ft. CO_2 per hour, or as much as 10 men. If, therefore, a man were shut closely up in a small room he could live one hour in the dark; with a candle three-quarters of an hour; with a lamp half an hour; and with two good gas lights five minutes! But the CO_2 from gas is so pure, as compared with that from human beings, that in this case each cubic foot of CO_2 requires only 90 cubic ft. of air to dilute it per hour.

A Test for Pure Air. Every cubic foot of gas burnt produces half a cubic foot CO_2 and requires 450 cubic ft. of air to dilute, besides fresh air needed for respirating impurities. A simple test for pure indoor air is to fill two bottles (half-pint) with water and empty them in the room you wish to test, so that the air of the room takes the place of the water. Then to one bottle add one tablespoonful of limewater, cork the bottle, and shake it well. If the limewater remains clear the air is pure, and the CO_2 in it is very much under ·06 per cent. If it becomes milky it is impure, the air containing over ·06 per cent. CO_2.

To the second bottle full of air add two tablespoonfuls of Condy's Fluid and shake it. If the colour remains, the air is pure; if it disappears or changes to dirty brown, there is excess of organic impurity in the air.

Cattle require three times as much air as men; a pig the same. The sick require at least a quarter more than the healthy.

Let us look, now, at the ideal and the actual allowance of cubic space of air.

The Air Space We Need. Pure indoor air at 61° contains not more than ·06 per cent. per 1,000 cubic ft. of CO_2 and 75 per cent. of its capacity of water vapour. To maintain this, theoretically, requires a supply of 3,000 cubic ft. of fresh air per hour per human being. It is found, moreover, that, as air can only be changed in this climate three times an hour without draughts, 1,000 cubic ft. of air space is required to admit of the circulation of 3,000 cubic ft. per hour. It is very seldom, however, that 1,000 cubic ft. is allowed. A man himself takes up 3 cubic ft.; a bed, 10.

A common allowance of air space in certain buildings is as follows: factories, 400 cubic ft.; lodging-houses, 240 cubic ft.; public schools and barracks, 600 cubic ft.; hospitals, 1,200 cubic ft.; some London schools, 130 cubic ft.; some Edinburgh schools, 100 cubic ft.; prisons, 860 cubic ft.; infectious hospitals, 2,000 cubic ft.

It has been found in schools that with 230 cubic ft. per head there was ·14 per cent. CO_2, being an excess of ·08 per cent. (with two ventilators open); with 200 cubic ft. per head there was ·32 per cent. CO_2, being an excess of ·26 per cent.; with 100 cubic ft. per head there was ·37 per cent. CO_2, being an excess of ·31 per cent. (with one small ventilator)

This state of things is being improved every year as the principles of good ventilation are more and more widely practised.

Small rooms actually get much more impure than larger ones, even when air is changed at the same rate, owing to the little diffusion, and the clinging of the organic matter to the walls.

Change of Air in Rooms. The rapidity of the change of air in a room practically depends mainly on the difference between the inside and outside temperatures. The mere existence of an opening does *not* make air move. It is when a room is hot and the atmosphere cold that air is drawn in in such quantities. Hence, a small aperture in winter lets in as much air as a larger one in summer. Indeed, there are days when, with all the doors and windows open, the air does not move, and any purification is by diffusion, and not by currents of air.

Air comes direct through walls. It was found that a closed room, containing 3,000 cubic ft., had its entire air changed in one hour when the inside temperature was 65° and the outside 32°. Air should not move more than 5 ft. a second in this climate if there is to be no draught. The opening to admit fresh air for each person is thus 24 sq. in., and is worked out in this way.

Twenty-four square inches is one-sixth of a square foot of 144 in., and if the air moves at 5 ft. per second, five-sixths of a square foot enters this aperture per second; or per hour (60 × 60), 3,000 sq. ft., which is just the amount required by one person. Practically, therefore, seeing 24 in. is a space 6 in. by 4 in., a window 4 ft. wide—*i.e.*, 6 × 8 in.—open 4 in., gives entrance to enough fresh air to supply eight people in a room. Of course, this is without lights. Theoretically, therefore, at night when the lights are on, the operation should be increased; practically, it is decreased; hence, the air in a room is nearly always much fouler at night than in the day.

We are now in a position to consider intelligently the question of natural ventilation; by this we mean the natural movements of air as distinguished from artificial ventilation, by which the air is extracted or pumped in.

SPIDERS, LOBSTERS, & CRABS

Scorpions and their Poison-bags. Spiders. Mites. Gill Bearers. Lobsters, Crabs, and Hermit-crabs. Water-fleas and Barnacles

continued from page 1727

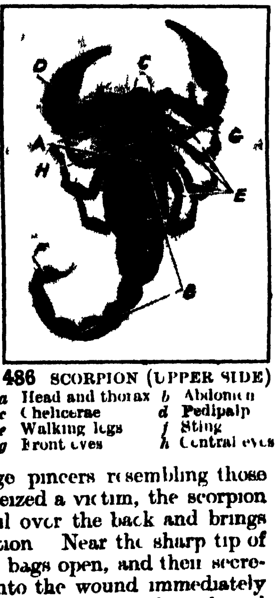
By Professor J. R. AINSWORTH DAVIS

Scorpions and Spiders

Arachnids (including scorpions, spiders, mites, etc), though sometimes popularly confounded with insects, differ from them in a number of ways, some of which are sufficiently obvious The head and thorax are always fused together, and the former does not bear slender feelers (*antennæ*) ; there are four pairs of walking legs ; wings are never present, and the young, when hatched, resemble the adult in form

Scorpions. Scorpions [**486** and **487**] are characteristic of the hotter parts of the globe, but some of the smaller species live in South Europe Here, as in Arachnids generally, the rings or segments which make up the head and thorax are so intimately fused together that their boundaries cannot be seen The segments of the abdomen, however, are very clearly demarcated [**486**], and it is characteristic of scorpions that this region should consist of a broad basal part followed by a narrow "tail," at the end of which a sharp curved sting is situated

The food consists chiefly of insects and spiders, as well as of other small creatures These are seized by means of the first two pairs of appendages, situated in front of the walking-legs The first (*chelicerœ*) are short and terminate in sharp nippers, while the much larger second appendages (*pedipalpi*) bear large pincers resembling those of a crab Having seized a victim, the scorpion raises the narrow tail over the back and brings the sting into operation Near the sharp tip of this two little poison bags open, and their secretion being injected into the wound immediately proves fatal The prey is not chewed and swallowed, but its juices are extracted, the stomach of the scorpion being a sort of suction pump and its mouth exceedingly minute



486 SCORPION (UPPER SIDE)

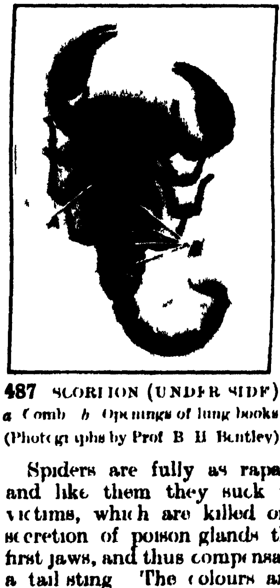
c Chelicerae *d* Pedipalp
e Walking legs *f* Sting
g Front eyes *h* Central eyes

Midnight Marauders. Scorpions lurk under stones and in other dark places, and are nocturnal in their habits In colour they are mostly dull—or even black, harmonising with their surroundings, and thus securing a measure of protection as well as being made inconspicuous to their prey There are two eyes on the top of the head, in the middle, and two groups of somewhat simpler ones on either side, at the front corners of the same region These, however, do not seem to be particularly efficient. On the under side of the body, just behind the last walking legs, are two curious comb-shaped structures representing a modified pair of limbs, and probably serving as organs of touch [**487***a*]

A scorpion does not breathe, like an insect, by means of air tubes, but by four pairs of lung-books, the slits opening into which are easily seen on the under side of the broad region of the abdomen [**487***b*] A large number of delicate plates, resembling the leaves of a book, project into each of them, and hence the name *lung-book* It is in these that the blood is purified

Spiders. These familiar animals differ from scorpions in several respects, as a glance at **495** will clearly show The abdomen, instead of being elongated and clearly divided into rings, is a rounded mass in which the boundaries between these are not visible The jaws do not terminate in pincers, but, in the first pair (*chelicera*), the end joint can be bent down for grasping purposes like the blade of a pocket knife [**488**] The second jaws serve as feelers There are from six to eight simple eyes upon the top of the head



487 SCORPION (UNDER SIDE)
a Comb *b* Openings of lung books
(Photographs by Prof B H Bentley)

Spiders are fully as rapacious as scorpions, and like them they suck the juices of their victims, which are killed or paralysed by the secretion of poison glands that open upon the first jaws, and thus compensate for the absence of a tail sting The colours and markings, as in scorpions, make these creatures inconspicuous, serving the same double purpose Breathing is effected either by four lung books, or, more commonly, by two of these organs together with air tubes resembling those of insects

Web-spiders. The most familiar spiders construct webs of various kinds to serve as snares for their insect prey, a device which fully compensates for the absence of wings Taking the common garden spider (*Epeira* *diadema*) as a type, we shall find that the silk-glands open on six little teat-like projections, the spinnerets, situated on the under side of the abdomen near its hinder end [489]. The ends of these are studded with about 600 minute tubes, some larger than the rest. The fluid which exudes from each of these at once hardens into a thread of almost inconceivable tenuity Every line of the web is exceedingly complex, for it consists of some 600 strands woven together. Hardening takes place much more quickly than if it were in one piece, and it is also very much stronger than it would otherwise be. And yet it is so exceedingly delicate that it is very much finer than the most delicate human hair.

489. SPINNERETS OF GARDEN SPIDER
I — *a* Front, *b* middle, and *c* hind spinneret II — *d* Large, and *e* small silk tubes of a middle spinneret *f*. Threads (much enlarged)

Making the Web. The web of the garden spider, noted for its great beauty and regularity, is vertically disposed in a hedge or some other convenient place, often in the neighbourhood of water, where flies and gnats abound The web is made by the female. To begin with, a roughly four-sided quadrangular *frame* is constructed, the upper side being made first [490]. Fixing the beginning of this thread (A) to a support, the spider crawls horizontally to a convenient distance, spinning as she goes, pulls it taut, and then attaches its other end. The other three sides of the frame (B, C, D) are constructed in a similar fashion.

The second or radial part of the web, arranged like the spokes of a wheel, next receives attention. Climbing to the middle of the upper side of the frame the spider fixes to this a thread (E) and drops down to the lower side of the frame, where the other end is made fast. Ascending to the middle (O) of this vertical thread, she attaches a new one and, ascending to the top of the frame, pulls it tight and fixes it at a suitable distance from the vertical one (F). There are now three completed radial threads, two of which are the upper and lower halves of the vertical line. The radial part of the web is completed in similar fashion.

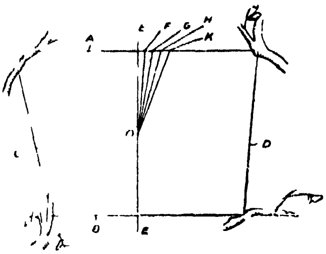
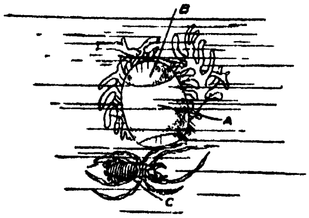
493. A WATER MITE

The numerous radiating threads which have now been made are next united by a spiral one (the *first* spiral), the formation of which takes place from within outwards. This first spiral is then gradually removed and replaced by a *second* spiral, which is of sticky character, and serves to entangle the prey. It starts on the outside of the web, but does not reach the centre, where a piece of the first spiral is allowed to remain. It is here [496] that the ingenious weaver commonly stations herself and patiently awaits the expected booty. In some cases, however, she lurks in the vicinity of the web, and the vibrations of a special "signal line" enable her to tell when a victim has fallen into the toils. It must be added that the exigencies of the case usually involve more or less departure from the type described, especially in the outer part of the web [496].



490 BEGINNING OF A GARDEN SPIDER'S WEB
a, *b*, *c*, *d*. Frame *e* Vertical thread *f*, *g*, *h*, *k*. Radial threads *o* Centre

The Legs of the Spider. The four legs of a spider do not all play the same part in the making of a web The two first pairs are concerned with maintaining the proper distances between the threads as they are spun, while the last two pairs have to do with weaving the same, holding them clear till attachment points are reached, and then securing their fixation. When we further remember that the spider climbs over her web with ease and speed, and without doing it the least damage, we shall not be surprised to find that her feet are of peculiar construction. Each of them [491] bears a couple of comb-shaped climbing claws, extremely smooth so as to obviate



494. WATER SPIDER
a. Nest *b*. Eggs *c*. Spider with air-bubble

entanglement with the web. During the progression on earth or vegetation these are protected by a strong curved "walking claw." The toothed base of the latter helps in weaving, as does also a curious toothed bristle which is present.

Cobwebs. The webs of the common house spider (*Tegenaria domestica*), woven in some convenient corner [492], consist of a horizontal net, the actual snare, and a covered lair at the back of this, where the owner can wait unseen. The lair is provided with a back door or emergency exit. Grains of sand and similar substances are sometimes employed to weight down the web and keep it in proper position.

Gossamer. The floating lines of silk which drift through the air in spring and early autumn are often believed to be the work of a special kind of "gossamer spider." This, however, is not the case. They are spun by young spiders of various species to serve as means of dispersal. The little aeronaut commences operations by standing on some firm object, facing the wind, and spinning mooring-strands. The end of the abdomen is then turned up and a thread woven which streams out in the wind. When sufficiently long to support the weight of the spider the moorings are cut and the little creature is wafted away.

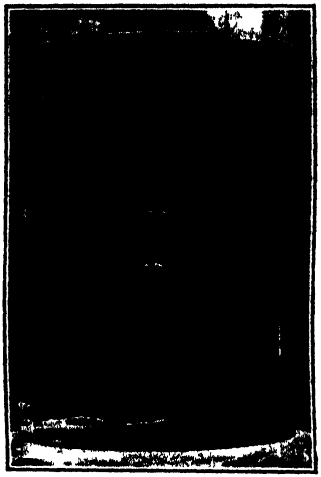
Water Spiders. Among the inhabitants of ponds and ditches in this country is to be found the water spider (*Argyroneta aquatica*), which hunts down small crustaceans but does not construct a web. For the protection of the eggs a thimble-shaped nest is woven [494], moored by threads to stems or leaves, and smeared externally with liquid silk to make it watertight. The nest is filled with air brought down from the surface of the pond in successive bubbles adhering to the hairy body of the spider.

496. WEB OF GARDEN SPIDER (REDUCED)
(Photographs by Prof. B. H. Bentley)

Hunter Spiders. A great many species construct no webs, but use their silk merely for lining their dwellings—which are commonly underground—or the construction of protective investments for the eggs. Such forms simply stalk their prey, seizing the victims when near enough by a sudden spring. One such type is the tarantula spider (*Lycosa tarantula*), which was once supposed to be virulently poisonous. Violent and prolonged exercise was prescribed as the only means of cure, and the dance known as a "tarantella" seems to have been invented to promote this.

The clever trap-door spiders are widely distributed hunting spiders, noted for the neat way in which their underground dwellings are constructed. A cylindrical burrow is dug out and lined with silk tapestry, intruders being excluded by means of a circular door. This is made of particles of earth cemented together with silk, and provided with a strong hinge of the same material. A combined home, lurking-place, and nest is thus provided.

Bird-spiders. Some of the tropical species are of gigantic size compared with our native forms. Well known among them is the bird-spider (*Mygale avicularia*) of South America, the hairy body of which is little short of three inches in length [495]. Its prey consists of insects, other spiders, frogs, lizards, and even small birds.



495. BIRD-SPIDER (REDUCED)

Courtship and Mating. The male spider is relatively small and weak, while the female is apt to be savage, so much so that incautious advances on the part of a lover are not infrequently fatal to him. The body of the deceased furnishes light refreshment. In many species the male is beautifully coloured, and exhibits his charms to best advantage in the course of a weird sort of dance.

Mites and Ticks. These are mostly of very small size, and all three regions of the body are fused together into an ovoid mass. Mites are terrestrial or aquatic [493]. Of the former the cheese-mite (*Tyroglyphus siro*) is the most familiar. Many are parasitic, some damaging cultivated plants, such as gooseberries and currants, others giving rise to certain diseases of animals, particularly itch and mange. Ticks are somewhat larger forms, which suck the blood of various mammals, and even attack human beings. They pierce the skin by means of their sharp proboscis, and only let go when gorged with food.

GILL BEARERS

King-crabs. These remarkable creatures live in shallow water on the western shores of the North Atlantic and Pacific, feeding chiefly upon marine worms They are the last survivors of a waning group, and in some respects resemble arachnids, though they breathe by means of gills and are also allied to the crustaceans The front part of the body (head and thorax) is covered with a strong semi-circular shield [498], on the upper side of which the eyes are situated. This region bears six pairs of limbs, corresponding to the chelicerӕ, pedipalps, and walking-legs of a scorpion or spider. Their bases surround the elongated mouth, and are roughened to serve as jaws The last pair are used for digging

The rings making up the abdomen are also fused together, protected by a shield above, and bearing a tail-spine which serves to right the animal if accidentally turned on its back. There are plate-like abdominal limbs, on the upper surfaces of which delicate folds play the part of gills.

501. HERMIT CRAB AND SEA ANEMONES
(Photographs by Professor B. H. Bentley)

Eurypterids and Trilobites. These are two ancient groups of animals, long since extinct, but resembling the king-crabs in some respects Many of the body rings were distinct. Some of the Eurypterids [505] were as much as 6 ft. long—for details see GEOLOGY.

Trilobites [497], which came into existence long before the Eurypterids, were mostly of small size, the largest species not exceeding a length of 1 ft There were delicate feelers on the head, and numerous slender forked limbs, some of those in front being modified into jaws. Eyes, sometimes of great size and complexity, were usually present, but some species were blind. Certain kinds were able to roll themselves up like hedgehogs when alarmed.

Crustaceans. This large class of jointed-limbed animals includes lobsters, prawns, shrimps, crabs, and other familiar forms, the great bulk of which are aquatic, though the wood lice have become adapted to a life on land. The body is clearly divided into rings, though those of the head are fused together, and this is more or less the case—in higher forms—for those which compose the thorax Limbs are borne on all three regions of the body, and are typically forked, but in many instances the outer branch of the fork has been lost The head bears two pairs of feelers Crustaceans commonly hatch out as free-swimming larvæ, more or less like the adult in form.

Higher Crustaceans. In these the body is made up of 20 rings, 5, 8, and 7 of which belong to head, thorax, and abdomen respectively There are two large compound eyes, and the larval form is known as a *zoœa*, distinguished by the possession of a large shield covering the front part of the body, and a slender, limbless abdomen [506] The group is divided into (*a*) stalk-eyed and (*b*) sessile-eyed forms.

Stalk-eyed Crustaceans. The lobsters, crabs, etc., included in this subdivision possess a strong shield or carapace, belonging to the head and thorax, all the rings of which are intimately united into a solid mass. The horny covering of the body is more or less strengthened by limy matter, so as to constitute a hard "crust," whence the name crustacean (Latin *crusta*, a crust). This is unable to increase in size as the body grows, and is therefore cast off or moulted periodically. The lack of mobility in the front part of the body that results from fusion is partly compensated by the stalked eyes, which can be moved about to a considerable extent. The members of the group are often known as the "ten-footed" crustaceans (*Decapoda*), because there are ten obvious limbs —the two great pincers and four pairs of walking-legs—all belonging to the thorax.

Large-tailed Decapods. These include lobsters, crayfishes, prawns, and shrimps, all marine except the crayfish, which lives in rivers. It will be convenient to take the last-named as a type [499]. The large tail consists of seven segments, all bearing appendages except the last (telson). These are forked paddles (swimmerets), which constantly swing to and fro, keeping up a current of water useful for breathing purposes; besides this they are used to some extent in swimming (especially in shrimps and prawns). The eggs of the female are attached to them, and are thus well protected up to the time of hatching.

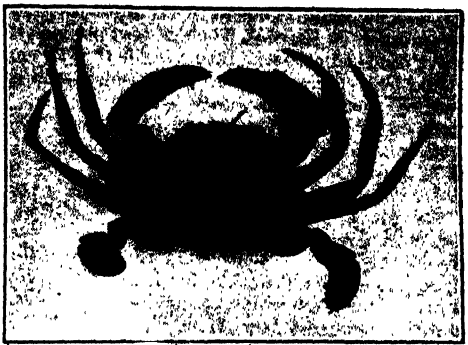
504. SHORE CRAB WITH (A) SACCULINA ATTACHED
(Photographs by Professor B. H. Bentley)

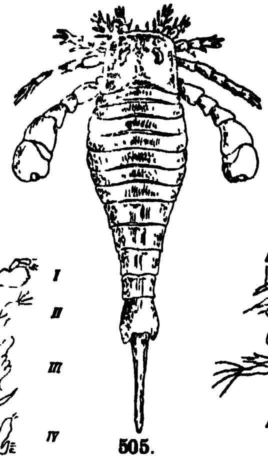


502. SWIMMING CRAB

The Swimmeret. A swimmeret [507] consists of a short stalk, an outer branch, and an inner branch. In those borne by the last segment but one the stalk is very stout, while the outer and inner branches are broadened into plates which, together with the telson, make up a powerful tail-fin. Swimming is effected by powerful downward movements of the tail (abdomen), during which the tail fin is spread out to its fullest extent. By this means the crayfish is propelled rapidly backwards. Every time the tail is straightened in readiness for a downward stroke, the tail fin folds up, so as to reduce the resistance of the water as much as possible. The front part of the body, covered by the carapace, is divided by a neck-groove into head and thorax. On either side of the latter is a chamber containing a number of plume-like gills. They are covered by the side of the carapace and thus protected from injury. The pincers and walking-legs borne by the last five segments of the thorax have lost the outer branch seen in the swimmerets. These are present, however, in the three pairs of *foot-jaws* [508] attached to the first three segments of the thorax and helping to break up the food. Some of the gills are attached to the thoracic appendages.

Powerful Jaws. The last three of the five head segments bear *jaws* [508], named, from behind forwards, *second maxillæ*, *first maxillæ*, and *mandibles*. The last (which, like the first maxillæ, have lost the outer branch) are extremely powerful. An oval plate, the *baler*, is attached to the second maxilla, and lies in the front of the gill cavity. Its constant movements help to keep water moving over the gills. Jaws and foot-jaws alike move from side to side. These biting structures are supplemented by a complex chewing arrangement, or *gastric mill*, contained within the stomach. This is present in all the higher crustaceans.

In front of the jaws are two pairs of forwardly-directed feelers (*antennæ*). The hinder pair are large and relatively long. They are chiefly concerned with touch, and constantly describe sweeping movements. The small first feelers are obviously forked, and have to do with both touch and smell, while an open sac is lodged in the base of each. Though this is often described as an organ of hearing, its chief, and perhaps its only, use is to assist in maintaining the balance of the body by acquainting the crayfish with its varying positions in space. The front end of the carapace tapers into a sharp spine, on either side of which is a deep notch occupied by the stalked eye.



505. EURYPTERID

Relatives of the Crayfish. The marine relatives of the crayfish hatch out as larvæ, but such an arrangement is unsuitable for life in rivers, for these would be unable to resist the current, by which they would be swept down to the sea to perish. The crayfish that is just hatched closely resembles the adult in appearance, and for some time holds on to a swimmeret by means of its sharp pincers. Even when somewhat further advanced it receives a share of maternal protection, sheltering under its mother's tail on the approach of danger.

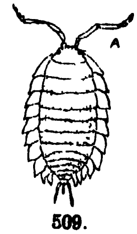
a. Stalk
b. Outer, and
c. Inner branch

Among other long-tailed crustaceans the little Æsop prawn (*Hippolyte varians*) is of particular interest on account of the way in which it is able to change colour for protective purposes. A red, green, or brown livery is assumed, according to the hue of the seaweeds among which it lives. On the approach of night it changes to a beautiful blue, but the meaning of this "sunset" colouration is not fully understood. Some of the deep-sea prawns are blind, others possess enormous eyes, and many emit a phosphorescent light.



509. WOOD-LOUSE
a. Eye

Short-tailed Decapods. These are the *Crabs* [502-4], in which a swimming habit has been abandoned for a creeping one. The head and thorax are enormously broadened out, while the insignificant and dwindled tail is tucked up on the under side of the body out of harm's way. All crustacea are scavengers, but the crabs are notoriously so. Some of them have taken once more to swimming, but not by means of the tail, which has been too much reduced to be again enlarged for the performance of its original function. The swimming organs are here the last pair of walking-legs, which have been broadened out into paddles [502].

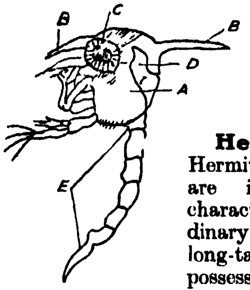
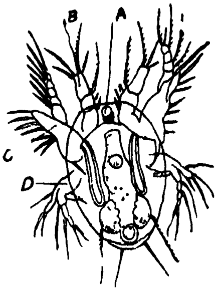
l. Abdominal limbs

Protective Colouration. Most crabs are so coloured and marked as to resemble their surroundings, thus escaping to some extent from their numerous foes. Others are protected by a chevaux-de-frise of long, sharp spines. Others, again, make themselves inconspicuous by cultivating seaweeds or sponges on their backs. Sponges smell and taste unpleasantly, besides which they are full of sharp spicules; and hence, fishes and other enemies leave them alone. We also find a sort of comradeship between certain crabs and sea-anemones attached to their carapaces [see Plate facing page 4081]. The anemone gets carried about and, therefore, has a better chance of securing food, while its stinging powers go far to shield its messmate against attack.



506. ZOAEA LARVA
a. Shield b. Spines in shield c. Eye
d. Heart e. Abdomen

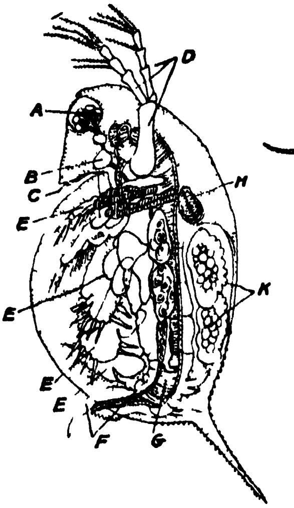
Hermit Crabs. Hermit crabs, which are intermediate in character between ordinary crabs and the long-tailed lobster tribe, possess rather long tails, which are, however, quite soft and defenceless. To make up for this the empty shell of a sea-snail is used as a covering. Upon this shell one or more sea-anemones are usually found as messmates [501]. From time to time a new and larger shell has to be appropriated, to which the hermit crab is said to transfer his guardian anemones.



510. NAUPLIUS LARVA
a. Unpaired eye b. First feelers c. Second feelers
d. Mandibles

Sessile-eyed Crustaceans. These are much smaller than the stalk-eyed forms, and only the front ring of the thorax is fused with the head. There is but a single pair of foot-jaws, and the eggs are sheltered in a brood-chamber on the under side of the thorax. The eyes are devoid of stalks, giving origin to the name *sessile*. The group includes (*a*) sand-hoppers and their allies, and (*b*) slaters. The *sand-hoppers* and their allies are distinguished by the strongly bent body, which is greatly flattened from side to side [511]. This not only promotes swimming, but also springing, the latter movement being particularly obvious in the common sand-hopper (*Talitrus*), which lives in vast numbers between tide-marks on sandy shores

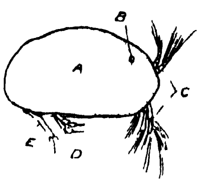
Slaters are creeping forms with the body greatly flattened from above downwards This is an adaptation to life in chinks and crevices Sea-slaters are common on rocky coasts, but the most familiar crustacean of the kind is the land-slater or wood-louse (*Oniscus*) [509], common under stones and in the crannies of old masonry An allied form protects itself by rolling up The water-slater or water wood louse (*Asellus*) is a common inhabitant of our ponds but its numbers are kept down by many enemies, of which the water spider is one of the most formidable



512 WATER FLEA
a Compound eye *b* Brain *c* First feeler *d* Second feeler *e* Thoracic limbs *f* Abdomen *g* Intestine *h* Heart *k* Embryos in brood pouch

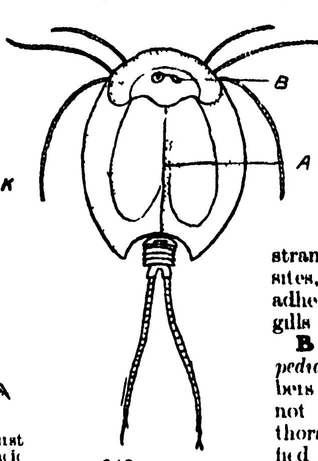
Lower Crustaceans. These are generally small or even minute creatures, presenting considerable variation as to the number of the rings and the character of the appendages They commonly hatch out in the form of an oval *nauplius* larva [510] which rows itself about by means of the feelers and mandibles, the only appendages present at this stage There is a simple unpaired eye

Gill-footed Crustaceans (*Branchiopoda*) These forms are so named because their flattened limbs are used for breathing purposes and bear the gills when these are present One of the largest and most interesting types, Apus [513], lives in stagnant water, and possesses a large head shield which covers the chief part of the body It rows itself along on its back by means of the numerous leaf like appendages, to which soft, pear-shaped gills are attached Much more specialised are the water fleas one kind of which (*Daphnia*) [512] abounds in ponds and is a very attractive object for the microscope The tail is greatly reduced, and most of the body is enclosed in a large bivalve shield The enormous second feelers are used as oars Between the shell and upper side of the body is a space used as a brood-pouch Mussel-shrimps (*Ostracoda*) are small forms which swarm in both salt and fresh water The tail is reduced to an insignificant stump, as in water fleas, and the whole of the body is enclosed in a strong bivalve shell [514]



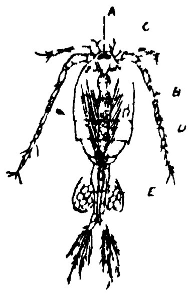
514 MUSSEL SHRIMP
a Shell *b* Eye (showing through) *c* Feelers *d* Legs *e* Abdomen

Fork-footed Crustaceans (*Copepoda*) These minute creatures live in vast shoals at the surface of both salt and fresh water, and receive their name from the shape of most of their appendages The female of a common freshwater species (*Cyclops*) is here figured carrying her pair of egg bags [515] The feelers are the chief swimming organs The members of this group are of great economic importance, for they figure largely in the food of fishes, such as, for example, the herring Many of them are strangely modified parasites, which may be found adhering to the skin or gills of fishes



513 APUS
a Shield *b* Eye

Barnacles (*Cirripedia*) In those members of this group that are not parasitic most of the thoracic limbs are modified into long, hairy filaments, used as a sweep net to produce food The tail is reduced and the body fixed by its head end to some firm object as well seen in the ship barnacle (*Lepas*) [500] and the acorn barnacle (*Balanus*) which abounds on rocks between tide marks In both cases the body is protected by shelly plates, but the head end of a ship barnacle is drawn out into a long, fleshy stalk



515 CYCLOPS
a Eye *b* First and *c* second feelers *d* Intestine *e* Egg bags

Many creatures of the barnacle kind are degenerate parasites a remarkable example being afforded by a form known as *Sacculina* of which the adult female will be found attached to the under side of a crab's tail [504] Dissection shows that this is provided with branching root like threads, which ramify within the body of the unfortunate host, extending even into the tips of its legs These absorb the blood of the crab to serve as nourishment for the parasite, which is little more than an egg producing arrangement The life history, however, proves that Sacculina really belongs to the lower crustacea, for it hatches out as a typical nauplius larva

JOURNALISM, THE IDEAL CAREER

The Fascination and Power of Journalism. The Character of the Journalist. Sincerity a Decisive Factor. The Sense of Wonder

By ARTHUR MEE

THERE is a calling that makes a man a king. The man who, having a thought, has discovered the secret of spreading his thought throughout the world, is a king among men. To this royal line belong Plato and Shakespeare and Herbert Spencer, and a great host whose names would make a longer list than those of lesser kings and queens whose names we learnt at school. All civilised countries, says Carlyle, are governed by books.

The Democracy of Journalism. At the gates of the kingdom of letters lies the broad field of journalism. Here, at his will, with no sceptre but a pencil, with no authority but his intellect, with no force but that of character, a man may sit and earn his bread and rule the world. No career that is open to man can compare with it. No career can place a man so quickly on the very heights of power, can invest a man so simply with all the possibilities of fame. Journalism is the most truly democratic of all callings. It is open to all, yet on the roll of its followers we come continually across the names of poets and statesmen and the very elect of the earth.

It has been a greater power in the world than any mechanical force controlled by man; it has controlled those forces. In the history of mankind newspapers have been stronger than armies. Napoleon feared four hostile papers more than a thousand bayonets—"a regent of sovereigns, a tutor of kings," he said of the journalist.

The Power of the Journalist. And, in truth, it is no exaggeration to say that the power of the journalist cannot be exaggerated. If he cannot make laws, he makes the lawmakers. He is the silent force in every Parliament, the unseen factor in every polling booth. He is present, invisible, in every Cabinet. Not a prince upon his throne, not a draper behind his counter, is beyond his reach or outside his interest. He has, by right of mind alone, the open sesame to every place. No door is locked to him; even those doors most jealously guarded are open, though the public knows it not, to the journalist who can keep a secret better than he can tell it. He is everywhere, always. Nothing happens that he has not seen; there is no corner of the world to which he has not been. He has the master key of government—at his command is the only vehicle in the world by which one man can communicate instantly with all other men. He can make wars and bring peace; he can make revolutions and destroy them. He has more power in the market than the Stock Exchange. Even the scales of legal justice may be subject to his will.

Without him life as we know it would be impossible. He stands between light and darkness, between social peace and civil war, between democracy and despotism, between the freedom of the twentieth century and the inquisition of the Middle Ages. He is the guardian of the liberties of the human race.

Well may the journalist be proud of his calling. To him who cannot be a statesman or a king, or who finds the golden gateway of letters closed to him, journalism offers a power and joy of life which perhaps nothing else can give. One man may find a country hitherto unknown, another may discover a new source of energy, the astronomer may discern a new star, the chemist may reveal new marvels in creation, the engineer may span a great gulf with steel or save the time of the world by cutting a great canal; but there can be nothing in these things, momentous as they may be to the world, comparable with the shaping of the world's thought which is the power of journalism.

The Reflector of Human Life. Neither exploration nor engineering, no kind of business, none of the professions, not science itself, can give a man so wide an interest in life as journalism. The astronomer reading the stars, the engineer constructing a waterway, are interested in their own achievements, but not necessarily in each other's. It has nothing to do with the engineer that the organic world would come to a standstill if chlorophyl could be destroyed; the chemist in his laboratory is unconcerned that the voyage to India has been shortened by ten days through a great canal. Neither is *necessarily* interested in the work of the other. It is the glory of journalism that the journalist is, *must be*, interested in both.

Since journalism is the reflector of human life, nothing in human life can happen that is outside its scope. As memory, whether we will or not, engraves upon itself the everlasting remembrance of everything we see, or hear, or do, or know, so journalism brings all life, all activities, all thought, all labour, into its boundless field. Nothing is too trifling for its interest, nothing can be too important for its debate. The analogy, indeed, may go farther, and become exact. As the mind edits the memory, calling up at will those things which interest it, whether facts, or scenes, or men, or things, whether they have been treasured there 50 years or only 50 hours, so the mind of the journalist edits the happenings of every day and every hour, lays them out upon his sheet before him, appreciates this, questions that, casts aside the other, and presents his picture to the waiting world with a judgment born of an intimate relation with men and a knowledge of the relative values of things.

A Daily Record of Good and Evil. The whole world is alive to the journalist who knows his work and is in earnest. The well-edited newspaper has no "dull" season. Until the world is a dead place, until men cease to think and roses cease to smell sweet, life can never be dull to the journalist worthy of the name. What, indeed, could be more full of tragic interest than the very despair of a man whose business it is to watch and interpret the ceaseless panorama of human life who wakes up in the morning to see the panorama passing before him, but finds that "there is nothing to write about to-day"?

It can hardly be too strongly insisted upon that the business of the journalist is to give to the world a living record of its own life. It is, no doubt, to be insisted upon as strongly that there are things with which the journalist has no business; but, on the whole, the editors know their business a great deal better than the critics who would teach them. It can never be admitted that the journalist should give only the better side of things. Those mistaken advocates of a journalism which would whitewash the world, of newspapers which would fill our minds with only pleasant things, have never surely thought for an hour of what would happen if they had their way.

Let them imagine a patient who hides his symptoms from the doctor, a witness who keeps back vital evidence from the judge. If the power of journalism is anything but a phrase, it depends chiefly or entirely upon its unique capacity for the exposure of wrong, the denunciation of tyranny and injustice. Could we ever hope that the world will one day be free from the curse of drink, if it were not that its trail of sin and ruin runs across every paper we pick up? Could we ever hope that the poor will one day be better housed, if it were not that every paper in the land is filled with pictures of the wretchedness of their lives?

Should an Editor Lose His Temper? Let us remember, in making up our minds to be journalists, that a simple picture of something that exists is sometimes the most powerful agent in improvement that could be devised. There are times, no doubt, when good men feel that journalism oversteps its bounds, when good men would welcome for an hour a censorship of the Press. But only for an hour. And, after all, it is still true in these times that the newspapers reflect the nation. Shall we, then, censor a nation?

"Is it not, then," the young journalist may ask, "the greatest tribute that can be paid to the newspapers to say that they reflect the nation in its hot temper as well as in calm, in its worthiest and least worthy moods?"

That would be so if there did not enter into our consideration here a vital function of journalism which the true journalist can never overlook. It may be held, no doubt, that the entire business of the journalist is to hold a mirror up to nature and reveal the world unto itself. That, once upon a time, was true in practice; in theory it is admirable still. Nothing could be better for an ideal world.

But there has grown up in the development of civilised societies a mysterious and wonderful factor, with the full authority of a judge but without the limits of a court, sitting in judgment over the good and evil of society at large. It is the newspaper editor.

And, just as a judge, though the system of justice he administers reflects the average sense of justice in the nation, is still calm and unmoved by the excitement in the streets outside, so the editor, though his paper reflects the average mind of his reader, should be unmoved by the wild temper of the mob and calm amid the dangerous excitements of the hour. Who claims the right to sit in judgment must prove himself fit to be a judge.

It is one of the misfortunes of journalism as a profession that it attracts to itself men who enter upon it as a career without an adequate sense of its importance or a serious consideration of their fitness for it. The very democracy of journalism, which is one of its finest characteristics, is in some senses a drawback. Open to all, demanding no tools but a pencil and a notebook, with pleasant prospects and "quick returns," it is not surprising that the newspaper offices are besieged, and that the number of people who would gain a livelihood by writing for magazines is ever increasing.

Character and Learning. At the very outset of our course let us emphasise for ourselves a truth of the utmost importance.

The road to success in journalism is as free as the air we breathe, and we need have no sympathy with any attempt to make journalism a close profession—a profession, that is, which can be entered only through a particular door, under particular conditions. It is as impossible as perpetual motion, and we need not consider it.

But it does not follow from this that there is no need to guard the gates of journalism, as the gates of medicine, of law, of banking are guarded—though not by the same means or for the same reason. There is no way of closing the door of journalism against a man who has not passed an examination. Such a rule as that, if any means existed of enforcing it, would have made it impossible for Herbert Spencer to be a journalist, for Herbert Spencer never passed an examination. A journalist without education is, of course, a contradiction in terms, but education is not the only, not even the chief, bulwark of journalism. It is not *learning* but *character* that should be the decisive factor in the choice of journalism as a profession, and it is a thousand pities that men should enter upon a career so full of responsibility, so fraught with possibility, without realising that journalism is something more than a wage-earning career. The surgeon who would perform an operation solely for his fee, without any regard to the value of life, and the journalist who writes purely for his pay, without any regard to the effect of his writing, belong to the same category of men who are unworthy of their profession.

The Two Kinds of Journalism. It does not follow, of course, that a journalist must have settled convictions about everything on which he writes. That cannot be, nor is it necessary. Journalism is of two kinds—the kind that *interests* and the kind that *influences.* We may compare them with a public meeting called together in support of a particular cause, and a lecture by, say, Mark Twain, whose business it is only to entertain.

It would be impossible to defend a speaker at a public meeting who moved a resolution in favour of a cause to which he was in his heart opposed, but Mark Twain need not be called upon to defend anything he may choose to do or say in entertaining his audience. We do not ask Mr. Pett Ridge to substantiate his statements, or whether he really believes in them, and, happily, the vast majority of journalists are in the same position It is not necessary for them to perjure their conscience, or to sink in the esteem of sincere men, by writing what they do not believe.

There is another side to journalism, however—a journalism which shapes opinion ; and here it cannot be too emphatically said that the first of all considerations is sincerity. The journalist who cares for the honour of his calling cannot have too great a contempt for the man who brings his mind but not his soul into work which should engage his deepest feelings and enlist his warmest sympathies. There are hundreds of men, it is true, who make a living to-day by writing in absolute contradiction of what they wrote yesterday, and who will make a living to-morrow in denying what they wrote to-day But we need not call them journalists. We could much more correctly describe them as men who will sell their souls to anybody who will pay for them, or, in the slang of the profession, penny-a-liners, or sixpence-a-liners, according to the profit their empty phrases bring them

We may have opportunities of discussing this matter again ; but to the candidate for journalism it may be said here that the man who will write anything he is paid to write never rises high in his profession. The great names in journalism are those of men who wrote finely because they felt deeply, who wrote interestingly because they thought earnestly.

Factors in the Journalist's Success. It is not an exacting demand that journalism makes upon those who would enter its ranks. The man who brings to it a clear head, plenty of common sense, good judgment, a sense of the relative importance of things, an average experience of the world, a capacity for interesting himself in anything and of expressing himself plainly, is likely to succeed.

He must have many other things, of course, which we shall have to consider in their place. He must never, for example, admit to himself that the age of wonder is past. A sense of wonder—with something in it of the surprise of the little child that the stars do not fall from the sky, with something of the terror of the child at the approach of an express train—is a gift for which a journalist can never be grateful enough.

Is it a commonplace thing to you that from three seeds should come in one place a violet, in another a wallflower, in another a turnip ? Can you take down the telephone or send off a telegram without feeling that you are touching a miracle ? Can you stand in a country lane at night watching a well-lighted train flying through space with a thousand lives without feeling that here is something of the majesty of man and the supremacy of mind ? Are these things nothing to you ? Then there may be somewhere in journalism a bushel under which you can sit and hide the little glimmering of light that may come from your mind ; but you will not do great things. You will not interest a vast public in the things that happen day by day. You will not take up a book and make it live. You will not think of a great idea and stamp it on the minds of your fellow-men. You will not carry your reader into a world of imagination where you can do with him as you will.

You will find that the world prefers somebody else's poetry to your prose, and you will wish, when it is too late, that you had earned your bread at something wanting less of the wonder of a little child than journalism.

The Journalist at Home. One other aspect of journalism may be touched upon here The journalist leads " the intense life that eats into the souls of men," and one point may be insisted upon as of great practical importance to the candidate for this strenuous career. It is his domestic atmosphere. If it is the attraction of journalism that all life comes into it, it is also its great temptation. For, obviously, if all that happens comes into his work, nothing that happens will take him away from his work. The power of detachment, the capacity for putting things out of his mind, is of the greatest value to him, and no means of reaching this happy state of being is so easy and so simple as sympathy at home. Congenial friends, sympathetic interests, pleasurable associations, are half of life to us all, but to the journalist wrapped up in his work they are much more than half the secret of a happy life. The accountant goes home from his office leaving the world of figures behind. The merchant finds at home a welcome pause from the stress of business. The shopkeeper puts his work out of his life when he puts up his shutters. The journalist takes his work home, for his work is life itself.

Of profound importance to him, therefore, are the atmosphere in which he lives and moves and the hours which belong to himself, when, if ever, he may be encouraged to detach himself from the things that possess him, to change his mental vision, to find fresh stimulus in the affections and pleasures of home.

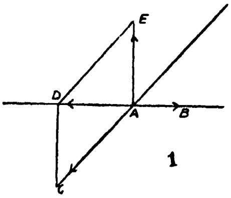
RAILWAY CONSTRUCTION
continued from page 3752

By C. O. BURGE, M.Inst.C E.

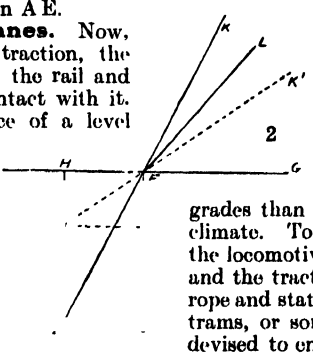
RACK-and-pinion railways have been devised to overcome the difficulties arising from the slipping of the engine wheels when excessively steep gradients have to be negotiated in mountainous districts, and are therefore much used in Switzerland and similar countries for tourist and other traffic. To understand the necessity for some such contrivance as a rack-and-pinion arrangement, which adds considerably to the cost and maintenance of a line, the following law of physics must be recognised.

If on a fixed horizontal plate of smooth steel a steel rod be pressed vertically, no action will take place ; but if the top of the rod be gradually inclined, with the pressure continued, until a certain angle between the rod and plate is reached, the point of the rod touching the plate will slip. This angle is called the *angle of repose* or *friction*, and it differs according to the nature of the materials in contact. In this position [1] the friction, represented by A B, is insufficient to counteract the resultant A D [see MECHANICAL ENGINEERING, page 411] of the pressure A C, and its reaction A E.



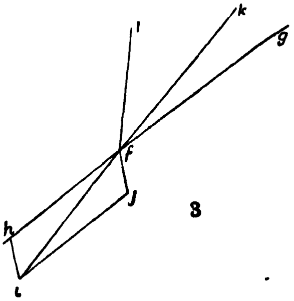
1

Weights on Inclined Planes. Now, let us apply this to railway traction, the smooth plate being the surface of the rail and the rod being the wheel at its contact with it. Let H G [2] represent the surface of a level railway. Let the length F J represent the weight on the driving wheel of an engine, and F H the force which it is able to exert—that is to say, the pressure—in the direction F H, at the circumference of the wheel, which, if resisted by friction at F, represents the tractive force drawing the train, including the engine, in the direction F G. The resultant of the pressure of gravity, F J, and the resistance, F H, of the train is F I, which, produced towards K, makes an angle G F K with the rail H G. Now, let G F L be the angle of friction of steel on steel. It is evident, therefore, that if this angle be less than G F K, the steel of the wheel will not slip on the steel of the rail, and the force of the engine, exerted against the surface of the rail at F, will be utilised in drawing the train in the direction F G.



2

Two conditions may vary the angle G F K and destroy this result. First, the weight F J on the driving wheel may be reduced to, say, F J′, when the angle G F K′ will be less than G F L, and the engine will become powerless through the wheel slipping; and, secondly, the railway may be on such an incline as in *h g* [3], when the resistance of gravity is added to such an extent to the ordinary resistance of the train that the resultant *f i*, produced towards *k*, forms a smaller angle with *hg* than the angle of friction *g f l*, and the engine loses its hold, or *purchase*, as it is called. Hence, given the weight on the driving wheel and that of the train, there is a limit to the grades on which ordinary adhesion suffices. By multiplying the driving wheels by coupling them, and by the locomotive carrying its own supply of water with it, in the form of what is called a *tank* engine, so that more of its weight may be utilised on the drivers, and *f j* and the angle *g f k* increased accordingly, the limiting grade may be extended.



3

Locomotive Power on an Incline. The angle of friction of steel on steel varies with the weather, the greasy state of the rails affecting it; but, ordinarily, an engine, even with all wheels coupled, can seldom take any reasonable load beyond its own weight up steeper grades than 1 in 15 to 1 in 20, according to climate. To overcome such inclines, either the locomotive must be abandoned altogether and the tractive force supplied by means of a rope and stationary engine, such as in the cable trams, or some special contrivance must be devised to enable the locomotive to retain its hold on the rails. Such a special contrivance is the rack and pinion.

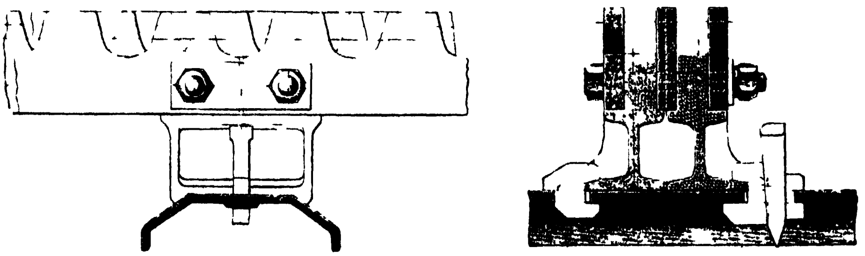
The Rack and Pinion. This invention of the rack and pinion is almost contemporaneous with the introduction of the locomotive. Trevethick's engine of 1804, owing to its lightness as well as its want of power, could not do much more than draw itself. Blenkinsop, in 1811, not seeing that additional weight would overcome the want of adhesion, provided the rail with teeth, and the driving wheel itself was the pinion, and by this his 5-ton engine succeeded in drawing 90 tons at 4 miles per hour on the level, and 15 tons up 1 in 20.

George Stephenson, however, with his keen insight, perceived that as the great additional power which he foresaw as inevitable would, with its heavier boiler, cylinders, and all parts, provide sufficient weight for adhesion, reverted to the simpler plan of the smooth rail, and subsequent designers increased it by coupling the wheels. The advance of railways necessitating steep grades revived the idea of Blenkinsop, and Cathcart, in 1847, devised a rack line in America, but placed it between the rails with a special pinion worked by the engine, the outer rails and wheels merely bearing the load, and all subsequent improvements have been based on this principle.

4. ENGINE PINIONS

The next development was by Silvester Marsh, in 1858, in America, and by Riggenbach, in Europe, in 1871. In these an apparatus of ladder-like form was fixed in the centre between the rails, on the rungs of which corresponding protuberances on a centrally driven wheel acted. The Mount Washington line on Marsh's plan, and the Righi [6], the Wengern Alp, Brunig, Appenzel, and others in Europe on the Riggenbach system are examples. Roman Abt, however, who might be called the George Stephenson of the rack railway, introduced, in 1882, the system called by his name and now almost universally followed. Fig. 7 shows a portion of the Zermatt railway on the Abt system.

Present Day Practice. In the Abt system the ordinary adhesion principle, as the smooth wheel on the smooth rail is called, and the rack-and-pinion system are combined in one engine, one pair of cylinders working the driving wheels on the ordinary smooth rails, which carry the weight, and another pair actuating the pinions [4], which engage with the rack between the rails. By this method, when the train is on the level or on an easy graded part of the line where there is no rack, the pinion engine is stopped, the adhesion one doing all the work; but when the steep rack portion is reached, the whole power of both engines is put into action. It may be asked, How can adhesion help in this case? But it must be remembered that the boundary between the grading on which adhesion alone is sufficient and that on which it fails is very indeterminate, depending on two factors—the condition of the rails and the load to be drawn. For example, on a fairly steep grade an engine may be able to draw itself up by simple adhesion, but fail to draw a load behind it in addition, and to the former extent the rack mechanism of the engine is relieved of its work. It has also been found by experience that, should the adhesion driving wheel be inclined to slip, the action of the pinion and rack not only prevents any running back, which would increase the tendency, but by impelling the engine forward causes the adhesion wheel to bite on a new place, and thus regain its purchase.



5. ELEVATION AND SECTION OF RACK

A German Mountain Railway. The Hartz Mountain railway, in Germany, which has a heavy goods and passenger traffic, is one of the most notable examples of the Abt system, and, with some slight modifications, a description of it will serve for all. The line, though making a considerable aggregate ascent, is uneven, having many comparatively easy grades in its length of 19 miles, 4¾ miles made up of several separate short lengths being provided with the rack. The steepest grade on the adhesion part is 1 in 40, and on the rack portion 1 in 16·67, the sharpest curves being 9 chains and 12½ chains radius on each respectively. The permanent way, which is on the standard gauge, 4 ft. 8½ in., consists of steel rails weighing 60½ lb. per yard, laid on steel sleepers of about 90 lb. weight each and 2 ft. 10¾ in. apart from centre to centre. The rack is of three steel bars, each 4·33 in. deep and 0·79 in. thick, and these are separated from each other by a distance of 1·36 in. The rack bars, which are suitably fixed to the steel sleepers are what is called *staggered*—that is to say, the teeth on one bar are not opposite to those on the one next to it, but are one-third of a tooth space in advance of them. In the pitch-line the teeth and spaces on each bar measure 2·36 in. [5]. The top of the rack is 2¾ in. over the rail level.

With regard to the pinions on the engine, there are two sets, one behind the other, each consisting of three discs at the same distance apart, 1·36 in., as that of the rack-bars, so as to engage with the latter. Their teeth are also staggered in such a manner that fresh cogs are being continually engaged, and there are always nine teeth in contact with the rack. By this arrangement [4] great smoothness in running is attained.

Entering the Rack. The transitions from the adhesion to the rack portions are not confined to where stoppages at stations occur, hence a device is necessary so that the engine, with its train, can run on easily from the former to the latter without stopping.

The entry on the rack is by means of a straight triple rack-tongue [8], about 10 ft. long, supported on pairs of volute springs, based on a longitudinal sleeper in a pit, so as to admit of the vertical depression of the tongue if the teeth of the pinions should not engage perfectly on approach, and ride upon the teeth of the tongue-rack. The tongue is hinged at the end where it joins with the ordinary rack, and is tapered, as to its depth, at the other end, so as to facilitate the entry.

The steam is shut off from the pinion machinery on those lengths where the rack is not laid; but when approaching it the regulator of the pinion machinery is slightly opened so as to cause the pinions to revolve slowly, and enable them, as they ride on to the tongue, to engage the teeth of the tongue-rack without concussion. As soon as this is effected the regulator is fully opened, when the pinions take their fair share of the work in the ascent. As the engine is placed at the rear of the train in the ascent, the rack extends on to the adjoining lower adhesion length to the maximum length of the train, as otherwise the engine would not get the help of the rack when a portion of its train ahead is on the incline. Similarly, the rack is extended to some distance beyond the top of the incline, so that the engine, which leads in the descent, may have its pinions safely geared into the rack before the actual descent is begun.

6. RIGHI MOUNTAIN RAILWAY

The Locomotives. The engines are of the tank type, working without turning. The three axles of the adhesion wheels, 4 ft. 1½ in. in diameter, which are in front of the firebox, are coupled. In addition there is a fourth pair of wheels on a Bissel truck under the footplate. The pair of cylinders working the adhesion drivers is outside; those driving the pinions are inside. Each pair has separate steam-pipes from the same boiler, and has independent action. The two sets of pinions, which are 22·56 in. in diameter, are coupled, the rear one being the driver.

The toothed gearing is supported by an entirely separate frame resting on the leading and trailing driving axles of the adhesion wheels, so that the grip of the pinions is in no way affected by the play of the springs, and this inside frame is lifted from time to time to allow for the wear of the adhesion-wheel tyres.

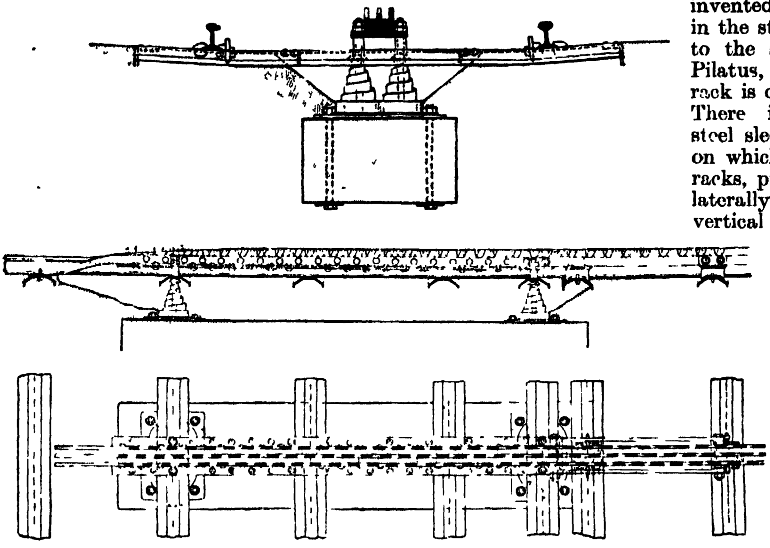
The total weight of the engine in working order is 55 tons, and the maximum gross load behind the engine is 137 tons. The ordinary load, however, is much less, and the coal consumption is about 50 lb. per train mile.

The wear of the pinion teeth, of course, is much greater than that of the rack-bar teeth, as each one of the former has a contact for every revolution, while each of the latter has only two contacts for the passage of each train. The pinion discs are taken off from time to time and reversed, so that each side of the teeth may wear evenly.

Brakes and Points. There are four brakes on the engine, two hand-brakes, one acting on the tyres of the wheels in the ordinary way, and the other on grooved discs on each of the pinion shafts, which latter are, of course, effective only on the rack lengths. The other two are compressed-air brakes, one

7. ZERMATT RAILWAY ON THE ABT SYSTEM.

acting on the adhesion mechanism, and the other on the pinions, and they operate by preventing the free escape of the air from the cylinders, thus using the compressed air in retarding the progress of the engine. The two hand-brakes are used for shunting purposes, while the latter two are for the descent. By the Government regulations, half of the vehicles besides the above must be provided with brakes, but these are not required, as a rule, to control the train, the engine brakes being sufficient.



8. PLAN, ELEVATION, AND SECTION OF RACK TONGUE

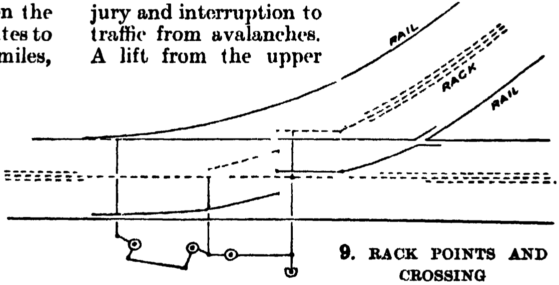
On the Hartz line there are no points and crossings on the rack length, hence these are of the ordinary description, but on other Abt rack lines they are made of the type shown in 9, which fully explains the movement of the switches of the rack in harmony with those of the bearing rails, the rack being here reduced for simplicity to a single bar.

Speed. As to speed, the trains take from 1 hour 56 minutes to 2 hours 20 minutes on the ascending journey, and from 1 hour 44 minutes to 2 hours 29 minutes descending, to do the 19 miles, the ordinary speed on the rack being about 4 miles per hour. On the Nilghiri Abt line in India a much higher speed is attained on the rack. The traffic is comparatively heavy on the Hartz railway, and on many of the 42 lines on different gauges in all parts of the world which now exist on the Abt system two rack-bars are found to be sufficient. Having the racks and pinions duplicated or triplicated, as in the Abt system, affords a good guarantee of safety in case of the breakage of a tooth. In fact, such a thing is not known to have happened.

Steel sleepers are generally used in order that, through their stiffness, the relative levels of the rail and rack should be well maintained; but on the Nilghiri line in India, and in other places where good hardwood timber is easily procurable, the latter is found to be sufficient. There are several Abt lines in which the grade is as steep as 1 in 4.

Other Systems. In the "Locher" system, invented in 1885, and used in the steep tourist line up to the summit of Mount Pilatus, in Switzerland, the rack is of a different form. There is a longitudinal steel sleeper in the centre on which is mounted two racks, projecting outwards laterally from a central vertical rib. The pinions of the locomotive, which are in horizontal pairs, engage with these, gripping the rack between them. The maximum grade is as much as 1 in 2·08.

The Strub rack, invented in 1896, reverts to the vertical type. It is being used on the Jungfrau metre gauge electric line, and is of very heavy construction. It was considered that, as so much of this railway was situated at a great elevation above the snow line, and was difficult of access for maintenance, a special heavy form of rack was required, and also on account of the severity of the grade, much of it being as steep as 1 in 4. As only about 100 days of summer tourist traffic in the year were available for working, heavy loads for such a grade were, therefore, to be expected as concentrated within that period, and a strong rack was consequently necessary. The line is about 7½ miles long, and the greater portion of the upper part is placed underground in tunnel, to avoid injury and interruption to traffic from avalanches. A lift from the upper terminus, which is underground at 13,425 ft above sea-level, will take the passengers to the summit of the mountain.

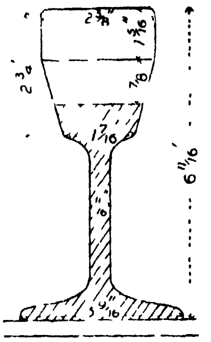


9. RACK POINTS AND CROSSING

Details of the Strub Rack. The rack, which is single, is fixed centrally on heavy hollow steel sleepers 5·91 ft. long, $9\frac{3}{16}$ in. wide, and $2\frac{15}{16}$ in. deep, 3 ft. $3\frac{3}{8}$ in. apart, centre to centre, and weighing 81·57 lb. each. The rack [**10 and 11**] is $6\frac{11}{16}$ in. deep, and $2\frac{3}{8}$ in. wide at the top, narrowing downwards to suit the grip brakes employed. Its tensile strength is 28·57 tons per square inch, and it weighs 68·55 lb. per yard.

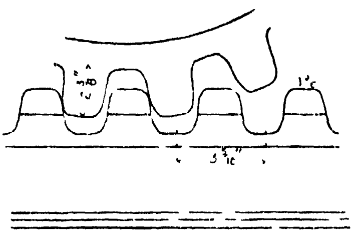
The train is composed of a compound vehicle comprising an electric motor carrying 30 passengers, and another car with 50 passengers, the whole weighing about 26 tons. The motor, as well as the electric installation of this line, is referred to in courses of Electricity.

The brakes are of the shape of a forceps, worked by hand from the floor of the vehicles, and their action can be fully understood from 12. When not closed on to the rack for actual braking, the jaws of the brake project under the head of the rack so as to prevent derailment should the vehicle tend to rise from any obstruction on the line or other cause. They also prevent the side-slipping of the pinion.



10. SECTION OF STRUB RACK

In the excessively steep lines, it is found necessary to anchor the road—that is to say, to drive piles down at intervals at the lower side of the sleeper, otherwise the combined effort of the steep slope, the vibration, and the pressure of the pinions would cause the whole permanent way to shift gradually downwards, distorting itself at the curves. In the very steep tourist lines in Switzerland the seats in the cars are inclined so as to be as nearly level as possible when on the grade.

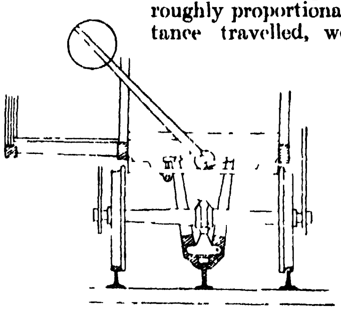


11. ELEVATION OF STRUB RACK

In the two railways last referred to, which are on very steep inclines to mountain summits, and in similar ones, there is evidently no alternative between the rack or rope and stationary engine, and any other system. Adhesion alone is out of the question. But it sometimes happens that in a section of an ordinary railway, where a mountain range has to be overcome, a choice may lie between a comparatively easy adhesion grade and a steep rack. In the former case it would be necessary to climb the mountain side gradually in order to attain a given elevation, the line being made much longer than it otherwise need be, or developed, as it is called, curving round spurs and valleys for the special purpose of giving the necessary length in proportion to the height, so as to have a workable adhesion grade.

In the latter case, the height, by means of the steep grade which the rack admits of, can be reached in a very much shorter length. Each problem of this kind has its own conditions, and must be solved on its own merits, no general rule being possible. However, the advantages and otherwise of each alternative may be briefly shown.

Respective Advantages. First, as to the adhesion line. This has the advantage of involving no departure from the usual type of permanent way and engine proper to the rest of the line, the latter running through the whole length; and though by the Abt combination engine this could be done, yet if the rack forms only a small portion of the whole railway the pinion mechanism would be largely unemployed. If the rack engines were limited to the short-rack incline, unless there were a very large traffic they would be probably often standing idle waiting for traffic. Secondly, as to the rack; the cost of construction, apart from the rack, would be less, not only because the line would be shorter, but because, being less limited as to grade, greater choice of alignment is open to the surveyor when locating it. Again, the construction and maintenance of the permanent way, though heavier mile for mile, might be much less, owing to the shorter length, and, apart from the pinion mechanism, the wear and tear of all rolling stock, which is roughly proportionate to the distance travelled, would be less. Thirdly, the dead weight of engine in proportion to load drawn is less, so that the fuel, etc., expended per ton of paying load lifted is less. Subject to the last consideration, the actual mechanical work, and therefore the working cost of raising the load, would be much the same in each case, for the greater speed on the adhesion line would be neutralised by its greater length.



12. SECTION OF STRUB BRAKE

Where, in any general railway system, a rack section is interposed between two groups of ordinary lines, such, for instance, as a connection between a coast and a tableland country, the rack grade should not, if possible, exceed that on which an ordinary engine could draw itself up. Otherwise the circulation of engine stock between the two systems would be hampered.

Rack railways have had their chief development in Switzerland, Austro-Hungary, and Germany, but they are in use also in France, North and South America, Australasia, India, Japan, and other countries. The development has not been great in the United Kingdom, the necessity for steeply-graded railways being limited.

CHEMICALS IN FOOD

The Value and Danger of Certain Chemicals in Milk and other Foods. Tea as it Should be Made. The Alkaloids—Animal and Vegetable

By Dr. C. W. SALEEBY

Benzoic Acid. The acid which has the formula C_6H_5COOH is the characteristic constituent of the gum known as benzoin, and is found in various balsams. It used to be extracted from benzoin by sublimation. This process carries away with the acid a certain quantity of the volatile oil contained in the resin, thus giving it a very pleasant odour. Nowadays, however, the acid is largely prepared from coal-tar. It crystallises into very delicate and very light colourless needles. In the presence of water vapour it is volatile. It is only very slightly soluble in cold water (1 part in 400), but dissolves readily in hot water, alcohol, and solutions of alkalies. We have already seen that this acid is the valuable constituent of *Friar's balsam.* It is a powerful and volatile antiseptic. When administered internally, it is found that benzoic acid appears in the secretion of the kidney as a closely allied acid called *hippuric acid.* This acid may be regarded as a compound of benzoic acid and the body known as *glycocoll* or *amido-acetic acid,* which has the formula $C_2H_5NO_2$. This is a rather remarkable case of synthesis, the building up of compounds into more complex compounds within the animal body. Outside the body, hippuric acid can readily be converted into benzoic acid and glycocoll by boiling it with dilute hydrochloric acid.

Benzoic Aldehyde. Benzoic acid, C_6H_5COOH, corresponds to benzoic aldehyde, C_6H_5COH, just exactly as acetic acid, CH_3COOH, corresponds to acetic aldehyde, CH_3COH. Furthermore, we know that acetic aldehyde is derived by removal of two atoms of hydrogen from ethyl alcohol; similarly, benzoic aldehyde has corresponding to it an alcohol known as *benzyl alcohol,* which contains two atoms of hydrogen more than the aldehyde, having the formula $C_6H_5CH_2OH$. The aldehyde may be produced by oxidation of the alcohol, which thus loses two atoms of hydrogen. Its natural source, however, is of very great interest, and has already been referred to. The oil of bitter almonds contains a highly complex body which, since it yields glucose on decomposition, is known as a *glucoside.* It has the name of ***amygdalin,*** derived from *amygdala,* the botanical name for the almond. This amygdalin is normally decomposed by a ferment known as ***emulsin,*** which is also a normal constituent both of the bitter and the sweet almond. The action of the emulsin is to hydrolyse the amygdalin, and the products are sugar, benzoic aldehyde (which is therefore often known as *oil of bitter almonds*), and prussic acid. When the so-called oil or aldehyde has been purified by the distillation of the prussic acid, it is quite harmless, as well as pleasant. The reaction, which depends upon the presence of moisture, is represented by the following equation, the first term of which is the formula of amygdalin:

$$C_{20}H_{27}NO_{11} + 2H_2O = C_6H_5COH + 2C_6H_{12}O_6 + HCN$$

Benzoic aldehyde, often known as *benzaldehyde,* has reactions which closely correspond with those of acetic aldehyde; thus, nascent hydrogen reduces it to its alcohol, and oxidising agents form benzoic acid from it.

Salicylic Acid. Very closely allied to benzoic acid is *salicylic acid,* which is, indeed, a hydroxy-benzoic acid—that is to say, benzoic acid, one of the hydrogen atoms of which has been replaced by hydroxyl. Thus its formula is $C_6H_4 . OH . COOH$. This acid is known in commerce in two forms. One is known as the *vegetable acid,* being derived directly from the vegetable world, while the other is known as the *artificial acid,* or *synthetic acid,* but must ultimately also have its origin referred to the vegetable world, coal being a vegetable product. A comparison of the two processes of manufacture is of interest, and of very considerable practical importance. The plant known as the *winter green* yields an "oil of winter green," the chief constituent of which is a methyl salt of salicylic acid. This methyl salicylate readily yields salicylic acid on decomposition. This natural or vegetable acid is relatively very expensive, but has the great virtue of purity. Thus, the salicylate of sodium formed from it, and now recognised as one of the most valuable of all drugs, is pure and safe.

On the other hand, salicylic acid, destined to be a source of salicylate of sodium, may also be prepared by the action of carbon dioxide upon the carbolate of sodium. If dry carbon dioxide be passed through this salt at a temperature of about 400° F., an impure sodium salicylate results, and this, under the action of hydrochloric acid, yields salicylic acid. The following is the equation for this interesting reaction:

$$2C_6H_5ONa + CO_2 = C_6H_4 . ONa . COONa + C_6H_5OH.$$

Pure salicylic acid occurs as needle shaped, colourless crystals soluble only to the extent of 1 part in 500 of cold water, but readily soluble in hot water, alcohol, and ether. Watery solutions of it yield a beautiful reddish violet colour, with a solution of ferric chloride.

The artificial acid is extremely cheap, and is widely used as (1) a source of sodium salicylate for medical purposes and (2) a preservative of foods—for it is a very powerful antiseptic indeed.

Synthetic Salicylic Acid. The synthetic acid, however, invariably contains a considerable quantity of impurities—allied acids called *cresotic acids*. Certain of these are very highly poisonous, so that extremely minute quantities of them may cause serious symptoms. Now, sodium salicylate is a drug which has to be administered in very large doses, so that the difference between two or three pence and 7s. 6d. per lb.—which represents the ratio of the two prices, at any rate—is an important matter. The use of the salicylate of sodium derived from the synthetic acid has led to the belief that the drug is dangerous, especially to the heart, and must be used with caution. The salt which is derived from the natural acid, however, and which contains no salts of cresotic acid, is remarkably free from any injurious consequence, and as much as 300 grains of it have been given in a dose without any injurious result. In the case of a drug which is the only known specific for a disease so important as rheumatic fever, these chemical considerations demand most serious attention. It is worth noting that just as benzoic acid unites with glycocoll in the kidney to form hippuric acid, so salicylic acid unites with glycocoll to form what is called *salicyluric acid*.

Salicin. Salicylic acid derives its name indirectly from the willow tree, the botanical name of which is *Salix*. The bark of various species of Salix contains a crystalline glucoside known as *salicin*, which, under the influence of a mildly alkaline fluid and warmth, is decomposed, yielding glucose and salicylic acid. This decomposition occurs in the blood, and the value of the acid was first discovered by the administration of salicin. The pharmacologists are at present unable to tell us why the salicylate of sodium is so extremely valuable in rheumatic fever, but the great student Professor Binz, of Bonn, has suggested that the salt is decomposed by the carbonic acid which is known to exist at a considerable pressure in inflamed joints, and that salicylic acid, a powerful antiseptic, is thereby liberated slowly and without irritation. Rheumatic fever is known to be due to a microbe, so that this most attractive explanation may possibly be verified some day.

Salol. Another close ally of salicylic acid deserves mention. Its common name is *salol*, and it may be regarded as phenyl salicylate, being prepared by the interaction of salicylic acid and carbolic acid, and consisting of sixty parts of the former and forty of the latter. This is an extremely insoluble substance, but is very valuable indeed as an antiseptic in the bowel, the reason being that it undergoes no decomposition until it is subjected to the action of trypsin—the powerful ferment which it meets in the bowel, and which slowly decomposes it, with deliberation of the two potent antiseptics of which it is composed.

Salicylic Acid in Food. It remains for us to discuss the extremely important question of the use of salicylic acid as a preservative of food, and thereafter we must raise a few general considerations concerning the chemistry of food preservation, this being a practical subject of very great importance, which is now recognised as a matter for discussion and examination by various chemical authorities. Salicylic acid may be chosen as a typical chemical preservative of food, since it is used in enormous quantities, and in foods of very diverse kinds. In certain foods, salicylic acid, we have lately learnt, is a natural constituent, as, for instance, in such fruits as strawberries, plums and oranges. Hence the acid will occur in many jams, and this must be remembered, since it is the favourite antiseptic employed for jams and other forms of preserved fruit, as well as for a number of wines which may also naturally contain it. Besides being artificially added in considerable quantities to jams, wines, syrups, cider, perry, and beer, salicylic acid has "also been found in butter, sauces and ketchups, in meat juices, potted meat and sausages, in sherry, port, ipecacuanha wine, and orange and quinine wine. Occasionally it is employed, either alone, or more usually in conjunction with boric acid, for preserving milk and cream." This and the following quotations are from the most complete study of the subject in English: "Preservatives in Food, and Food Examination," by John C. Thresh, M.D., D.Sc., F.I.C., and A. E. Porter, M.D., M.A. (J. and A. Churchill, 1906).

Specific Value as a Preservative. The report of the Departmental Committee appointed in 1889 by the President of the Local Government Board to consider this subject shows that salicylic acid is generally sold under various trade names, like other chemical preservatives. This acid is not employed in very large proportions in any article of diet, and according to the best authorities "the declaration of its presence and amount will probably meet most of the objections that can reasonably be raised to its use." Other authorities discussed the subject quite recently, and have, more or less, refuted the assertions that the acid as used is injurious to health. The excretion of the acid is extraordinarily rapid, and since it does not tend to accumulate in the body, it has no cumulative action. Salicylic acid seems to be almost invariably found in lime-juice preparations, and especially in lime-juice cordial. "There is, apparently, no evidence that salicylic acid, employed as a preservative, has ever produced any injurious effects." The acid is one of those used for the preservation of milk, though much less frequently than boracic acid. Its use for this purpose is definitely to be condemned. It is very commonly found in cream and butter. In both of these cases, the use of boracic acid, if any preservative is to be used, is much preferable.

Official Recommendations. In concluding this brief study of our subject, and as an introduction to the study of the chemical preservation of food in general, we quote in full the very important recommendations which conclude the report of the Departmental Committee referred to.

"(*a*) That the use of formaldehyde or formalin, or preparations thereof, in food or drinks be absolutely prohibited, and that salicylic acid be not used in a greater proportion than one grain per pint in liquid food, and one grain per pound in solid food. Its presence in all cases to be declared.

"(*b*) That the use of any preservative or colouring matter whatever in milk offered for sale in the United Kingdom be constitued an offence under the Sale of Food and Drugs Act.

"(*c*) That the only preservative that it shall be lawful to use in cream be boric acid, or mixtures of boric acid and borax, and in amount not exceeding 0·25 per cent. expressed as boric acid. The amount of such preservative to be notified by a label upon the vessel.

"(*d*) That the only preservative permitted to be used in butter and margarine be boric acid, or mixtures of boric acid and borax, to be used in proportions not exceeding 0·5 per cent., expressed as boric acid.

"(*e*) That in the case of all dietetic preparations intended for the use of invalids or infants, chemical preservatives of all kinds be prohibited.

"(*f*) That the use of copper salts, in the so-called greening of preserved fruits, be prohibited.

"(*g*) That means be provided, either by the establishment of a separate Court of Reference, or by the imposition of more direct obligation on the Local Government Board, to exercise supervision over the use of preservatives and colouring matters in food, and to prepare schedules of such as may be considered inimical to the public health."

The use of salicylic acid and other preservatives in milk is forbidden in Austria-Hungary, Belgium, France and Switzerland.

Chemical Preservatives in Foods. To a race of city dwellers, the preservation of food is a vital matter, for it is a necessary condition of their life. Means to this end have been adopted from time immemorial. Whether chemically or otherwise, food most certainly must be preserved from decomposition if city populations are to be fed. Here we have no concern with what is in general, the safest, simplest, and best method of preserving food—that is to say, of killing the microbes which it contains. This method is boiling, or in any other way raising the food to such a temperature that the microbes in it are killed In general, the methods include exposure to great heat, and to great cold —this latter being of the utmost importance in the preservation of milk—the exclusion of air, drying, smoking, and the addition of salt, boracic (boric) acid, formalin, salicylic acid, alcohol and many other substances. A number of these means are not only innocent and effective, but necessary. The addition of chemical preservatives, our present concern, cannot be excluded from the number of these. The recent official inquiry showed that "practically every person in the United Kingdom who has passed the suckling stage consumes daily more or less food containing chemical preservatives. It is obvious, therefore, that if such food were markedly deleterious, some conclusive evidence should have been forthcoming." On the other hand, the extensive use of these processes coincided with a steady fall in the death-rate, "and it is very probable that one of the causes of this decline is the better feeding of the people in consequence of the introduction of cheaper foods, this being rendered possible by the use of chemical and other means of preservation. . . . The dangers arising from the use of preservatives have been greatly exaggerated. It is impossible to say definitely that a single case of illness has ever been conclusively traced to the preservative used in any article of food or drink." On the other hand, "danger may be apprehended from the indiscriminate use of certain preservatives. It may be desirable that there should be some restriction as to their employment, and that in certain cases their use should be forbidden, as, for example, in milk."

A Proof of Success. The public, if it were capable of learning the lesson, has lately been provided with an astounding proof of the practical success which attends processes of food preservation—in this case chiefly by heat. The tinned products of Chicago, we now know, are prepared under conditions which, until the last moment, are abominable in the highest degree. The food is infected with every kind of dirt, filth, and disease, and much of it is mere refuse from the first. Consumed in such a state it would spread death everywhere, yet millions and millions of people live and thrive on it. As the present writer has said elsewhere, "if, then, the preservation of food is a science so far advanced that it can actually make a palatable, nutritious and safe product, such antecedents notwithstanding, it is surely evident, *à fortiori*, that when the antecedent conditions are decent we may place very great faith indeed in the methods already known." This is the contention which Drs. Thresh and Porter have conclusively proved in their most important treatise. They show that methods of food preservation, for instance, enable the poor to be supplied with good, wholesome food at low prices which would have to be multiplied manifold if these methods were unknown. It is well that society should protest against abominations such as those of Chicago, but it is well also that our actions should be qualified by knowledge, and that we should seek merely for the legitimate use of methods, many of which have been found necessary and successful for ages past. How long, for instance, is it since sodium chloride—that is, common salt—was first added to food in order to preserve it ?

Why Milk Should not be Adulterated. And now, having endeavoured to state properly the general principles of this matter, let us consider and emphasise to the utmost a conspicuous and all-important exception. It concerns the most important of all foods, *milk*. It is the most important because it is the best of all foods, and because its state is a matter of life and death for every one of us during the first years of life. It is an ideal food, not only for man, but also for microbes. It is constantly used for this purpose by bacteriologists, who know no better "culture medium." Hence this best of foods is the most in need of preservation. When contaminated, as it constantly is, it may become the most deadly of poisons. The most common decomposition undergone by milk consists in that lactic acid fermentation which we have already discussed. On the whole, this lactic acid fermentation may be regarded as practically innocent; Professor Metchnikoff, as we have seen, thinks that even more may be said for it. All the other decompositions and contaminations of milk may be regarded as more or less deadly.

The Slaughter of Children. The lamentable thing is that whereas the innocent fermentation has a result obvious to the nose and the palate, the deadly fermentations and contaminations are inconspicuous to those organs—though they play a great part in the death-rate, killing babies in tens of thousands every year and forming one of the chief factors, if not the chief factor, in the spread of tuberculosis—the most deadly of all diseases—of diphtheria, typhoid fever, scarlet fever, and many other diseases of less importance. Now, the second most unfortunate fact is this—that the lactic acid bacteria can be killed by proportions of chemical preservatives, such as boracic and salicylic acid and formaldehyde, which are not injurious to health and which do not affect the flavour of the milk. But these bacteria are the most delicate of all that infest milk, and the proportions of preservatives which kill them are impotent to affect the dangerous microbes, though these proportions unfortunately succeed in keeping the milk sweet and, therefore, apparently safe. No more unlucky combination of facts could be imagined. We say, then, dogmatically—and this is one of the most important facts for the public health that can possibly be stated—that the use of chemical preservatives in milk does not lessen in the slightest degree any dangerous properties that the milk may possess, but interferes merely with the multiplication of innocent microbes which, as we have seen, if allowed to multiply, would themselves arrest the development of certain dangerous microbes.

The conclusion, therefore, is that the use of chemical preservatives for milk is invariably useless. But this statement is only a feeble indication of the real facts, as we shall see in a moment. Here let us meet the objection that such methods are inevitable.

Preservatives in Milk Unnecessary. It has been conclusively proved, as, for instance, by the Aylesbury Dairy Company, which deserves all honour, that it is possible to supply, as they do, "at least a hundred thousand persons a day in London with milk absolutely free from preservatives, although a portion of their supply comes from Wiltshire, and even Cheshire, a distance of 200 miles." Ninety-eight per cent of the milk sold in Liverpool is free from any preservatives. Milk can be sent long distances and yet be supplied in a good condition to the consumers without the addition of any preservative and without the aid of heat. This can be done by immediate and efficient cooling, which ought to be a legal necessity in the case of all milk sold. Quoting again from the report of the Departmental Committee, we may note that the Aylesbury Dairy Company, who used to add 0·2 per cent. of boracic acid to their cream, have, for several years, been able to supply cream absolutely free from antiseptics. And the same is the case of the cream supply in Copenhagen. This last city is the model for the whole world in these matters. The only butter free from boracic acid which we import into this country comes from Denmark. We conclude, then, without any question or possibility of dispute that the use of preservatives in milk is unnecessary.

Dangerous to the Health of Children. We must go further, and say that their use is dangerous. This, as we have already seen, cannot be because of their mere in the milk. It depends upon the comparative chemistry of the lactic acid bacteria and the dangerous bacteria that commonly contaminate milk, in their relation to chemical antiseptics. The point, and the whole point, is that the addition of these preservatives to milk, killing the lactic acid bacteria but no others, *cloaks the results of the dirty conditions* under which the milk may then be produced. The report of the Departmental Committee contains a paragraph objecting to the use of preservatives in milk on the grounds that "there is evidence pointing to an injurious effect of boracised milk upon the health of very young children." The report goes on to say that there are no means of controlling the amount of preservative that may be added to milk. "The farmer or producer sometimes applies it; so does the wholesale purveyor; so does the retail dealer; lastly, the domestic use of preservatives is increasing, and has become very general, and hence the milk may receive a fourth dose before it reaches the unsuspecting consumer."

The Need for Cleanliness in Milk. But all these matters are relatively trivial. The vital objection is dealt with in the thirteenth paragraph of the report—which we quote in full. It embodies statements which should be part of universal knowledge:

"There is this further objection to the use of preservatives in the milk traffic—that they may be relied on to protect those engaged therein against the immediate results of neglect of scrupulous cleanliness. Under the influence of these preservatives milk may be exposed without sensible injury to conditions which otherwise would render it unsaleable. It may remain sweet to taste and smell, and yet have incorporated disease germs of various kinds, whereof the activity may be suspended for a time by the action of the preservatives, but may be resumed before the milk is digested.

"It has been put before us that it is not possible to supply large towns, especially London, with new milk without the aid of preservatives; but we have received abundant evidence to prove that this is no more than a matter of organisation and system. No doubt the prohibition of preservatives in milk offered for sale would tend to the disadvantage of small retailers who have no cold storage, but this is not a consideration which should stand in the way of a much-needed reform.

"As to the feasibility of conducting the traffic in the largest towns without preservatives we have no doubt whatever. In Denmark the use of all preservatives in milk is strictly prohibited, and the prohibition is stringently enforced. . .

London's Milk Problem. "In face of these facts," the report continues, "we are of opinion that it is idle to pronounce it impossible to supply London with milk not artificially preserved. The business would be attended with some inconvenience at first, but we are impressed with the need for facing that inconvenience, and for rendering the vendors of milk containing preservatives subject to penalties under the Sale of Food and Drugs Act. Obviously, the conditions under which milk is sometimes kept in the homes of the poor are likely to hasten the processes of decomposition, but we do not think this a sufficient argument in favour of the sale of chemically preservatised milk."

To this we may add that the argument is the more worthless in that the chemical preservation of milk in any proper sense at all is impossible, as we have shown. What has been said about milk applies entirely to cream—notwithstanding the small degree of licence suggested to be permitted by the Committee. [Since we prepared this subject for the reader the Local Government Board have issued a circular condemning the addition of any chemicals to milk.]

The Need for Legislation. Space does not avail for any further consideration of this very large and very important subject. For fuller study of it we would refer the reader to Swithinbank and Newman's "Bacteriology of Milk," and to the work of Thresh and Porter. We have been able merely to outline the general principles and to enter into some small detail regarding the most important aspects of the subject. We have had to pass unconsidered the comparative utility of many chemical bodies which are used, questions of the proportions which are effective and safe in each case, the relatively unimportant question of colouring matters (which now include the coal-tar colours, used very extensively in confectionery, jellies, jams, sausages, temperance beverages, and wines), and also the important practical matters of the detection and estimation of boracic acid, salicylic acid, etc., in actual samples of food. It is a pity also to have had to ignore the legal aspect of the question. The Food and Drugs Act of 1875 is in urgent need of revision, and it would be well for us to have a municipal laboratory in our large cities comparable to the famous laboratory in Paris. The Act of 1875 has led to conviction in cases where margarine or butter has contained as little as 51 grains of boracic acid per pound. In a case at Bootle the amount was actually 120 grains per pound. Conviction has frequently followed the detection of formaldehyde in milk and the presence of large quantities of salicylic acid in various substances, such as jam, marmalade, ginger wine, etc.

The day has for ever passed when chemistry consisted merely of the knowledge gained by the alchemists as they tried to transmute the baser metals into gold—or of little more; it has now invaded the whole of human life, and thus, as we consider in turn the more important organic compounds, it is both necessary and desirable that we should indicate the existence of great practical departments of chemistry, the importance of which increases daily.

Gallic Acid. We saw that salicylic acid is a hydroxy-benzoic acid. Of these there are many, of which two more must be discussed. These are *tannic* and *gallic* acids. Both are tri-hydroxy acids, three hyhroxyl groups being included in their composition. The formula of gallic acid is $C_6H_2(OH)_3COOH$. This derives its name from the curious excrescences which are found on the bark and the leaves of the oak and are called *galls* or *gall nuts.* These galls are due to the irritation caused by the deposit and growth of the eggs which a humble creature deposits in the substance of the bark or the leaf. The chief constituents of these curious galls are the two closely related acids which we are now discussing. Gallic acid is found in tea and coffee and may be obtained from various other vegetable sources. It may be obtained from galls by powdering them and boiling them with dilute sulphuric acid. In their natural state galls contain not more than five per cent. of gallic acid, and even as much as 75 per cent. of tannic acid. But this process causes the hydrolysis of the tannic acid with the formation of gallic acid, which crystallises out in white, silky needles or thin needle-shaped prisms, containing one molecule of water of crystallisation. The acid is soluble only in about 100 parts of cold water, but readily dissolves in hot water, ether, alcohol and glycerine. The most important chemical fact about gallic acid is that it has no power of coagulating albumin. We shall shortly see the importance of this. If gallic acid be heated it undergoes decomposition, yielding carbon dioxide and the body which is known as *pyrogallol, pyrogallic acid* or *tri-hydroxy benzene* and has the formula $C_6H_3(OH)_3$. This is a powerful antiseptic.

Tannic Acid. Much more important than gallic acid is its relative *tannic acid,* oftener known, perhaps, as *tannin.* It may be described as anhydrous digallic acid. We have already seen that it may be hydrolysed to form gallic acid by means of boiling with dilute sulphuric acid. A most important fact is that tannic acid undergoes a similar hydrolysis within the bowel, even at the temperature of the body, and is absorbed into the blood not as tannic acid at all, but as gallic acid or, rather, as the *gallate of sodium.* Gallic acid and its salts have no power of coagulating albumin. Hence, the value of tannic acid as an astringent, which depends upon its power of coagulating albumin, is absolutely confined to the skin, the mouth and the upper part of the alimentary canal. It is absolutely useless to administer this drug as a "remote astringent" since it undergoes the transformation we have seen.

Preparation of Tannic Acid. Tannic acid may be prepared from gallic acid by boiling a watery solution of the latter with arsenic acid, but it is very readily obtained from galls, which are powdered, are kept warm and moist so as to undergo a kind of fermentation, and from which the tannic acid can be extracted by a mixture of water and ether. Whereas gallic acid has an acid taste, the taste of tannic acid is very strongly astringent. To this astringency there is some bitterness added, and persons who like their tea to have "a little body" or taste in it are really seeking for a high proportion of tannic acid. The astringency of this acid ought not really to be described as affecting the nerves of taste. In reality it is none other than the local action of the acid, dependent upon the fact that it precipitates albumin (including the albumin of the cells that line the mouth) in the form of an insoluble tannate. Tannic acid is readily soluble in water and in alcohol. It forms with salts of iron a bluish black precipitate which is none other than ink. For this reason it is a matter of importance to the druggist that he shall not mix up, in one prescription, salts of iron and vegetable infusions or tinctures containing tannin. There is no real objection to the ink that is formed except that it gives the mixture a very unpleasant appearance. Tannic acid also precipitates alkaloids in general. Hence tannic acid or strong tea may form valuable antidotes in cases of alkaloidal poisoning.

The Abuses of Tannic Acid. We must now discuss in turn the uses and the abuses of tannic acid. This substance has no properties desirable for the human body in health. On the contrary, its chemical properties cause it to interfere, in proportion to the amount of it that is taken, with the processes of digestion from first to last. Its evil action begins in the mouth, where, by precipitating albumin, it interferes with the flow of saliva, and does not end till it reaches the bowel, the activity of the upper part of which is interfered with. The most familiar form of tannic acid is thereafter converted into gallic acid, which, as we have seen, has no astringent properties. The amount of tannic acid in a typical black tea is about 16 per cent., and in a typical green tea about 27 per cent. On the average, there is very much more tannic acid in Indian and Ceylon teas than in China teas. This difference is a matter of great importance because it suffices to make the China tea far more desirable as a beverage.

Tannic Acid in Tea. On this important matter we cannot do better than quote from the most authoritative book in English, the well-known work of Dr. Hutchison on "Food and the Principles of Dietetics." He says: "The composition of the infusion is of much greater practical importance than that of the leaves from which it is made. . . . The *caffeine* (or *theine*, the valuable stimulant alkaloid contained in tea and coffee) is so soluble that it is practically all dissolved out of the leaf immediately infusion has begun. With tannic acid this is not the case. There is certainly less tannic acid after three minutes infusion than after five, and less after five than after ten; but beyond that one does not find much increase, for by that time practically the whole of the soluble matters have been extracted from the leaf." In general, the proportion of tannic acid is much more affected by the length of infusion than that of caffeine. Hutchison quotes a large number of experiments made by others, and repeated and extended by himself, which show that "the longer tea is infused, the higher is the proportion of tannic acid dissolved out, while the proportion of caffeine, on the other hand, is but little affected. From this the practical inference is that if one wishes to avoid having much tannin in tea one should infuse it for as short a time as possible." In order to emphasise the great superiority of China tea, we may quote one series of experiments in which it was shown that while three minutes' infusion, on the one hand, and 15 minutes' infusion on the other, yielded respectively 7·7 and 7·9 per cent. of the tannic acid in a China tea, the figures for an Indian tea were respectively 11·3 and 17·7 per cent.

How to Make Good Tea. Dealing further with this very important matter, Dr. Hutchison shows—and the whole of expert opinion agrees with him absolutely—that tea should really be infused, not boiled or stewed, as is so often the case; also, that the amount of leaf commonly used is excessive; further, that infusion should be limited to, at most, four minutes, not only because prolonged infusion extracts too much tannic acid, but also because it "dissipates the volatile oil, to which much of the fragrance of a good cup of tea is due." It is also pointed out that the addition of milk or cream is to be commended on hygienic grounds—not, as might be thought, because the albuminous matter of the milk is a valuable food, but because it precipitates some of the tannic acid of the tea before it is swallowed, and so prevents it from doing harm afterwards. The reader would certainly not consider excessive the brief amount of space we have devoted to the chemistry of tea if he realised the very grave injury to the digestion which strong tea works in thousands of cases. A large part of the injurious effects of tea, commonly attributed to its action on the "nerves," is not really due to its stimulant ingredient at all, but to the injury which improperly made tea inflicts upon the digestion in virtue of the simple fact that tannic acid precipitates albumin.

The Uses of Tannic Acid. Ignoring the local medical uses of tannic acid, which all depend upon the important property already emphasised, we may refer briefly to the uses of this substance in the process of *tanning*, by which animal hide is converted into leather. And here it is necessary to point out that, as a matter of fact, there is a very large number of different kinds of tannic acid. Indeed, it may almost be said that every vegetable source of tannic acid yields a product somewhat different from every other. Hence, compound names have been invented. Ordinary tannic acid is known as *gallo-tannic acid,* since it is prepared from gall nuts; the bark of the oak yields a *querci-tannic* acid, which does not yield gallic acid when it is boiled with sulphuric acid. The tannic acid in coffee, again, has been sharply distinguished, as also *catechu-tannic* acid and *kino-tannic*-acid, derived from the vegetable products called *catechu* and *kino*. These two last are very much less soluble in water than ordinary tannic acid, and hence are of special value in medicine.

In general, it may be said that the process of tanning consists in the formation in the hide of a dense and insoluble tannate of albumen. Thus, the meal known as a *meat tea*, which ruins so many digestions, is almost equivalent to filling one's stomach with leather.

Naphthalene. In preparing for the study of the extremely important bodies known as *alkaloids*, we must begin with a substance, the supposed relation of which to benzene itself is very simple; this is known as *naphthalene*, and has the empirical formula $C_{10}H_8$. Long ago, Berthelot showed that we may suppose this, and many other complex bodies derived from the distillation of coal at high temperatures, to be formed by a synthesis from much simpler bodies, as the consequence of the action of high temperature alone. Thus, the quite simple substance ethylene, which we have already studied, yields not only benzene, but also naphthalene when it is passed through a porcelain tube kept at a high temperature.

Naphthalene is an important constituent of what is left when carbolic acid has been removed from coal-tar. It crystallises in the form of large, thin, and beautiful colourless plates which are only very slightly soluble in cold alcohol but readily in hot alcohol. It melts at about 80° C., and boils at 217° C. Small quantities of it are present in coal gas, and it is also added sometimes to ordinary coal gas—which is impregnated with naphthalene vapour just before it escapes from the burner—in order to increase its luminosity. Naphthalene also plays a part in the coal-tar colour industry.

Constitution of Naphthalene. There is every reason to believe that the molecule of naphthalene consists of two benzene rings joined together so that they possess two carbon atoms in common—the said carbon atoms, unlike the others in the molecule, not having hydrogen atoms attached to them. If the reader will draw two benzene rings for himself, side by side, he will readily discover the slight modification necessary to convert them into the graphic formula of naphthalene. A large number of chemical facts go to support this theory of the constitution of the body. Its numerous derivatives show a very close correspondence to those of benzene itself. The colour value of many of them has already been alluded to.

Chinolin. Very similar to naphthalene in many respects is the substance known as *chinolin*, the importance of which we shall soon see. It occurs in coal-tar. Instead of consisting of two benzene rings having two atoms of carbon in common, like naphthalene, chinolin consists of a benzene ring and a pyridin ring having two carbon atoms in common. The empirical formula of pyridin is C_5H_5N. It is a volatile, offensive-smelling base; it is, like benzene, very stable, and is found in coal-tar.

The chinolin thus constituted is a colourless, oily substance and, like pyridin, has a characteristic smell. Its special interest for us lies in the fact that it is very closely copied in constitution by the great group of organic compounds which are found in a vast number of plants, and also in the animal body under various conditions, and are known as *alkaloids*. A very large amount of work has been done on the pure chemistry of this great group of bodies in recent years, and lately a considerable number of them have been constructed by synthetic chemistry. Before we consider their characters in general, and those of the more important members of the group in particular, let us look as closely as possible at their relations to the compounds which we have lately been discussing. The importance of this question is two-fold. There is no need for us to emphasise its importance in pure chemistry; but it is important because the alkaloids in general exercise extremely marked and definite and sharply contrasted actions upon various kinds of living tissue. Now, it is coming to be found—as we are now well prepared to believe—that there is the most precise relation between the constitution of an alkaloid and its behaviour in the body. In other words, it is pre-eminently the alkaloids which promise to enable us to unravel many of the mysteries of the chemistry of life itself, and even of the chemistry of consciousness. Already they supply us with hundreds of facts which prove the relation between chemical constitution and pharmacological action—that is to say, action upon the life and function of various kinds of living matter.

The Evolution of the Alkaloids. Let us, then, briefly retrace the imaginary evolution of an alkaloid from the benzene ring. If it occurred to the reader to attempt to construct for himself the graphic formula of *pyridin*—which we have purposely omitted to discuss until now, so that he might have a chance of teaching it to himself—he would be able to guess that it is none other than the formula of benzene, with an atom of nitrogen substituted for one of the CH groups. This, then, being noted, there will be no difficulty whatever in writing the formula of chinolin, the constitution of which we have already described. Now, it can be shown that if we double the formula of chinolin, and make a few changes in the formula thus produced—changes no graver than the substitution of hydroxyl for hydrogen and so on—we obtain the formula of one of the most remarkable and important of all the alkaloids—namely, *morphia* or *morphine*. This has the complicated empirical formula $C_{17}H_{19}NO_3$, and the graphic formula naturally looks very complicated indeed, yet its architecture can be traced up without any difficulty from benzene through pyridin and chinolin.

Nor is this a mere lucky chance. On the contrary, we find that the simplest manipulations of the molecule of morphine, thus obtained, will provide us with many other alkaloids. The abstraction from it of one molecule of water, for instance, gives us the very characteristic alkaloid known as *apomorphine*, which has a unique action upon one particular spot of nervous tissue, and that alone—namely, the spot in the lower part of the brain, the activity of which reverses the normal movements of the stomach and causes vomiting. This dehydration of morphia can easily be effected in practice, apomorphine being prepared for medical purposes by heating morphine in sealed tubes in the presence of hydrochloric acid. Then again, if we replace a hydrogen atom in the molecule of morphia by the methyl radical, CH_3, we obtain the alkaloid *thebaine* which, like morphia, is contained in opium, and has an action on the body directly and specifically antagonistic to that of morphine itself. Thus the one molecule will depress almost to the point of death the motor nerve cells in the spinal cord, while the other molecule, identical in every respect of its architecture, except, so to speak, for the substitution of hydrogen by methyl at one odd corner, will violently stimulate those very same cells so as to cause extreme convulsions. Obviously, these facts have a meaning and an interpretation which must some day be discovered.

The Properties of the Alkaloids. We have already seen that a large number of the alkaloids, including some of the most important of the group, are to be regarded as modifications of chinolin, and we have observed how a minute change in the molecule may cause complete reversal of the chemical processes displayed by the alkaloid when it is imbibed by certain living cells. Now, before we consider the properties of the alkaloids in general, we must note a fact which will help us to understand those general properties—the fact that the alkaloids may be regarded as compound ammonias, that is to say, ammonias in which hydrogen atoms have been replaced by various radicals, usually extremely complicated. This view of the alkaloids is justified by purely chemical considerations, but it is also strongly supported by those more remotely chemical considerations which are involved in the action of the alkaloids upon the body.

We may define the alkaloids, then, as highly complex derivatives of ammonia or of benzene, formed in nature by the action of living matter alone. As the name implies, they strongly resemble alkalies and, most notably, the alkali called *ammonia*. Thus their solutions are definitely alkaline in reaction, and with acids they form definite salts. All alkalies contain carbon, hydrogen, and nitrogen. The great majority of them contain oxygen. A few containing no oxygen are liquid, but the remainder are solids, usually crystalline. The best instance of a liquid alkaloid containing no oxygen is nicotine, which we must afterwards discuss. The alkaloids are found to be electropositive on electrolysis. They are only very slightly soluble in water, but readily soluble in ether, alcohol, and chloroform. The solutions are very bitter to the taste. In general, we may say that ether dissolves alkaloids, water dissolves their salts, and alcohol dissolves both the alkaloids and their salts. If an alkali be added to the solution of an alkaloidal salt in water, the alkaloid is precipitated. Alkaloidal salts are formed on the plan of the salts of ammonia, as, for instance, in the formation of ammonium chloride, which is NH_3HCl. Water is not produced. All alkaloids yield precipitates with tannic acid, with tetrachloride of platinum, and with perchloride of mercury. In this respect the alkaloids are distinguished from the large group of substances found in the vegetable world, and known, in our present state of ignorance, as *neutral principles*.

Names in Chemistry. Of recent years chemists have made a serious attempt to obtain uniformity in the spelling of the names of the alkaloids. The authorised spelling nowadays is to terminate the name of every alkaloid in *-ina* as the scientific form of the name common to all countries. This we render in English as *-ine*. Closely similar bodies which are not alkaloids but neutral principles or glucosides are always to be spelt without the "e." Thus the termination we have indicated is recommended to be a conclusive mark of the alkaloidal nature of the substance to which it is applied. Hence the proper way to spell phenacetin is without a final "e"; and the same applies to the neutral principles such as *aloin* and to the glucosides such as salicin.

Structure and Function. Before we pass on we must insist once again upon the great importance of the alkaloids, dependent upon the intimate relations between their structure and their function. Students of biology and natural history are familiar with these two terms, and with the correlation between structure, on the one hand, and function on the other—anatomy on the one hand, and physiology on the other. Now, not only do the alkaloids exhibit the same correlation, but they promise to provide us with a key to the far greater questions of vital chemistry. Already we have noticed the effect of substituting a methyl for a hydrogen atom in morphine. Let us now add the general observation that a large number of alkaloids which may act in various ways in their original state agree in having a specific paralysing action upon the extremities of motor nerves just at the very point where these motor nerves are distributed to the ultimate muscular fibres—*provided that* a methyl has been substituted for a hydrogen atom in the constitution of the alkaloidal molecule. Instances of this are furnished by strychnine, on the one hand, and methyl-strychnine on the other. Similar facts are recorded of brucine and methyl-brucine and of thebaine and methyl-thebaine. Here, also, since our desire is to correlate different parts of knowledge, we may briefly note how the facts of chemistry and the facts of pharmacology agree with the facts of botany. It is found that plants of a given natural order yield alkaloids which are, in some cases, identical. In other cases the alkaloids are very similar in chemical constitution and, therefore, very similar in pharmacological action, or they may be markedly contrasted in pharmacological action because of chemical differences which, though slight, are crucial. Of such differences we have already seen illustrations. Opposing though allied alkaloids are often found in one and the same plant.

Animal Alkaloids. Before we consider the characters of the most important individual members of the alkaloid series, we must note the existence of a large number of alkaloids which are of quite different origin, and which may be described as animal alkaloids. They are the products of decomposition produced in dead animal matter by the action of microbes, and their poisonous character has caused great attention to be paid to them. The most important of these animal alkaloids used to be called, and are still called, *ptomaines*. Thus we frequently hear of "ptomaine poisoning," but this word has been variously used at various times, and it is really best abandoned altogether, as also is the companion term *leucomaine*, which used to be applied to alkaloids formed during life within animal tissues. It is far better to use merely the term *animal alkaloids*, which furnishes us with a convenient term in contrast to the *vegetable alkaloids*.

Food Poisoning. The animal alkaloids produced in food material in the course of decomposition effected by microbes are the active agents in cases of food poisoning—properly so-called. Not so long ago it was generally supposed that cases of illness following the eating of pork pie and so on were all due to what was called ptomaine poisoning, and it is still recognised that these animal alkaloids are capable of causing very serious symptoms. These alkaloids are most commonly discovered in tinned food, in cases in which the tins are "blown"—the ends being made to bulge by the formation of gas within the tin. Various animal alkaloids have been identified and have been proved to be capable of causing very severe symptoms, but it is quite time for the public to recognise that the term *ptomaine poisoning* is misapplied in nine cases out of ten. As a matter of fact, it is actually doubtful whether a sufficiency of ptomaines occurs in any food-product, however bad, to cause really deadly symptoms. In short, we may almost venture to say that ptomaine poisoning is a myth. In general, these animal alkaloids are very much less poisonous than the most familiar vegetable alkaloids, and some of them are practically inert.

Microbes in Food. The truth is that the presence of these animal alkaloids in food is important, not in itself, but as an index to something else—the presence of active and possibly dangerous *microbes* in the food. In all probability it will soon be generally believed by experts that all cases of ptomaine poisoning are, in reality, not cases of *intoxication* by a chemical poison already present in the food, but cases of *infection* by living microbes present in the food. It is true that microbes cause their serious effects by the production of poisons within the body, but only very rarely are these poisons alkaloids at all, and even if they were, the true facts of the matter—facts which must markedly influence our action in regard to it—are widely different from those which were supposed when ptomaine poisoning, so-called, was first described. The latest authorities on this subject say, "In practically all cases, when a substance is being examined for ptomaines, it is found that the liquid containing them is far more poisonous than the alkaloids isolated therefrom."

In short, so-called ptomaine poisoning is really either poisoning by the non-alkaloidal poisons or toxins already produced by microbes in the food in question, or else is none other from the first than an infection by living microbes.

The Education of Public Opinion. It is high time that public opinion on this subject should be educated up to the level of present expert opinion and not to the level of expert opinion of twenty-five years ago. It is especially to be hoped that no reader of the course on Chemistry in the SELF-EDUCATOR will forget that the animal alkaloids, very interesting and important though they be, are not really responsible for so-called ptomaine poisoning. We may here quote from Drs. Thresh and Porter an account of what typically happens in cases of so-called ptomaine poisoning:

"A cow or pig is attacked with diarrhœa, possibly due to the *Bacillus enteritidis*, or an allied species, and some of the bacilli enter the general blood stream. The animal is slaughtered and the flesh possesses the normal appearance. Probably at this stage no bacilli can be detected in the muscles, but a rapid multiplication takes place after death, when the circulation has ceased. The meat is cooked or made into pies, or pickled; the process is insufficient to destroy the bacilli in the interior, and an epidemic results, or it may be that while the bacilli have been killed the toxins produced have escaped destruction, and these may be present in sufficient quantities to produce poisonous effects."

In short, the result of modern inquiry by chemistry, on the one hand, and bacteriology on the other, is to transfer the subject of ptomaine poisoning from the domain of the older science to that of the newer. Thus, the sooner the term *ptomaine* and the term *ptomaine poisoning* are abandoned, the better. The first is useless, and the second is entirely misleading.

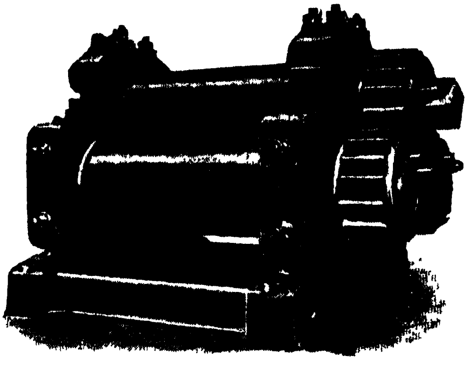
SUGAR

continued from page 3655

WE will now outline the process of manufacturing sugar from sugar cane. The sugar cane is passed through a sugar mill, and the juice that is expressed is submitted to processes of purification. The juice is concentrated until the sugar is obtained in a crystalline form. The sugar is then prepared for the market, or "cured," and the molasses treated so as to recover from it any remaining sugar. These processes are conveniently considered in the following divisions:

1. Separation of the juice.
2. Clarification of the juice.
3. Concentrating and crystallising.
4. Curing the sugar.

Separation of the Juice. The canes are cut as described in the previous lesson, and within as short a time as possible passed through a mill which squeezes out the juice. The oldest form of cane mill was provided with wooden or stone rollers, but, except in some parts of India, these have been replaced by iron mills. The three-roller mill is the most used. In this, one roller, the "head" roller, is placed above the other two, and moves in the opposite direction to them. The mill is so arranged that the cane can easily enter, the pressure being increased by the adjustment of the rollers. In Stewart's cane mill additional power is obtained by means of a massive crushing head forced down by hydraulic pressure. Merrilees, Watson & Co., dispense with the use of hydraulic appliances and make a mill with yielding ends, by means of *toggle* levers acted on by springs.



2. SUGAR CANE MILL
(A. & W. Smith & Co., Ltd., Glasgow)

The mill automatically relieves the pressure on one or more rollers and prevents jamming in case of irregular feeding. Simpler forms of mill have but two rollers [2], and others are used having rollers up to eight in number. The mills are often fed mechanically. As the crushing mill does not press out the whole of the juice, double and triple crushing are employed, and sometimes the crushed cane is soaked with hot water in its passage from one mill to the other. It is not possible to extract the whole of the sugar, but the loss is reduced to about one per cent. Recent patents embody the use of a diffusion process—a soaking in hot water in closed vessels—between the two crushings. The *bagasse* (crushed cane) from the first mill is passed into diffusers containing heated water, and after a time the bagasse is drained from the saccharine liquid, and pressed in the second mill. The weak liquid from the diffusers is re-heated and used in the diffusers for fresh bagasse. The diffusion process is universally used in making sugar from beet, and will be fully described in a later lesson. In manipulating sugar cane, diffusion is held to be a failure, as the results obtained by double and triple crushing are quite as favourable and much less expensive.

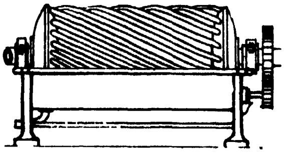
Preparing the Cane. Various methods have been suggested for preparing the sugar cane for the mill, such as shredding and cutting up the cane. The Ross apparatus cuts the cane into four-inch lengths, then slices the pieces, and passes them on to the mill. The Fletcher machine, for a similar purpose, was patented in 1894, and can be regulated to secure a product of the desired degree of fineness. Several patents taken out by Kidd in 1893 were devised on the plan of submitting the comminated cane to the action of steam before passing it on to the mills, the idea being to facilitate the extraction of juice. The objection to the use of heat in cane juice extraction is that gummy matter, which causes much trouble afterwards, is removed. The limit of economical extraction of residual sugar from bagasse is soon reached when large quantities of water have to be evaporated.

The cane juice is next strained through a wire-gauze screen to remove pieces of cane and other mechanical impurities.

Clarification. The strained juice is then submitted to the *clarification*, or *defecation*, process. The juice is run into a large copper vessel heated by steam and raised to a temperature of 130° F. Milk of lime, in the average proportion of 4 oz. of quicklime to a gallon of juice, is then added, and the heat continued until a temperature of 180° F. is reached. At this temperature a thick scum rises, and when the scum shows signs of "cracking" the steam is turned off. The juice is allowed to rest, and the intermediate layer of clear juice drawn off into an evaporating apparatus. The scum and sediment are transferred to a separate tank. The lime is used to neutralise the natural acids of the juice, which, if allowed to remain for any length of time, would cause inversion of the sugar.

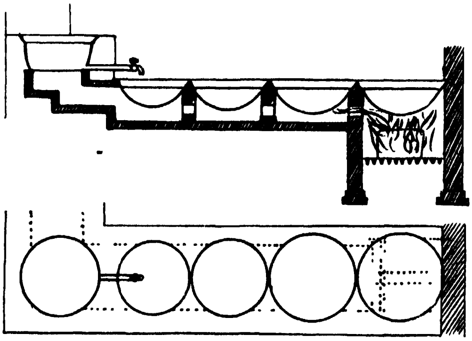
The heat removes the albuminous matters by causing coagulation, and the lime assists mechanically and chemically in removing the coagulated albumin as scum or sediment. The process of adding lime is called *tempering*, and as the quantity to be added varies, the lime is added until a faint alkaline reaction is indicated by means of litmus paper.

Continuous Defecation. Of late years continuous methods of defecation have been devised. Harvey's apparatus is a trough-like vessel heated by steam. Adjustable baffle plates or transverse divisions are fitted at spaced distances within the defecating vessel, forming practically separate chambers, while a settling chamber is fitted at the end of the defecator. Channels are arranged to draw away the scum and clear juice. By adjusting the temperature a continuous movement is given to the liquid, which readily parts with suspended matter in the settling chamber. In Deeming's superheat clarification method, the juice is heated in successive stages to a high temperature, and is thence passed to a special form of settling tank. This tank is a large cylinder with a conical bottom, and inside this is a conical vessel that reaches down to the conical part of the cylinder. The hot juice is conducted into the outer tank, and causes currents of juice which induce the sediment to fall into the conical bottom of the cylinder, the clear liquid being drawn off at the top.



3. THE WETZEL EVAPORATOR

The scums which have been yielded by the defecation process have steam blown into them to still further coagulate the albuminous matter and are then filtered, lime being sometimes added to assist the process.



4. THE COPPER WALL

Carbonatation. An alternative process of clarifying cane juice is known as *carbonatation*. The method is always used in beet sugar manufacture, and is described at a later stage. The advantage claimed for the process in the case of cane sugar is that the resulting produce is purer and fetches a higher price than sugar submitted to the usual defecation process.

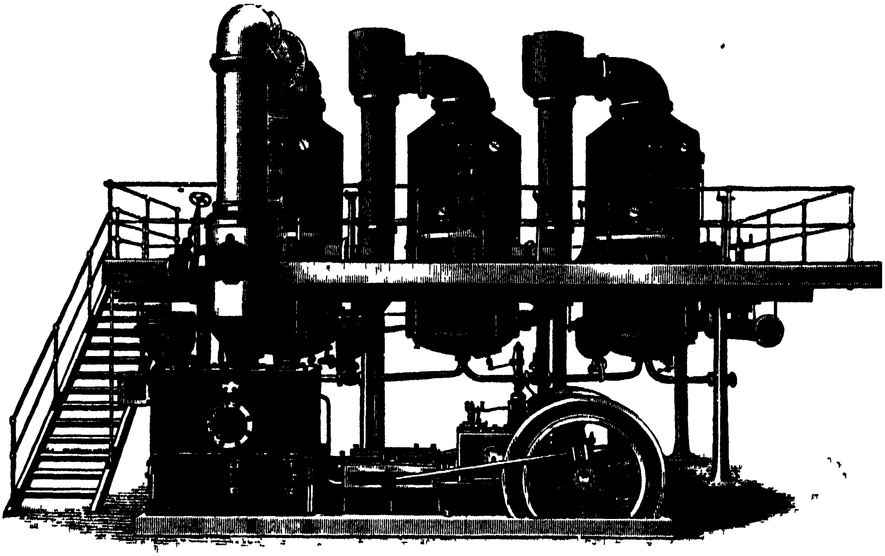
Concentrating. The next step in the manufacture of sugar is to remove the water from the clarified juice so that the sugar may be obtained in a solid state. Usually, this is done by evaporating the liquid until it reaches the syrup stage, when it is transferred to a vacuum pan, and concentrated until only 5 or 6 per cent. of water is left in the mass. The oldest method of evaporating the water from the sugar is effected by using a series of pans known as the *copper wall* [4], A description of it is useful as leading to a consideration of the improvements which have been made on the primitive apparatus. The copper wall consists of a series of open pans called *teaches* or *taches*, the set of four being placed over a flue. The fire is at one end and is directly beneath one of the teaches, the heat passing along the flue to the chimney at the other end. The clarified juice is first placed in the pan nearest the chimney, and when it has been concentrated a little it is clarified out into the next one, and so on, until it reaches the pan over the fire, where the evaporation is continued until the crystallising point is reached, when the mass is ladled out into cooling vessels. In this method a good deal of fuel is wasted, and there is danger of overheating the sugar, which not only spoils the colour of the product, but results in *inverting* some of the sugar—that is, preventing crystallisation of the full quantity of sugar.

Introduction of Steam Pipes. The next step was to replace the open fire by steam-pipes in the pans. This led, owing to the choking of the pipes, to what are called *film evaporators*. The earlier patterns consisted of a cylinder heated by steam, revolving in a trough of sugar juice. This gave place to the Wetzel evaporator [3], in which the cylinder was replaced by a number of copper pipes. The steam passes through the pipes from one end to the other, the apparatus revolving in a trough of juice. A modification of the Wetzel plan is that in which *discs* are employed instead of steam-pipes.

The Concretor. Fryer's concretor is a more economical method of applying heat to the evaporation of water. The object in the concretor is to pass a shallow stream of juice over a series of trays heated by an open fire or steam. The trays are divided by ribs running from one side nearly to the other, so that the liquid requires to take a narrow winding course during its passage from one end of the apparatus to the other. One of the concretors consists of a series of ten trays, measuring about 48 ft., and with the serpentine course which the juice must needs take, five or six times this length is traversed, and this in about five minutes. On leaving the last tray the juice is run into a trough with a revolving cylinder heated in its interior by hot air. The heating in this part of the apparatus is continued until the mass becomes flaky instead of liquid, when it is discharged into casks, where it solidifies, and is ready for the refiner. The whole process takes about half an hour, and the average yield of concrete is about 2 lb. to the gallon of juice.

Evaporation Under Reduced Pressure. Howard, in 1813, patented a method of evaporating sugar by what are known as *vacuum pans*, which it will be convenient to refer to here. He found that by reducing the atmospheric pressure by pumping out the air from a covered pan solutions of sugar boil at a much lower temperature, and thus no risks were run of injuring the sugar by overheating. Further, the process was more rapid, as, owing to the lowering of the boiling point of the liquid, the difference in temperature between the heating steam and the boiling liquid is greater, and hence greater transmission of heat is obtained for a given heating surface. The heating of Howard's vacuum pan was effected by means of a steam jacket, but this was afterwards replaced by steam coils within the pan. The steam jacket is not an economical method of transmitting heat, as the air introduced with the steam forms a non-conducting medium in the upper part of the jacket. The remedy in this case was to blow off the steam every now and then by means of a tap. Roth introduced the use of steam-pipes, and Degrand endeavoured to utilise the vapours of the pan for heating a further quantity of liquid.

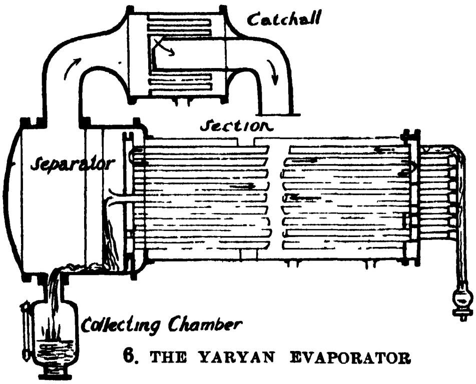
Multiple Evaporation. This plan of Degrand's was further developed by Rillieux, who designed a series of three vacuum pans, which he called *triple effet* [5]. The vessels are connected by means of valves so that the juice can be drawn successively from one to the other, but the most important principle is that involved in using the latent heat of steam three times over. Dr. J. Lewkowitch recently gave the following explanation of the principle of the multiple effet before a meeting of the Society of Chemical Industry: "Suppose," he said, "we have at our disposal heating steam of what is termed in practice *half an atmosphere* (or one and a half atmospheres expressed in absolute pressure), such as the exhaust steam from an engine. The temperature of such steam would be about 112° C. Suppose, further, that we have employed the best practical means for producing vacuum at the outlet of the third vessel, so that the temperature would be about 46° C. We have, therefore, a temperature difference of 112° – 46° = 66° C. available for evaporating purposes. This difference would have to be distributed over the three vacuum vessels or effets. If we make the heating surface of each vessel the same, it follows that the amount of water evaporated will be the same in each vessel. Consequently, the difference of temperatures in the three vessels must be the same—66/3 = 22° C. We have now the following state of affairs: the steam entering the first effet has a temperature of 112° C. We require 22° C. for raising the liquor in the first vessel to the boiling point; the liquor would then have a temperature of 112° – 22° C. = 90° C., and the vapours escaping from the outlet the same temperature of 90° C. To this temperature of the vapour corresponds the absolute pressure of 525 mm., or in technical parlance, a vacuum of 235 mm. —say 9 in. A gauge (*manometer*) fixed to the outlet of the first vessel would therefore register this vacuum. The steam enters the heating system of the second effet with a temperature of 90° C. The liquid in the second vessel requires 22° for raising it to the boiling point and has therefore the temperature of 68° C. If no loss of heat take place the temperature must be slightly higher, as the flow of liquid goes in the direction from the first effet to the second effet, and the liquid coming from the first vessel has



5. TRIPLE EFFET APPARATUS (McOnie, Harvey & Co., Ltd., Glasgow)

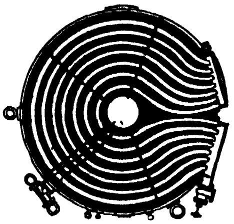
the temperature of 90° C.; but this point may be neglected here. The vapour escaping from this second vessel will have the temperature of 68° C., which corresponds to an absolute pressure of 213 mm. (8·5 in.) or a vacuum of 547 mm.—say, 21·5 in. This vapour of 68° C. enters the heating chest of the third vessel and brings the liquid therein to the temperature of 46° C."

The Yaryan Evaporator. Rillieux, the inventor of the system of multiple evaporation, employed horizontal cylinders furnished with a number of horizontal tubes. A disadvantage is that the steam passes through all the heating tubes with a uniform velocity, very low in the case of the second and third effets, thus making a rapid exchange of heat impossible. This led to the use of vertical vessels with shorter horizontal heating tubes such as are now employed. The next innovation was Yaryan's, in which the liquid is passed through narrow tubes while the steam circulates around them. Yaryan adopts in his apparatus [6] the two principles of evaporation *in vacuo* and multiple effet. The evaporator consists of a series of straight tubes passing from end to end of a shell or drum and coupled together by an ingenious arrangement of pockets to form coils, the main advantage gained being the ease with which the straight tubes can be examined and cleaned.



6. THE YARYAN EVAPORATOR

As a rule the coils consist of an odd number of tubes, the inlet being at one end of the evaporator and the outlet at the other. At the outlet end of the evaporator is a separating chamber in which the liquid discharged from the tubes is completely separated from the vapour. Below the separating chamber is a collecting chamber into which the liquid flows, whence it is drawn by superior vacuum into the vaporising coils of the second effet, in which it undergoes a second process of evaporation by means of the vapour that comes through the vapour pipe at the top of the separating chamber of the first effet into the shell of the second effet.



7. LYRE-SHAPED TUBES IN VACUUM PAN

As noted above, evaporation takes place within the interior of the vaporising coils, the heating agent being outside the tubes, and as the rate of the feed of liquid to be evaporated is arranged so that it cannot fill these coils, there is never any depth of liquid to be displaced by the vapour in its endeavour to escape from the heating surface. In addition to this the rapid circulation induced by the formation of the vapour in the interior of the tubes promotes a movement which brings into play the whole of the heating surface in a manner not attained in the multiple effet.

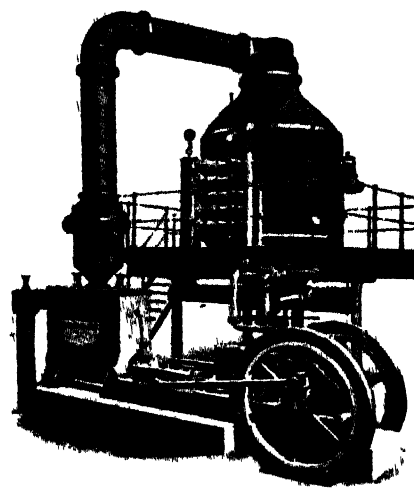
Lille's Evaporating Apparatus. This apparatus, introduced in 1893, has for its object the separation of suspended liquid particles from the vapours evolved during the evaporation of liquids. By means of perforated plates the juice is distributed over a series of horizontal pipes arranged in a closed chamber. Steam is circulated through the pipes. The vapour from the juice passes through and around baffle plates into a prolongation of the evaporating chamber called the subsiding chamber. The baffle plates cause the suspended particles to separate and fall to the bottom of the subsiding chamber, whence they are drawn off by means of a pipe below. The vapour passes off by an outlet pipe in a dry state, the pipe being in the upper part of the subsiding chamber.

Harvey's Evaporators. Patented in 1899, these evaporators are constructed of a series of steam-pipes with vertical juice-circulating tubes and vapour generating vessels which are superposed in vertical columns so as to act as triple or multiple effet. Rapid circulation of the juice is attained and a quick rate of evaporation.

There are numerous other varieties of evaporators, but each will be found to fall within one of the general kinds enumerated above.

Crystallising. In the copper wall, Wetzel apparatus, and Fryer's concretor, the juice is converted into solid sugar, while in the multiple effet and Yaryan evaporator the juice is only reduced to a syrupy consistence—until it has lost 70 per cent. of its bulk. When the juice has reached this stage it is transferred to a *vacuum pan* and boiled until grains of sugar are formed. The vacuum pan [8] is fitted with two or three coils [7] of steam-pipe sufficiently separated to allow of free circulation of the contents of the pan. The pan is fitted with pumps for making a vacuum and a contrivance called a *proof stick* for obtaining samples of liquid from the interior without breaking the vacuum. The working of the vacuum pan is as follows: The air pump is started, and as soon as the vacuum reaches 26 in. or 27 in. the feed cock on the side of the pan is opened and sufficient liquor drawn in to cover the bottom coil. Steam is then turned into the coil and the liquor rapidly evaporates. Further supplies of liquid are admitted at short intervals, the feed cock being opened for about 15 seconds at a time until the contents of the pan show signs of "graining," when samples are taken with the proof stick. The grain is "fed" carefully, the cock being opened frequently and each time the quantity admitted increased. As the amount of syrup in the pan increases steam is turned on in the other coils until at the completion of the charge the pan is nearly full or up to the "bull's eye," or sight hole, in the side of the pan. In this way the grain "grows" in size. The whole skill of the pan-boiler consists in inducing the grains to grow to their utmost, and this can only be done very slowly and by manipulating the temperature.

Striking the Pan. The mass in the pan at the finish of the boiling is termed *massecuite*, and the operation of discharging or emptying the pan is known as *striking*. The striking point is judged by the firmness of a sample taken from the pan and suddenly cooled in water. When the grain is very small the pan is sometimes only half emptied and fresh syrup admitted, the half-emptying process being known as *doubling*, and the discharged massecuite as *first cut*. The process with pure juices can be repeated several times, but a point is reached at last when the crystals do not increase in size, and the whole charge is *struck*.



8. THE VACUUM PAN
(McOnie, Harvey & Co., Ltd., Glasgow)

To save time in boiling it is now general to add sugar grains to the pan instead of forming grain from the syrup, this being known as *seeding*. In a pan containing about 30 tons of massecuite one ton of sugar is required, the sugar used being that recovered from the molasses.

Demerara Sugar. The yellow crystals known under this name are produced by adding to the massecuite sulphuric acid so as to slightly char the sugar grains, and give the bright yellow colour so much admired. About three gallons of sulphuric acid diluted with one and a half gallons of water is used for five tons of sugar. It was formerly the practice to employ a small quantity of chloride of tin, but this has been discontinued in view of the fact that the cumulative effects of the metallic impurity might be injurious, although no cases of bad effects have been reported. Artificially dyed sugar in which aniline colour is employed has been sold as Demerara sugar, but legal proceedings have now stopped this.

Curing the Sugar. The massecuite from the last operation consists of a mixture of crystalline sugar and molasses. The problem now is to separate the two. The oldest method is to run the massecuite into coolers and when set to dig out the mass and put it into casks with perforated bottoms. In this way the molasses drained out partially and yielded raw or *muscovado sugar*. This crude method has been replaced in most countries by treatment of the massecuite in centrifugals. This process and crystallisation in motion, which now accompanies it, is dealt with in the lesson dealing with refining.

The recovery of sugar from molasses is dealt with at the end of the article on beet sugar as the processes are common to the manufacture of cane and beet sugar.

Cane Syrup. There is such a decided preference in the United States for sugar in the form of syrup that attention should be concentrated on syrups. The Florida sugar cane is particularly well adapted for syrup production. In canning syrup the important point is to destroy all ferments in the syrup and the vessel by heat, and therefore prevent germs from entering. For family use fruit jars with rubber bands are quite suitable. Golden-coloured table syrup manufactured in Barbados and Porto Rico commands such a fancy price in the United States that it would pay the growers better to convert the whole of the cane sugar crop into syrup. The addition of a little citric acid helps to clarify the syrup and is advantageous, because it inverts some of the sugar and thus prevents crystallisation. When an acid syrup is used in cooking it advantageously reacts with the bicarbonate of soda employed as a baking-powder. The casks in which the syrup is stored should have been steamed and sulphured before being filled with syrup.

Cane Sugar Factory. A factory capable of dealing with 100 of cane per 24 hours and employing engines of 150 h.-p., turning out 8 tons of sugar daily, could be erected and equipped for about £40,000. The cane mills are placed on the ground floor and the juice is pumped up to the top floor and descends as it is manufactured. In the laboratory a *polariscope*, such as is figured in the lesson on sugar testing, costs £40; a balance costing about £10 will also be required as well as dishes and other pieces of apparatus. The establishment of central factories has been urged as a means of resuscitating the sugar industry in the West Indies. A factory in which modern machinery and scientific control are installed would be able to obtain a better yield of sugar than smaller factories. The position of the factory would be determined by the facilities of transport, and if the factory were worked on a co-operative system among the cane growers friction would be avoided. In buying sugar cane the sugar yield is the only satisfactory basis.

AN AGE OF MARTYRDOM

Fall of Cardinal Wolsey. Sir Thomas More. Accession of Edward VI. Queen Mary and the Persecution of the Protestants

By JUSTIN McCARTHY

WE must go back some years to record the fall and death of Cardinal Wolsey. His fall was as rapid as his rise. He displeased the King by his indecision about Henry's divorce, and his many enemies quickly took advantage of his misfortunes. In 1529 he was prosecuted under the Statute of Praemunire, and resigned his office of Chancellor. He was afterwards impeached in the House of Lords, but the Bill was thrown out in the Commons, partly by the influence of Thomas Cromwell and partly, it is said, by that of the King. His property was confiscated. He withdrew to York, but in 1530 was arrested on a charge of high treason. On account of his health he was allowed to travel to London by easy journeys, but he became so ill in consequence of an attack of dysentery that he had to stop at a monastery near Leicester, where he died on November 29th, 1530.

Sir Thomas More. The reign of Henry VIII. is made painfully memorable by the manner in which death sentences were inflicted on some of his most distinguished subjects. Sir Thomas More, scholar, author, and statesman, born in London, February 7th, 1478, came to hold high public offices. He was a member of the legal profession as well as of the House of Commons, was elected Speaker of the House of Commons in 1523, and was later made Lord Chancellor. Like Colet and Erasmus, with both of whom he was acquainted, More was of the new order of thinkers, and went with them in the desire for certain reforms in the Church. But he could not consent, any more than they, to a complete rejection of the ecclesiastical authority of Rome. When Henry VIII. was declared head of the English Church, More, who had resigned the office of Lord Chancellor in 1532 because he was altogether opposed to the King's assumption of supremacy, refused to recognise any other head of the Christian Church than the Pope. His refusal to take the Oath of Supremacy was made the occasion for a charge of high treason against him, and after more than twelve months' imprisonment he was sentenced to death, and was beheaded on July 7th, 1535.

The Career of Thomas Cromwell. The fate of Thomas Cromwell is another event of Henry's reign which has been almost universally condemned, although not, as in the case of Sir Thomas More, through admiration for the character of the sufferer. Thomas Cromwell is said to have been the son of a blacksmith and innkeeper in Putney, and to have served in his early years as a common soldier in Italy, and then to have been a clerk in Venice, Antwerp, and other places. He returned to England and became very successful as a lawyer and money-lender; he attracted the attention of Cardinal Wolsey, who made much use of his services, and was probably the means of getting him into the House of Commons. He became Wolsey's secretary, and through him got into favour with King Henry. Cromwell advised the King to declare himself the supreme head of the Church of England, so that he would thus be able to settle the question of his divorce in his own Ecclesiastical Courts. Cromwell's action also brought about the suppression of the monasteries, although it is understood that he himself remained a member of the Church of Rome. He was made Chancellor, Secretary of State, and, finally, Earl of Essex. Then the tide of success suddenly turned, the reaction against Henry's claims to absolute spiritual domination set in, and Henry found himself embarrassed by the unpopularity of Cromwell's measures and character.

When Henry could no longer with safety make use of any favourite minister, it seldom cost him much time to discover the quickest way of getting rid of the encumbrance. Cromwell had not been for quite two months the bearer of an earl's title when he was arrested on June 10th, 1540, and sent to the Tower. He was accused of high treason by the Duke of Norfolk, was not allowed any form of trial, but was condemned on a Bill of Attainder, an antiquated and odious practice which had been much favoured by Cromwell himself during his days of power.

The Bill of Attainder. The effect of a Bill of Attainder in those days was that when once it had been declared in force by the ruling powers against any obnoxious person that person was thereby put outside the range of legal trial, and had to be forthwith condemned. Cromwell was accordingly beheaded on Tower Hill, July 28th, 1540.

There were several other executions during the reign of Henry VIII. which seemed as sudden and as capricious in their character as those we have mentioned, executions which appear to have been mere judicial murders, committed to gratify some humour or to secure some supposed interest of the sovereign. The foreign policy of Henry continued for some time in alternations of antagonism, now with France and now with Germany, but the historical responsibility for this continuous warfare cannot be laid altogether on the shoulders of the English monarch. The whole condition of Europe at that time tended to resolve itself into a struggle for superiority between England, Germany, and France, the great rising and rival Powers of the world; the political life of Europe was then only at an early stage of development, and there seemed to be something going on which resembled a mere struggle of organic physical forces.

Peace Between England and France. France gave much excuse for some of Henry's hostility to her by her constant endeavours to obtain control over Scotland, and to convert the northern and the southern division of the British island into two entirely separate States, the Scottish kingdom becoming a sort of partner with the realm of the French monarch. In 1546 a peace was concluded between England and France which, among other advantages to Henry, relieved him for the time from the interference of the French monarchy with Scotland. Henry's life was now drawing to a close. He had overtasked himself in every sense, had put a strain upon all his powers, physical and intellectual, had had too much work, too much pleasure, too much passion, and his life came to an end on January 28th, 1547, when, according to our modern estimate of man's age, he had not long passed the most vigorous period of his existence.

History is still engaged in controversy concerning the political and personal character of Henry VIII. He lived and reigned during a period when one of the greatest political and religious convulsions which had come upon Europe since the birth of Christianity was passing over England. By one class of historians he is regarded as one of the greatest impelling forces of that movement, while by others he is set down as merely one of its involuntary instruments. Many of his deeds as a sovereign and a man are incapable not merely of defence, but even of excuse; and the most favourable plea that can be made for these passages in his career is that other monarchs have committed sins as great and have yet been allowed by the general verdict of posterity to have made their country greater and stronger than they found it. So much, at least, must be acknowledged when we study the reign of Henry VIII. He made his country greater than he found it, and if his life was stained with sin and crime, it must be owned that he lived at an age when the successful maintenance of his country against many powerful enemies was believed to be a sovereign's best excuse for his sins against the codes of morals and religion.

Edward VI. The reign of Edward VI. is memorable chiefly because of some of the strange and even grotesque incidents and characters which it encloses. Edward, the son of Henry VIII. by his third wife, Jane Seymour, was only in his tenth year when he succeeded in the January of 1547. The boy's uncle, Edward Seymour, Earl of Hertford, in defiance of the will of Henry VIII., by which Edward VI. succeeded to the throne under the regency of a council of sixteen members, mostly Reformers, got himself made Protector to the young sovereign. He invaded Scotland in 1549, with the object of enforcing the contract of marriage between Edward and the Scottish princess, afterwards famous in history as Mary Queen of Scots. Mary was the daughter of James V. of Scotland, and was born at Linlithgow on December 8th, 1542, when her father was lying on the bed of sickness from which he was never to rise. Mary thus became a queen a few days after her coming into the world. It was arranged by the Regent of Scotland that Mary should be given in marriage to Prince Edward of England. The Scottish Parliament, however, annulled the contract; thereupon the English Protector invaded Scotland, and the Scots were defeated at Pinkie on September 10th. The marriage between Edward of England and Mary of Scotland was not accomplished, and Mary was affianced to the Dauphin of France. The Protector, who had now created himself Duke of Somerset, received information, on his return to England, that his brother, Lord Seymour, an Admiral in the Service, had been intriguing against him, which Somerset regarded as intriguing against the welfare of the King and the State; and without troubling himself about considerations of family and feeling, he had Lord Seymour executed in March, 1549. Lord Seymour was the second husband of Catherine Parr, widow of Henry VIII.

same year there were two uprisings in one of the Catholics in Devonshire, who felt themselves heavily oppressed by the new laws following the Reformation, and another of the discontented agrarian population around Norwich. Both risings were suppressed without much mercy by Somerset. But Somerset's power was soon to come to an end. He found an opponent in the person of John Dudley, Earl of Warwick, who was making himself very influential throughout England. The country turned against the Protector; he was accused of ambitious designs dangerous to the State, and was executed on January 22nd, 1552. No sooner was Somerset executed than the country found it had reason to regret him, for the new manager of affairs proved to be even a more selfish and, if possible, a less statesmanlike ruler. Dudley's great ambition was to bring his own family into the line of succession. He had by this time obtained the title of Duke of Northumberland, and married his fourth son, Lord Guildford Dudley, to Lady Jane Grey, who was the g daughter of Mary, younger sister of Henry VIII and to whom, by the will of that sovereign, the crown was to pass if there were no children of Edward or of either of his sisters, Mary and Elizabeth.

The young King was now dying of consumption, and Northumberland induced him to consent to a project for the exclusion of his sisters from the succession, and the nomination of Lady Jane Grey. He prevailed on Edward to accept this arrangement, and a declaration embodying its purpose was formally drawn up. The boy King died at Greenwich on July 6th, 1553. Northumberland was supposed by some to have hastened his death by poison, but of this there is no authentic evidence. Edward had no opportunity of proving that he had any capacity for rule, though he seems to have possessed much of the talent as well as some of the vices of the Tudors, and he lives in history only as a name.

On the death of Edward, Mary, daughter of Henry VIII. by his first wife, Katharine of Arragon, became Queen. Mary was born at Greenwich on February 18th, 1516. She had been remarkably well educated, loved reading and books, could read many languages, and was devoted to the Church of Rome. Northumberland had prevailed upon his half-brother and his Council to set aside her claims. Lady Jane Grey was actually proclaimed Queen in London, July 10th, 1553, but had no support. The force of public opinion throughout the country was exerted for the maintenance of Mary's claim, and she received a triumphal welcome on her public entrance into London. The English people had become thoroughly weary of Northumberland and his policy, and he and two of his confederates were sentenced to death and executed.

A Friend of Rome. It was not long before Queen Mary began to take measures to prepare the way for the restoration of the old form of faith in England. She restored to their Sees the Catholic Bishops who had been dispossessed, and she even went so far as to imprison some of the most prominent Reformers, although she did not as yet venture to take any steps for the re-establishment of Papal supremacy. Her first great trouble arose out of her proposed marriage with Philip of Spain, only son of the Emperor Charles, who afterwards became, on the death of his father, the sovereign of Spain, the two Sicilies, the Netherlands, Mexico, Peru, and other regions. Philip became the husband of Mary, in spite of the protests raised against the marriage by the great majority of the English people, who regarded Spain as the enemy of England, and were convinced that the union of their Queen with the Spanish prince could mean nothing less than an attempt at the restoration of the Catholic religion.

One of the first measures taken by the new Queen and her Council was the bringing of Lady Jane Grey to trial, her imprisonment in the Tower, and her sentence to death. Lady Jane Grey might probably have been spared if she had consented to give up the Protestant faith, but she scorned every proposal made to her, and the rebellion raised by Sir Thomas Wyatt against the marriage with a Spanish prince only served to stimulate the supporters of Mary to the harshest deeds. Mary at this time suspected her sister Elizabeth of complicity in Wyatt's rebellion, and imprisoned her in the Tower. As no evidence could be found against her, however, she was released in a few months and sent to Woodstock in the care of Sir Henry Beddingfield. Lady Jane Grey, her husband and father were publicly executed in 1554, even before the marriage of the Queen.

Protestant Persecution.. After the marriage began the reign of persecution, which brought upon the Queen the odious and well-remembered popular name of "Bloody Mary." How far Mary was responsible for the cruelties committed in her name it is hard to say, for she appears to have had at the opening of her public career a generous and a loving nature; but she certainly made herself responsible for the outrageous acts of persecution committed during her reign. Cardinal Pole, an Englishman by birth, was sent over to England as a Papal delegate, and became one of Mary's most favoured counsellors, and was created Archbishop of Canterbury. Such eminent men as Latimer, Ridley, and Cranmer were tried for heresy, found guilty, and burnt at the stake. Latimer was burnt with Ridley in front of Balliol College on October 16th, 1555.

It is believed that during the last three years of Queen Mary's reign no less than 300 victims of religious persecution were put to death on the scaffold or at the stake. We must bear in mind that in those days religious persecution by ruling powers expressed itself in deeds unknown to the modern world, and that long after the reign of Mary there was a persecution of Catholics which brought its victims to the axe and to the flames. But even for Mary's time such cruelties were extravagant, and have marked the history of her reign with a horror which must live for ever among the world's most ghastly records. Mary, meanwhile, suffered from many disappointments. She was the victim of long illness; she had found that her husband was selfish and worthless, and it was a bitter disappointment to her that she had no children to maintain the succession.

Calais Recaptured by France. She dragged the country into a war against France to support her husband, who had succeeded to the dominions of Spain. The people of England could not throw their souls into this war, and it had hardly begun when the French won a decided victory and recaptured Calais, which had been taken by Edward III. Mary was wounded to the heart by this calamity, for which she must have felt herself to be mainly responsible. Her health broke down completely, and she died on November 17th, 1558.

Before the war had gone much farther, England was left without any territory in France. If Mary had lived longer, it is probable that the country would have risen against her disastrous rule. Her death at that crisis seemed to light a ray of hope in the hearts of the majority of her subjects, whose patience was almost exhausted

METALLURGY

Classes of Ores and the Various Methods of Recovering their Metal Contents. The Physical Properties of Metals

By A. H. HIORNS

METALLURGY originally implied a knowledge of the art of extracting metals from their ores in a sufficient degree of purity to enable them to be employed for industrial purposes. The methods employed were largely empirical, depending partly on chance and partly on knowledge handed down often from father to son; and although great skill was acquired by the workman, only special ores could be treated, with the expenditure of enormous labour and an excessive consumption of fuel. At the present time metallurgy is tending to become a true science. The importance of the professional art is diminishing each year before the applications of science, methodically conducted by experts in every branch of the subject, who are applying the laws of chemistry, physics, and mechanics to metallurgical operations of all kinds.

What is Metallurgy? The term *metallurgy* has now acquired a much more extended meaning; it includes a knowledge of the properties of the various metals and the modes of their application to manufacturing purposes. It comprises a number of physical and mechanical operations many of which are conducted at very high temperatures, so that a knowledge of the principles of heat and refractory materials is necessary. Metallurgy is essentially a chemical art, and an acquaintance with that important branch of science is necessary to its study. But metallurgical *chemistry* is a special branch of chemical science which does not come within the ordinary sphere of academic teaching of chemistry, and purely analytical and laboratory methods are often inapplicable to processes conducted on the large scale at high temperatures.

Only a few years ago temperatures were determined in a very uncertain manner, the temperature of a metal being judged by the changes of colour perceived by the eye, and the terms dark red, cherry red, orange, white, yellow, etc., were used to express different temperatures Now a manager without leaving his office or laboratory may ascertain each moment the precise degree of temperature of a furnace or of a metal by placing in it a thermo-couple, which generates a current of electricity, the value of which is signified by a suitable recorder.

Ores. Metals occur in nature in ores, which may be termed *metalliferous matter.* Ores require special preparation before they are submitted to the smelting operation. The ore proper is associated with more or less extraneous matter, termed the *matrix* or *gangue.*

The nature of an ore depends on the nature and condition of the contained metal. Iron ores are seldom smelted when they contain less than 30 per cent. of iron. Ores of lead and zinc are poor with 30 per cent., while a copper ore is considered very rich with 30 per cent. of the metal. Silver, and especially gold, ores are very valuable when they contain a few ounces to the ton. The metallic minerals are generally oxides, carbonates, silicates, sulphides, arsenides, chlorides, etc., sometimes alone, but very frequently associated together, forming *complexes.* The gangue may consist of quartz, lime and magnesia, silicates, flourides, sulphates, etc., and these sometimes perform useful functions in the extraction of the metal.

Classes of Ore. Ores may be classified under two chief categories—ores with earthy gangue and ores with metalliferous gangue; the latter are chiefly oxides and carbonates of iron and iron pyrites. Many metals occur in the earth as sulphides, and these are often converted into oxides and carbonates by the action of air and moisture, so that many sulphides are found with a cap of oxide or carbonate.

Ores vary considerably in the amount of metal they contain and in the nature of the contained metals. In many cases there is only one metal present; in others the ores are complex—that is, they contain two or more metallic compounds, hence it is often necessary to submit them to preliminary processes, such as washing, crushing, dressing, and roasting, in order to prepare them for smelting.

Concentrating Ores. It is desirable to crush most ores to a more or less finely divided state. For rough crushing a rock-breaker is generally used, and for fine crushing a stamp battery or a pair of rolls. After crushing valuable minerals, it is often necessary to submit the material to a concentrating process, whereby the lighter gangue is mechanically separated from the heavier and more valuable metalliferous matter. Concentration is best effected by the agency of water, the mineral matter being separated by its higher specific gravity. When a mixture of light and heavy particles of equal size is stirred up with water and allowed to settle, the latter naturally sink towards the bottom, and the former settle towards the top. If such a mixture be conveyed by a stream of water, and the course of the stream be slightly checked, the heaviest particles will subside first. By passing the stream through a series of receptacles the grains may be collected according to their specific gravity. By allowing a stream of water to flow over very finely-divided ore, spread out on a slightly sloping surface, which is slowly revolving, the lighter particles are swept away, leaving the heavier behind.

Roasting or Calcining. Ores, after having been suitably prepared by mechanical means, may be treated directly for the extraction of the metal or submitted to a preliminary operation termed *calcining*, or *roasting*, at a moderate temperature, in order to expel volatile matter, and, if necessary, to convert the metal into the form of oxide which is chiefly effected by the oxygen of the air. In some instances it is desirable to form a sulphide, an arsenide, or a chloride, in which cases sulphur, arsenic, or chlorine takes the place of oxygen; such an artificial sulphide is termed a *regulus*, and the arsenide a *speise*.

In the case of sulphides the roasting may be conducted so as to remove the whole of the sulphur, when it is said to be "dead-roasted," or it may be necessary to remove only a portion of the sulphur. In some instances the roasting is performed at a moderate temperature so as to convert one or more of the sulphides into soluble sulphates. If the temperature be allowed to rise too high, the sulphates are decomposed, forming oxides. With some sulphide ores the roasting has to be very carefully conducted to prevent partial fusion and clotting. To prevent this, lime or some other inert substance is added to the charge. Clotting is very marked in ores containing sulphide of lead or antimony.

Metallurgical Processes. Metallurgical processes may be classified under the following heads:

1. LIQUATION. In this process an easily-fusible metal or compound may be separated from an infusible or difficultly-fusible one by taking advantage of the different melting points. In this way bismuth and sulphide of antimony are obtained from their ores, and argentiferous lead is separated from copper

2 DISTILLATION AND SUBLIMATION. By heating ores of mercury and arsenic the solid metals are driven off in the form of vapour and condensed in a liquid or solid state.

3. REDUCTION OF OXIDES AT HIGH TEMPERATURES. Reduction of oxides is usually effected by heating with carbon or carbon compound, or other bodies having a greater affinity for oxygen than is possessed by the metal.

4. REDUCTION OF SULPHIDES BY IRON. Lead and antimony are reduced by iron at high temperatures, forming sulphide of iron and liberating the metal.

5. LEAD METHOD OF EXTRACTION. Gold and silver are extracted from certain of their ores in virtue of their solubility in molten lead.

6. ZINC METHOD OF EXTRACTION. Gold and silver are separated from lead by means of molten zinc.

7. MERCURY OR AMALGAMATION METHOD OF EXTRACTION. Mercury is used cold for extracting gold and silver from their ores, the mercury being afterwards driven off by heat.

8. WET METHODS OF EXTRACTION. By means of acids and saline liquids, ores of copper, silver, nickel, etc., are dissolved, and the metal or a compound of the metal is precipitated by another metal or reagent.

9. ELECTROLYTIC METHODS OF EXTRACTING AND REFINING. This method is employed for the production of aluminium, nickel, and several of the rarer metals, such as calcium, chromium, molybdenum, etc.; also for the refining of copper, silver, and nickel. Iron is also now being extracted by electric furnace methods.

10. By the action of highly oxidisable substances on metallic salts, as in the precipitation of gold from its solution by ferrous sulphate.

11. CRYSTALLISATION. Lead is crystallised out from a molten bath of argentiferous lead in what is known as Pattinson's Process, and argentiferous zinc is removed from lead on a similar principle in Parkes' process.

Metals are extracted from their ores by dry or furnace processes, by wet processes, and by electro-chemical processes.

Physical Properties of Metals. Metals are capable of existing in the gaseous, liquid, solid, and semi-solid states, and although the properties vary according to the physical state, the difference is one of degree rather than of kind. A *solid* is a body which can, to some extent, resist a change of state, or which can, to a certain degree, sustain a vertical pressure without being supported laterally. Metals may be regarded as typical solids. A *liquid* consists of particles which have considerable mobility, and may therefore be moved about among each other with the greatest facility. Hence two different metals mixed together in the liquid state will diffuse into each other and form an alloy.

A liquid differs from a solid in being destitute of the power of sustaining pressure unless supported laterally, and its surface will be flat when the whole mass is at rest. A semi-solid, or plastic body, possesses properties intermediate between those of a solid and those of a liquid. Wrought iron at a welding temperature is a good illustration of the case in point. A gas is distinguished by the power of indefinite expansion, so that, however small the quantity, it will at once expand and fill the empty vessel, however large, in which it is placed, and will exert a pressure against the interior surface in all directions.

Liquid and Solid Metals. Liquids and gases are all included under the general name of *fluids*. There are many points of resemblance between solids and fluids which it will be useful to consider now. All substances are porous, because the particles of which they are composed are not absolutely in contact at every point, but are more or less separated by intervals of empty space in the interior.

All such cavities which can be perceived, even with the aid of the most powerful microscope, may be termed *sensible pores*, but the different molecules, of which the mass of any matter is composed, are also separated by spaces which no optical instrument can enable one to detect, and it is probably in virtue of such spaces that gases can be absorbed by metals and possibly condensed to a liquid state.

In a similar way may be explained the fact that mercury will penetrate, and even pass through, many metals. Thus, a bar of tin is easily permeated by mercury without being destroyed, although the mercury makes it very brittle. In consequence of porosity both liquids and solids are sensibly compressible, but the latter more so than the former.

"Flow" of Solid Metals. Solids may be made to flow like liquids under the influence of pressure, otherwise it would be impossible to fashion metals into various shapes by the mechanical processes of hammering, rolling, and spinning. One of the best illustrations is that of lead, which is made into pipes and other shapes by *squirting*, as it is called, in an apparatus constructed on the same principle as the syringe. The forging of iron may be cited as another good example of the flow of a solid. Even a brittle solid is not destitute of this property, if time be allowed to enable it to flow from one point to another. Professor Spring has also proved that the particles of a metallic powder may be forced into a compact mass by strong compression. In this way alloys have been perfectly formed without the aid of heat, and possessing much the same properties as they would when formed in the usual way by fusion in a crucible. It has been shown that the ease with which fluids diffuse into each other is characteristic of the fluid state. But Professor Abel has proved that carbon in a plate of solid steel can pass from it into a plate of solid iron if the two plates be tightly pressed together, even at the ordinary temperature.

Lastly, liquids, when exposed to the atmosphere, or especially when placed *in vacuo*, gradually vaporise, and solid mercury when solidified by extreme cold slowly evaporates.

Colour and Lustre. Most of the white light which falls upon a polished surface is reflected, but a small portion is absorbed, and this, being decomposed, is robbed of certain of its constituents, and the residual rays produce the effect of colour. In some metals, such as copper and gold, the absorption is more marked, hence copper is red and gold is yellow, while most of the other metals are white or greyish white. The differences of colour enable one to distinguish one metal from another. The colour of a metal is often modified by the presence of an impurity, and in some cases the nature of the impurity may be judged by the difference in the shade of colour. The lustre of a metal is independent of its colour, and depends upon the perfection of its power of reflecting light.

It varies with the purity and the degree of polish which has been imparted to it The same metal may have a different colour according to the state of division of its particles. While most metals are opaque, some are semi-transparent, and transmit only certain of the constituents of white light. Thus gold leaf is green when observed by transmitted light.

Fusibility. All metals are fusible, but some require the very highest temperature to melt them. When strongly heated, metals pass from a brownish red to a clear red colour, which gradually increases in luminosity and transparency to a dazzling white. It is convenient to use three colours to express roughly certain ranges of temperature, thus:

PHYSICAL PROPERTIES OF METALS

Metal.	Melting point in degrees Centigrade	Specific gravity	Electric conductivity Mercury = 1	Tenacity in tons per square inch approximately
Aluminium	625	2·56	31·7	12
Antimony	632	6·71	2·0	0·5
Arsenic ..	500	5·67	2·7	0·5
Bismuth ..	268	9·8	0·8	0·5
Copper ..	1,080	8·82	55·9	8·5
Gold ..	1,060	19·32	43·8	7
Iron ..	1,600	7·86	8·3	25
Lead ..	326	11·37	4·8	1
Mercury ..	39	13·59	1·0	—
Nickel ..	1,500	8·8	7·4	25
Platinum ..	1,770	21·5	8·3	22
Silver ..	960	10·53	57·3	10
Tin ..	232	7·3	8·2	6
Zinc	420	7·15	16·9	7

Incipient red	525°	Centigrade.
Dark red	700°	,,
Cherry red	800°	,,
Orange	1,000°	,,
White	1,200°	,,
Dazzling white ..	1,500°	,,

The following table gives the approximate melting points of various metals:

Metal	Melts at	Metal	Melts at
Tin	232° C.	Silver ..	960° C.
Bismuth	268° C.	Gold ..	1,060° C.
Cadmium	320° C.	Copper ..	1,080° C.
Lead ..	326° C.	Nickel ..	1,500° C.
Zinc ..	420° C.	Palladium	1,500° C.
Antimony	632° C.	Pure Iron	1,600° C.
Aluminium	625° C.	Platinum	1,770° C.
Magnesium	750° C.	Iridium ..	2,500° C.

Advantage is taken of the fusibility of a metal to produce castings from a given pattern and to join metal parts together by soldering. Metals with high fusing points, such as iron, are used for fire-bars, melting-pots, and similar purposes [see also article beginning on page 2862].

Crystallisation of Metals. On solidification after melting, metals usually crystallise. Crystallisation also occurs when metals are condensed from a state of vapour, or deposited from solutions by means of electricity. This crystallisation of metals is of great importance, as the formation of crystals in metals due to continued vibration, intense cold, sudden alterations of temperature, or the presence of impurities may render a metal absolutely useless. Crystallisation may serve to indicate the quality of a metal, as in the case of foundry pig iron; to indicate the presence of impurities, as in the case of antimony in lead; or to separate metals on the large scale, as in the Pattinson process of desilverising lead.

Density or Specific Gravity. The density of a metal depends on the closeness of contact between the molecules. It is influenced by the crystalline structure, temperature of casting, rate of cooling, mechanical treatment, and the purity of the metal. The density of a metal is increased by wire-drawing, hammering, rolling, or other compressive force, which closes the pores. With the exception of bismuth, all metals are denser in the solid than in the liquid state. The densities of the metals are as follows:

Platinum	21·5	Copper	8·82
Gold	19·32	Cadmium	8·60
Mercury	13·59	Iron	7·86
Palladium	11·20	Tin	7·29
Lead	11·37	Zinc	7·15
Silver	10·53	Antimony	6·71
Bismuth	9·80	Aluminium	2·56
Nickel	8·80	Magnesium	1·74

The specific gravity of gold, being very high, renders it very suitable for coinage. On the other hand, the much lower relative weight of iron is an advantage in building, and aluminium, owing to its strength and lightness, is useful for many purposes where lightness is desirable.

Toughness. This is the property of resisting fracture by bending, twisting, or similar means, after the limit of elasticity has been passed. This is well exhibited in the case of copper and lead.

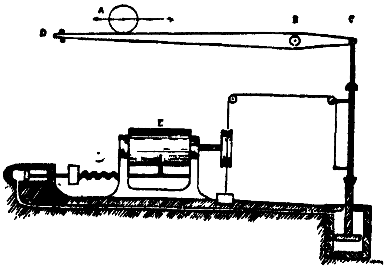
Malleability. When a body can be permanently flattened under a hammer or between rolls without cracking, it is said to be *malleable*. If it break, it is termed *brittle*. Malleability depends on tenacity and softness. During the working of metals, the particles are forced into unnatural positions, but by heating the mass strongly, and allowing it to cool slowly, they are brought back to their normal state. This is termed *annealing*. Gold is the most malleable of metals, combining the two properties of softness and tenacity in the highest degree. Some metals are malleable when hot, but not when cold; they are then termed *cold-short*. Other metals are just the reverse, and are then termed *hot-short*. Ordinary zinc is malleable only at 100° to 150° C. The order of metals for malleability is as follows: gold, silver, copper, tin, platinum, lead, zinc, iron, and nickel.

Ductility. When a metal can be drawn into wire, or lengthened by a tensile force combined with lateral pressure, without breaking, it is said to be *ductile*. The ease with which it can be reduced will depend on its softness, but the thinness to which it may be drawn will depend on its tenacity, which property has more influence on the ductility of metals than on their malleability. The rate at which the traction is applied also exerts considerable influence on the ductility. The following metals are arranged in the order of their ductility: gold, silver, platinum, iron, nickel, copper, zinc, tin. and lead.

Tenacity. This is the property of metals by which they resist, in varying degrees, the separation of their molecules by the action of a tensile stress. It not only varies with each metal, but also with the physical condition of the metal. It is generally diminished by a rise in temperature, while the reverse is often the case with regard to malleability and ductility. Some metals have a low tenacity, and are then often brittle. The tenacity or tensile strength is determined on a straight bar, held firmly at one end, and a gradually increasing weight applied at the other end until it breaks. The strength is usually expressed as the number of tons or pounds required to produce the rupture of a one-inch-square bar.

Elasticity. This is the property in virtue of which a body returns to its original bulk after its shape has been altered by external pressure. Any body which is thus capable of recovering its shape is said to be a *perfectly elastic body*. When a bar of metal is submitted to a tensile stress, it increases in length proportional to the weight applied. When a certain limit is reached, the stretching or strain increases more rapidly than the load, and then the bar will be permanently stretched. The point at which the stress and strain ceases to be proportional is termed the *limit of elasticity* of the metal. The elastic limit, breaking stress, and elongation, are of prime importance. In designing structures it is more important to know how much weight a metal will sustain without permanent distortion than to know its breaking stress, in order that the greatest load may be applied well within the elastic limit of the material.

Testing Metal Strengths. The above characteristics are determined by means of a tensile testing machine. This machine is made with two pairs of jaws in which the test piece is held, one pair being generally connected with the ram of a hydraulic cylinder and the other end with a lever carrying a weight, by which the tensile stress exerted by the ram is measured. Some machines have the jaw and test pieces so arranged that a pull is produced in a vertical plane, while in others the jaws are arranged so as to work horizontally. Sometimes it is advisable to obtain the stress within the limit of elasticity. This is determined by an arrangement similar to the following. A single lever carries a poise which measures the load, while the pressure is applied by means of a hydraulic ram [1]. The ratio of BC to BD is 50 to 1. The poise is one ton, and when it is at D, it balances 50 tons at C. E is a revolving drum which is actuated by the wire attached by clips to the specimen which is being elongated. The pencil, which is actuated by pressure in the hydraulic press, has an axial motion proportional



1. HYDRAULIC APPARATUS FOR TESTING METAL STRENGTH

to the stress; a stress-strain diagram is thus obtained. Some materials, such as cast iron, are tested for their transverse strengths. The standard test piece for cast iron is 3 ft. 6 in. long, 2 in. deep, and 1 in. wide, thus allowing for a distance of 3 ft. between the supports. [See also article beginning on page 1391.]

Welding. When two pieces of metal are joined together by pressure to form one compact piece, they are said to be welded. It is necessary that the metals should be soft, with clean surfaces, and that they should possess considerable malleability and toughness. The requisite conditions for welding iron are obtained only at a high temperature with the metal in a plastic state. The motion of the molecules at a high temperature is raised to such a degree that they are capable of penetrating into each other. Steel requires to be welded at a much lower temperature than iron because of its lower melting point, and because the carbon is liable to burn off if the heat be too intense. Soft metals like lead can be welded at the ordinary temperature.

Forging. When a metal is capable of being hammered out into various shapes, the operation is termed *forging*. This property is the same as malleability, but has a more limited meaning. Forging is an illustration of the solid flow of metals. [See also article beginning on page 2983.]

Soldering. This term is applied to the operation of joining two surfaces of a metal or metals together by heat. In what is termed "lead burning," as used by plumbers, two pieces of lead are fused together at the edges by means of the oxy-hydrogen blowpipe, as in some cases the introduction of solder would not be admissible. This is the case with the sheet-lead lining of acid chambers. Solders are divided into two classes—*hard*, or fusing with difficulty, and *soft*, or easily fusible. When a red heat is required to melt the solder the operation is termed *brazing*. Brass solder belongs to this class. The solder must in all cases have a lower melting point than the metal to be soldered.

Hardness. Hardness or resistance to abrasion or cutting is generally increased by the presence of impurities in a metal, so that softness in many cases is a test of purity. The softness increases with an increase of temperature Manganese, nickel, and cobalt are the hardest, and lead one of the softest of metals. Hardness depends on the degree of attraction of the molecules for each other.

Brittleness. When a metal readily breaks into fragments by the occurrence of a sudden shock, or if a metal be unable to resist fracture when subjected to a compressive force, as in rolling, it is termed *brittle*. Brittleness is not hardness, as sealing wax, for example, is brittle but not hard. A substance is brittle when it does not elongate under pressure. If a metal be crystalline and the cohesion between the crystals be feeble, then the metal is brittle.

Sonorousness. This property is possessed by the harder metals, and is very marked in certain alloys, such as those of copper and tin. Impurities often increase the sonorousness of a metal, as in the case of antimony in lead.

Conductivity. This is the property different metals possess of transmitting heat and electricity. The conducting power of metals for heat is as follows:

Silver .	1,000	Tin.. .	152
Copper ..	736	Iron ..	119
Gold	552	Lead ..	85
Magnesium ..	343	Platinum ..	84
Aluminium ..	313	Antimony..	40
Zinc	281	Bismuth ..	18
Cadmium ..	201	Mercury ..	13

In electrical language the resistance of a metal to the flow of an electric current is more often used than the conductivity, the latter property varying inversely as the resistance. The resistance of metals is increased by a rise of temperature and diminished by a fall of temperature. The following table gives the conductivity for electricity of the metals in a pure state:

Silver ..	1,000	Iron ..	164
Copper ..	999	Tin.. ..	152
Gold	806	Lead ..	88
Aluminium ..	551	Nickel ..	79
Zinc	302	Antimony	42
Platinum ..	167	Mercury ..	25
Palladium ..	164	Bismuth ..	12

Structure. The fractured surface of a metal or alloy often affords a general guide to its properties and adaptability to various uses. It is best obtained by nicking a bar with a chisel, gripping it in a vice, and striking it with a hammer. In this way either the brittleness or the toughness is shown by the angle through which it bends and the force required to break it. When broken, any great want of homogeneity is shown by the irregular appearance of the fracture. The bar is said to be *crystalline* when it is made up of visible crystals.

When the crystals are so small that they cannot be seen by the unaided eye the fracture is said to be *granular*; occasionally the grains are so minute that they present merely a silk-like sheen, as in hardened steel and wrought copper, when it is termed a *silky fracture*. Wrought iron, when broken, shows a fibrous fracture, due to threads of enclosed slag. Usually a coarsely crystalline or granular fracture in a metal indicates less satisfactory working properties than one of the same class in which the fracture is finer; and a fibrous metal is likely to be tough because the presence of the fibre is an indication that the metal was malleable enough to be rolled. The size of the grain is often largely dependent upon the temperature at which a metal was cast and upon the subsequent mechanical and thermal treatment that it has received.

A metal which has been poured into a mould at a temperature far above its melting point is generally coarser than one poured at a lower temperature. Rapid cooling also tends to produce a fine grain. Hammering a metal produces a finer grain, and overheating produces a coarser grain. Very hard and brittle metals often break with a glass-like, lustrous, and curved structure, termed *conchoidal fracture*.

THE PRIVATE SOLDIER

The Army as a Career. The Various Branches of the Service. Standard for Recruits. Artificers. Duties and Pay

By C. DUNCAN CROSS

As a means to amassing a fortune the Army is not to be recommended. The purpose of the SELF-EDUCATOR, however, is not to teach merely how to make money; it is to direct its readers toward the walk of life which affords a livelihood and at the same time offers an occupation which agrees with their tastes. That the Army, for itself, is an allurement to many a young man will not be denied; and though to-day it is less true than in former times that every drummer-boy carries in his knapsack the baton of a field-marshal, it will be our business to show how a young man of spirit can earn a livelihood with honour to himself and with benefit to his country.

Physical Standards. Any young man of good character and of good health may offer himself as a candidate for the Army. The standards of height and chest measurement vary with each arm of the Service. Of the most important branches they are as follow, though the figures are liable to alteration according to the supply of and demand for recruits.

	Arm of Service.	Height.	Age.
		ft. in. ft. in.	
CAVALRY	Household Cavalry	5 11 — 6 1	18—25
	Cavalry of the Line: Under 20	5 4 — 5 7	,,
	,, ,, Over 20	5 6 — 5 8	,,
ARTILLERY	Gunners, R.H.A.	5 7 — 5 10	,,
	,, R.F.A.	5 7 — 5 10	,,
	,, R.G.A.	5 8 and upwards	,,
	Drivers, R.H.A.	5 4 — 5 7	,,
	,, R.F.A.	5 3 — 5 7	,,
	Artificers and Tailors	5 4 and upwards	,,
ENGINEERS	Sappers and Pontoniers	5 4 ,,	,,
	Boatmen	5 4 ,,	,,
	Shoemakers, Tailors, Bricklayers	5 5 ,,	,,
	Drivers	5 5 — 5 7	,,
	Telegraph, and Railway Reserve	5 5 and upwards	19—30
INFANTRY	Foot Guards: Under 20	5 7 ,,	18—25
	,, Over 20	5 9 ,,	,,
	Line	5 3 ,,	,,
	Army Service Corps	5 3 — 5 6	,,
	,, Drivers	5 2 — 5 4	,,
	Royal Army Medical Corps	5 3 and upwards	18—28
	Army Ordnance Corps: Armourers and Machinists	5 4 and upwards	21—30
	Others	5 3 — 5 5	,,
	Post Office Corps	5 4 and upwards	19—30

Chest measurement is also taken into consideration. The body must be well nourished, and, above all, there must be a range of expansion between the chest contracted and expanded of not less than two inches.

Weight has something to do with the matter nowadays, particularly in the cavalry. The Army no longer requires heavy men, who make a good show but tire out their mounts. So, except in the case of the Household Cavalry, a heavy man is not accepted. Therefore, if a man scales over 150 lb. he had better turn his mind to some other branch of the Service. The same is true of the artillery. Big, strong men are required for gunners, but small men for drivers.

Skilled Tradesmen. In the Army, as in the Navy, there are openings for skilled tradesmen who desire to combine their skill with the pursuit of an adventurous calling.

In the cavalry and artillery, men who have any knowledge of horses are always welcomed; and a man who is willing to apply himself may hope for a ridingmastership, which carries with it an honorary lieutenancy. In the Royal Engineers there are openings for any trade which is needed by an army in the field. In the Army Service Corps are to be found men conversant with trades which are useful for the supply of an army in the field. The Army Ordnance Corps calls for many men of miscellaneous trades which have to do with the repair and upkeep of military works and stores. Lastly, for men with a certain professional leaning there is the Royal Army Medical Corps, in which an able man may always make his way.

For those who have no particular trade but a liking for soldiering, there is the infantry. The pay is not so high as in the more skilled branches of the Service, but, on the other hand, the work is less arduous.

In any case, let us impress upon the intending recruit one thing. The Army is a good master but a bad servant. That is to say, that the man who joins the Army as he would join a business, intending to make it his livelihood, allowing nothing to deter him from success, will find the Army a good place to live in. On the other hand, the man who joins the Army for want of something better, who shirks his work, and who means to get out of it as soon as possible, will find himself at the end of his short service little better off than when he started. So we would say, having made up your mind to be a soldier, join young, and make the Army your home. With close attention to business you will soon reach a responsible position, and will retire on a handsome pension, with a good prospect of civil employment in addition. With luck you may live to wear the sword of an officer.

Promotion. It will be evident that no fixed dates can be laid down in which a man may expect promotion to a certain rank, the varying conditions of service, and the element of luck which enters into the calculations, preventing such an attempt. A few general remarks as to possibilities may, however, be ventured. In a Line regiment of infantry a smart man with fair education may expect to gain his first step in from six months to a year from the time he becomes a private. His second step, with the corporal's stripes, may be hoped for in another six months or a year. As corporal he will have to serve another three or four years before he gains his sergeant's stripes; and beyond that probably another two years or more before reaching the rank of colour-sergeant. In the Foot Guards and the Household Cavalry, where a higher standard of efficiency and smartness is demanded than in the Line, this time may be considerably extended. In the skilled branches of the Army—the Engineers, the Army Service Corps, the Ordnance Corps, or the Royal Army Medical Corps, where the proportion of non-commissioned officers to men is greater, and individual responsibility has to be accepted to a greater extent, the prospect of promotion is very good to the skilled man; and there are many openings as storekeeper, foreman of works, and so forth, with good pay and comforts to those on the watch for them.

A Commission. The hope is sometimes held out to intending recruits that they may work their way to a commission. In time of war a man may be, and often is, promoted to a commission for gallant conduct or special service in the field. In peace time, however, it is extremely rare for a man to be promoted from the ranks unless he has a first-class education, backed by a certain amount of money and influence. The most that a young man should expect, therefore, is to reach warrant rank and, perhaps, an honorary lieutenancy; but, on the other hand, he should always be ready to grasp a chance which will lift him beyond, for it is true in the Army, as elsewhere, that the best men are bound to come to the front, and that the so-called lucky man is merely the man who has prepared for the opportunity and has grasped it when it has arrived.

With these general observations we will pass directly to the conditions of the Service and the method of entering it.

How to Join the Army. Facilities for joining the Army lie around on every side. To begin with, there are the main recruiting stations in London, the head office near Charing Cross, and the other branch offices. In the country and the provincial towns a man can be enlisted at every barracks of Regulars or Militia, and every sergeant-instructor of Volunteers is ex-officio a recruiting agent, who will be pleased to give information, advice, and assistance to a young man who desires it. Last of all, and this is not so generally known, every soldier serving in his Majesty's Army is a recruiter who will take charge of the young man, will convey him to the nearest point where he may join, and will draw the sum offered by the Government to its agents for the body of a recruit. Certain regiments—the Guards, for example—have special recruiting stations and special methods of attracting recruits; but a man can present himself at any of the before-mentioned stations, and, if he come up to the Guards' standard, he will be drafted there.

Choice in the Service. The choice of the arm of the Service to which he will belong will be a matter of anxious consideration to the recruit. To the average man the more showy branches of the Service will appeal most—the cavalry or the artillery; but unless he has some acquaintance with horses these are not altogether to be recommended, and it should never be forgotten that when the day's work is done the horse or the gun has to be cleaned up, whereas the infantryman has only himself to look after. A man is allowed to choose which arm of the Service he prefers, but unless he has some special connection with a regiment he must accept any regiment to which he may be drafted as the good of the Service demands.

The periods of service vary according to the arm of Service, as is shown in this table:

—	With Colours Years	In Reserve Years.
Household Cavalry	8	4
Cavalry of the Line	7	5
Royal Horse and Field Artillery	6	6
Royal Garrison Artillery ..	8	4
„ „ „ Artificers	3	9
Royal Engineers, Drivers ..	2	10
„ „ „ Sapper. ..	3	9
„ „ Mily. Mechanists	12	0
Foot Guards	8	9
„ „ Bandsmen ..	12	0
Infantry of the Line	7	5
Army Service Corps :		
Drivers	2	10
Others	3	9
Royal Army Medical Corps	3 or 1	9 or 11
Army Ordnance Corps ..	3	9
Machinery Artificers and Armourers	12	0

The Recruit. At the recruiting station the young man is measured, is put through a severe medical examination, which embraces physical condition, eyes, and teeth, and, should all be satisfactory, he swears the oath of allegiance required by his King, and is drafted either to the depot, or in some cases to his own regiment.

Army Pay. The question of pay is complicated by the fact that regimental pay varies in the different arms of the Service. A table showing the pay of the principal branches of the Army is given on the following page.

In addition to this it must be remembered that all these men have allowances and additional pay. The infantryman, for instance, drawing 1s. a day regimental pay, draws an extra 2d. per day for up-keep of kit, and 3d. a day for messing, after six months' service. After two years (if he has extended his service) he draws an extra 3d. or 6d. a day, as proficiency pay, according as he is classed I. or II.

The deductions are 3d. a day for extra messing and the cost of his washing—say in all 2s. 6d. per week—as an outside figure for the infantryman. The deductions in other corps—the

Household Cavalry particularly—are heavier. On the other hand, deductions from one cause or another should never exceed 3s. 6d. per week in any corps, so that we must revise our figures somewhat. A private, after two years' service, would receive, according to his class:

WEEKLY PAY—WITH ADDITIONS—OF A PRIVATE SOLDIER

Cavalry		Artillery		Infantry	
Household	Line	R H A	R F A	Guards	Line
s. d. 16 11 to 18 8	s. d 12 10 to 14 7	s. d 14 0 to 15 9	s. d 13 1½ to 14 10½	s. d. 12 3 to 14 0	s. d. 11 8 to 13 5

Soldiers enlisted as Boys draw proficiency pay on attaining the age of 20.

In addition to these rates, men of certain corps draw extra duty pay, working pay, engineer pay, and corps pay, at rates varying between 3d. and 2s. per day, according to their qualifications. When we consider that this is in addition to free board and lodging, it will be admitted that for a steady man the Army is not so badly paid as many trades outside.

Duties and Discipline. At first the work is very dull to the recruit, who is harassed, too, by the numberless restrictions of a discipline which is new to him. All the time, however, he is under constant surveillance. If he proves himself apt at drill, respectful to his superiors, clean and sober, he will gain the confidence of his officers and the respect of his fellows. In from four to six months this phase of his instruction will have ended, and if at a depot he will be drafted to his regiment; or if with his regiment, will find himself on an equal footing with the trained men.

It is now that the young soldier should settle on a career. He can elect to be an officer's servant, in which case his military duties will be considerably lightened, and he will receive an addition to his pay from his master. On the other hand, this leads nowhere, and is hardly a career for an ambitious young man.

Another avenue is to become a clerk in the orderly room; but this, though it involves certain advantages and relief from duty, is an indoor life, and will probably fail to satisfy the thirst for glory which every soldier should have.

Now, we shall suppose that our private decides to fight his way through the ranks as a plain soldier. His good behaviour as a recruit has merited approval already, and a continuance cannot fail to attract the notice of his colour-sergeant. Of all virtues that appeal to a soldier the one most sought is smartness on parade. This, combined with readiness in thought and action, the strictest sobriety and civility, will bring its own reward in due course when the private is recommended for his first step.

WOOD JOINTS AND FASTENINGS

Advantages of Building Up. Screwed and Nailed Joints. Glued Joints. Butt, Dowelled, and Tongued Joints. Fitting, Securing, and Subsequent Treatment

Group 4
BUILDING
27
CARPENTRY

continued from page 3759

By WILLIAM J. HORNER

THE jointing and fastening of a number of pieces together is necessary in practically all woodwork, and it is chiefly in the knowledge of how to do this efficiently that the woodworker's art consists. The fitting of separate pieces is often more necessary in timber constructions than it is in those of metal, which material, being destitute of "grain," is practically as strong in one direction as another. Neither is it liable to shrink and warp as wood does, and it is often as strong or stronger when in one solid piece than if built up of a number of parts. Wood is really strong only in the direction of its fibres—that is, it will stand a great deal of tension, compression, bending, or shearing stress across its grain—but is very weak indeed if subjected to stress in line with the fibres. It is necessary, therefore, to strengthen it in its weakest direction by connecting it to pieces with their grain at right angles to it, or by metal attachments in the form of bolts or straps In the case of pieces of wood of considerable width, this stiffening across the grain is necessary even if it is to be subjected to no actual stress of any kind, because, if it is not so stiffened, it will warp.

Joints in Woodwork. Joints in woodwork, if properly made, are not an element of weakness, but in most cases quite the contrary. The chief objection to joints, in fact, is the trouble of making them Across the grain, the greater the number of pieces used in making up a given width the less trouble is likely to arise subsequently from shrinkage or cracking. End grain joints can always be made if necessary, and be as strong as the solid wood; but except for very great lengths, it is simpler and better to have the wood in one piece without joints. Accurate fitting is essential in all joints, not only for appearance, which in many cases might be disregarded, but primarily for strength.

There is much variety in the forms of joints that can be employed even under almost any given circumstances, but there is usually only one form that is the best possible for each particular case. The nature and direction of the strains to which the two or more members will be subjected have to be considered in deciding on the most suitable form, and also the amount of work in making it, and the desirability or otherwise of permanence and good appearance.

Joints with Screws. Both screws and nails are very commonly employed in all woodwork, sometimes in conjunction with glue, but more frequently alone. In most cases they are more reliable than glue; and another reason why they are often preferred is that there is then no waiting for glue to dry. Screws are superior to nails in holding power, but the chief consideration which favours their use is that they can easily be withdrawn if necessary without injury to the work, and they can also be inserted without the jar to delicate work that nail driving involves. Nails, however, are often quite as satisfactory from these points of view, and have the advantages of being more quickly inserted and cheaper.

Screw Holes. Fig. 118 shows in section a screw in place holding an upper piece of wood to a lower. The hole for the screw is bored entirely through the upper piece, and is of a diameter that permits the screw to slip easily into it up to the head. In neat work the bevelled enlargement for the head is countersunk with a suitable bit, but in many cases, especially if the wood is soft, the screw is merely tightened down into the bored hole until the head is flush, or slightly below the surface. The objection to forcing it without countersinking is that it slightly twists and compresses the grain around the head. If it be desirable to sink it to a considerable depth, a centre-bit hole is bored for the head to sink into [119], and generally this hole is plugged after the screw is home. Often screws are sunk in this way solely to conceal the head by plugging, the grain of the plug running the same way as that of the wood into which the screw is inserted; but occasionally it is done because the stuff is very thick and it is desired to use a comparatively short screw.

The hole in the lower piece of wood is always bored smaller than the threaded portion of the screw, and shorter than the distance to which the point will penetrate. Its precise relation to the size of the screw depends on the character of the wood, a larger hole being required in hard wood than in soft wood. The ability of the wood to resist the splitting action of the screw must be considered also, a small, short-grained, narrow piece being much weaker than a long piece of large area. In the latter case, in fact, if the wood be soft and the screw not large, it is not necessary to bore a hole at all in the under piece of wood, but merely to give the screw a tap with the hammer to start it, and run it in with the screwdriver. To ensure a close joint, a chisel should be passed over the holes in the joint, to remove any splinters.

When screws are inserted in this way, the upper piece of wood is held by the bevelled head, and the lower by the threaded portion of the screw. If the body of the screw be a tight fit in the upper piece of wood, there is difficulty in drawing the joint together as the screw is being tightened. Grease may be used with advantage on both screws and nails to assist them in penetrating, and it also makes their withdrawal easier at any subsequent period.

When a number of screws have to be inserted, and the left hand is not required for holding the work, the most expeditious method is to use a screwdriver bit in a ratchet brace, making continuous turns with the brace until the screw is nearly home and getting tight, and then using the ratchet movement in short turns to give power. If much force be applied, through not having the hole bored large enough, it is not unusual for a screw to break in hard wood, either at its head, or to twist off near the top of the threaded portion. If one half of the head breaks off, it may be twisted back with pincers or pliers. If the entire head is off it is best to slip the wood off it if possible, and withdraw it from the joint; or if it be broken at the joint, this method may be adopted. If it be necessary to go below either surface to get at it, the wood must be cut or punched away until a grip on it can be obtained. If this be objectionable, it is best to leave it embedded, and insert another near it. Very tight screws can often be loosened for withdrawal by a few blows delivered by a mallet on the end of the screwdriver. This also may be carried far enough to make the screwdriver cut and penetrate deeper into the head, and so obtain a better hold. Care should be taken not to let the screwdriver slip and damage the head when trying to turn it, because the more a head becomes worn the less chance there is of being able to turn the screw.

Joints with Nails. Nails are simply driven in with a hammer, and holes are bored for them only when there is a risk of their splitting the wood. They are withdrawn with pincers, or the claw of a claw hammer [**120**], but in either case it is necessary to have the head standing a little above the surface of the wood to obtain a hold on it. This, however, is generally the case when a nail has to be withdrawn, because if it bends or goes out of the direction required, the person who is driving it sees before it is completely home that it will have to come out again. When nailed work has to be taken apart, the nails are not usually withdrawn first, though there are patent appliances for withdrawing them, but the wood is prised or knocked apart, and the nails removed after if required.

Neither screws nor nails hold so well in end grain as in side or "plank way" of the grain, and consequently they are generally put closer together, and often driven at angles, as in **121**, or a greater length is selected than would be used in side grain. The spacing is decided by the nature and size of the work and the strength required. When inserted in a line in side grain at short spaces apart, the number of holes or breaks in the continuity of the grain weaken the wood considerably, and render it very liable to split along the line of nails. If there be not more than an inch or so of width in which to drive them, as in the edge of a box, this cannot be avoided, but in a piece as wide, for instance, as the battens shown in **122**, a double line would be inserted rather than one line down the middle, the spacing of each line being about doubled, and the screws or nails *staggered*, *chequered*, or placed zig-zag. This throws them out of line in the under piece of wood also, and, moreover, one line of nails or screws down the middle of a wide batten would nullify the advantage of width in the batten, rendering it of no more value than a batten just wide enough to take the screws without splitting. Another undesirable feature would be the tendency of the edges of the batten to curl up from the surface unless held down by nails near the edges.

The Butt Joint. The simplest form of joint possible is a *butt*, in which two flat surfaces are brought together and are held by glue, nails, screws, bolts, battens, fish-plates, or other means; or are not actually connected, but merely abut together, and are held in that position by being fastened separately to some other part of the structure, as, for instance, when flooring boards are laid side by side and nailed to the joists upon which they rest. This is the form of joint usually employed when glue is used to unite pieces of wood side by side in building up either a greater width or greater thickness. If the joint be well fitted and properly glued, it is practically as strong as the solid wood, but it is suitable only for the side or plank way of the grain. On end grain, glue is almost useless, and, owing to shrinkage and swelling of the wood across grain, glue cannot be used for uniting pieces crosswise.

As a close fit everywhere is essential in a glued joint, the simplest way of obtaining this is to plane both surfaces absolutely true. In small joints it is a very simple matter to plane them to a fit; in larger ones considerable skill is required; and in the case of very large surfaces, where the material is so large, or comparatively thin, as to be pliant, an absolutely true surface is not so necessary, but the joint is brought close everywhere by clamping. In the making of long edge joints also, the surfaces may purposely be planed either very slightly hollow, or rounding lengthwise, preferably the former, so that they will need clamping only at the open part, and when this has been squeezed together the other parts will have bound themselves tightly. If left clamped in this way for about a day, until the glue is thoroughly hard, the clamps may then be taken off without fear of the joint opening again. Glued joints, except the very smallest, should always be clamped, or otherwise pressed tightly together until the glue is set.

Fitting Glue Joints. In making long edge joints of the character shown in **123**, the two pieces of wood are generally held side by side in the vice and planed together. This makes it easier to get the edges square with the faces, or if there be a slight inclination to one side, they will counteract each other when the joint is fitted together. The try square is used to see that the edges are approximately square, but the final fitting is done by trying the two pieces together and examining the joint. If open places be visible anywhere, the close parts must have shavings removed from them until there is close contact everywhere, the exception, of course, being when the joint

JOINTS IN WOODWORK

118. A screw inserted in the ordinary way **119.** A screw countersunk below the surface **120.** Drawing a nail with a claw hammer **121.** Nails driven at angles **122.** Boards held together by battens **123.** A glue joint cramped **124.** Testing an edge joint from the face **125.** Applying glue to a joint **126** A dog **127** A glue joint held by dogs **128.** A joint held by handscrews **129.** A cleat tongued on an end **130.** A mitred cleat dowelled **131.** A dowelled joint **132–139.** Tongued and other forms of edge joints **140.** A plough **141.** Using a plough **142.** Using a rebate plane is purposely being made open at the middle or ends to be closed in clamping; but this can be done only in large joints. If the pieces fitted together be very wide, as in **123**, it will be important that they shall be as nearly as possible in line when glued, and therefore a mere square test on the joint should not be relied upon, but a straightedge should be tried across the entire width [**124**], when the pieces are together in fitting the joint. A very slight inclination on the joint will throw the faces considerably out, and necessitate a great deal of planing and reduction in thickness to get them true after the joint is glued. This, therefore, is a point which must not be lost sight of when the attention is engaged in making the joint as close a fit as possible. Very slight differences in the angle of the joint can easily be made by keeping the plane to one side on the edge as it travels along the joint, so that the middle part of the iron where the shaving is thickest may be at one side, and the side of the iron where the shaving tapers to nothing may be at the other side, thereby cutting a shaving of unequal thickness and altering the angle of the joint.

Edge joints are usually planed with the wood in the vice, and the plane used as shown in **102**, but sometimes short joints, not exceeding 2 ft. or 3 ft., are planed with the wood on a shooting board, as in **101**, the advantage of the latter method being that the edge cannot then be otherwise than approximately square. When the wood is too long to be held properly in the vice alone, the front end only is gripped by the vice, and the back supported at the same level.

Gluing and Cramping. The glue is applied as quickly as possible to both pieces, which are held as shown in **125**. The glue should be as hot as possible, and the joint closed before it has time to get cool. In gluing a long joint two men are necessary, one at each end, to rub superfluous glue out by sliding the upper piece on the lower and to see that the sides and ends are flush when the rubbing ceases, and also to assist each other in cramping or driving dogs without loss of time. Small joints can easily be manipulated by one person.

Either dogs [**126**] or cramps [**123**], or both, may be used for holding a joint together while the glue is setting. Cramps are more powerful and decidedly better for large joints. For edge joints where the cramps have to span a considerable width, bar cramps tightened by a screw, or various forms of shop-made cramps tightened by wedges are used. A simple form suitable for cramping almost any width is shown in **123**, A, B, and C. It may be tightened merely by knocking it diagonally across the joint until it holds (A), or by driving a wedge between the pin and the edge of the board (B), or more securely still by driving two wedges in opposite directions (C). Numerous other forms of cramp are used in which the extension is fixed to suit work of fixed size, such as doors, that are constantly being made, but the means of tightening is nearly always the wedge.

Joints with large surfaces, such as **127** and **128**, are made by planing the surface of one of the pieces perfectly true, and then fitting the other to it. Square, straight-edge, or winding strips are used in the preparation of the first piece, and sometimes in roughing down the second, but the final fitting is done by trying the two pieces together and examining the joint round the edges, especially at the corners, to see whether it is in close contact everywhere. The sense of touch may also be employed to find whether there is any rocking or unequal bearing between the two pieces. A very common method is to rub chalk all over the surface of the joint of the piece that has been planed true, and then rub the surface of the other piece on it. This transfers some of the chalk to the second piece and shows all over the surface just where contact exists and where not, and the joint can thus be very expeditiously brought to a fit by planing from those portions where the chalk marks indicate the high places. This is a very satisfactory method of fitting any surfaces to each other, whether for glue joints or not, or whether the surfaces be flat, curved, or irregular in shape.

For cramping joints of broad surface, and wood of comparatively shallow depth, handscrews are the most suitable, and are more commonly used for glued joints than any other kind of cramp [**128**]. They are not suitable for edge joints because their extension is too limited. They can be screwed up to give a uniform parallel grip, or, if the work requires it, the pressure can be increased or diminished at point or back by relaxing one of the screws and taking up the slack with the other.

Glue. Glue is stronger when freshly melted than after it has been reheated or kept hot for a long period. The proper way to make it is to break it up into small pieces and soak it in cold water for several hours to soften. Then put it in the glue-pot and heat it, adding enough water to cover it. Glue is always heated in a double pot, the inner containing the glue, and the outer the hot water. Water is used to thin the glue down to the required consistency. This thinning depends to some extent on the kind of work for which the glue is required. For small work it should be rather thick, for large joints it should be thinner. It is sometimes more convenient to use liquid glue than to melt glue for use, but in shops where large quantities are required the latter method is preferred.

When melted glue is used, it should be applied as quickly as possible while hot, and in gluing large joints in a cold atmosphere it is best to warm the surface of the wood first, so that the glue shall not be chilled and commence to set before the operation can be completed. It should be applied to both surfaces of joints, and then the endeavour is to rub and squeeze as much as possible of it out and to bring the wood into contact with no very appreciable film of glue between. While doing this the surfaces should never be separated, but merely slid to the extent of 2 in. or 3 in. over each other, the distance depending on the size of the joint. When this is done properly the two pieces will rapidly become very difficult to slide, and they should then be adjusted exactly in relation to each other, and cramped. If the pieces are allowed to separate slightly while rubbing them together, especially at the finish, the joint will not hold satisfactorily. In that case it is generally better to take them apart, wash the glue off and apply fresh, and "make the joint" again.

The Cleat or Batten. Instead of gluing boards edge to edge to make one wide piece, they may be held together by laying them edge to edge without glue, and screwing or nailing other pieces of wood, termed *cleats* or *battens*, across them [**122**]. This method is sometimes adopted in addition to gluing, but the battens are then more for the purpose of keeping the surface of the wide piece from curving or splitting than for holding the joints together. Joints held by battens are rather a rough class of work, though satisfactory as far as strength is concerned. When boards are battened together without gluing, the joints open slightly if the wood shrinks, but in battened work this is usually not objectionable, and moreover, if the joints could not separate, the wood would probably split in places. When battens screwed on the face, as in **122**, are objectionable, either on account of appearance or because they are in the way, a neater but not quite so strong a method is to tongue them across the ends [**129**], as is often done in drawing-boards. A refinement of this method again is to mitre the corners [**130**] so that no end grain is exposed. The objection to bringing the end grain of battens flush with the width of the board is that when the board has shrunk the ends project beyond. Battens attached to the face as in **122** are always cut slightly short of the full width.

Dowelled Joints. Although, as already stated, a plain side grain glue joint properly made is practically as strong as solid wood, there are cases where it is advisable to make the joint of more complicated form, while still using glue as the means of holding. In edge-glued joints the two chief variations from a plain flat surface are the *dowelled* joint [**131**] and the *grooved and tongued* joint [**132**]. The dowelled joint is used in many ways in addition to an edge joint like that shown. It is very commonly adopted in end grain where glue has little holding power. Dowels are shown in the end grain of the mitred cleat joint [**130**]. Very often tenons are preferred in such a case. The main idea in using dowels, however, is not so much to hold the parts together as to prevent side movement, though, if glued well, their assistance in holding together is considerable. As long as glue holds, side movement is impossible, but glue cannot always be trusted. Its quality varies, and in damp situations it is not of much value. A glued joint at its best is as strong as solid wood. Some men even assert that it is stronger. But nevertheless glue joints sometimes break, often tearing away some of the wood on either side, but with the main break through the joint. In the case of a joint subjected to a bending or shearing stress which would tend to split the timber, dowels extending a short distance on each side of the joint would prevent the joint from breaking; or, if the glue failed, the joint might separate by shrinking, but the parts would still be kept flush with each other by the dowels. One disadvantage of a dowelled joint is that it is not easy to make a thoroughly satisfactory glued joint of it, because rubbing the parts together is impossible, and the dowels are a slight hindrance in getting it quickly together as soon as the glue is applied. Extra force is therefore advisable in cramping it.

Dowels. *Dowels*, or *dowel pins*, are round rods of hard wood. They are usually employed only in narrow joints and on small surfaces. The joints are fitted in the ordinary way, and then the centres of the dowel holes are carefully marked opposite each other in the joint on each of the pieces. These centres must exactly correspond in each half, or trouble will be experienced in getting them together. The two pieces are generally placed side by side with their jointed faces upward, and lines are scribed across each at the positions where dowels are to be inserted. Then a gauge is set to about the centre of the thickness of the wood, and longitudinal marks gauged from the same side of each piece. The intersection of these lines indicates the centres of the dowels. Another method is to lay ordinary pins in suitable positions in the joint and to press the parts together in correct position, thus obtaining corresponding impressions of the pin heads on both pieces, these impressions serving as centres on which to bore the dowel holes. The dowel holes are then bored with a centre-bit of a size which permits the dowel to be driven in a tight fit. The dowel pin is then driven in with a little glue in each hole of one of the pieces, and sawn off 2 in. or 3 in. above the surface. Care must be taken to bore the holes in the other piece amply deep enough to receive the projecting dowels. Sometimes instead of entering only 2 in. or 3 in., dowels are put entirely through, thus stiffening and preventing the wood from splitting. Dowels may be purchased ready made, but if wanted only occasionally they can be planed in an angle board and sometimes are driven through a hole of the correct diameter in a piece of iron or steel plate. It is important that they fit the bit hole tightly, but it is not essential that they should be perfectly cylindrical. Some men prefer them simply planed with a series of flats round their circumference. This tends to keep them from turning, and prevents them from being an air-tight fit and consequently troublesome to insert.

The Tongued Joint. The *tongued joint* [**132**] is variously known as *ploughed and tongued*, *tongued and grooved*, *grooved and feathered*, or *matched*, the last mentioned term applying only to boarding with tongues worked out of the solid [**133**]. Edge joints of this class are more commonly employed in carpentry and joinery than either the plain, square butt joint, or the dowelled joint. They are not much more troublesome to make than the dowelled joint, and for most purposes are decidedly superior to it. The tongued joint may be put together either with or without glue. Its two chief advantages are, that no matter how much the wood shrinks, the tongue prevents light or dust from passing through what would otherwise be an open crack between the boards, and also it keeps the boards flush with each other throughout their entire length more effectually than dowels at intervals could. The tongues, or feathers, are thin strips of wood sawn to fit the grooves, generally with their edges convex to facilitate insertion. Usually they are cut with their grain running the same way as the boards; but some workmen prefer them with the grain crosswise, or diagonally. Sometimes also, hoop iron is used instead of wood, so that they can then be made very thin, with, at the same time, a gain of strength both to themselves and to the boards, which do not require such wide grooves. When the grooving is done by hand a plane termed a *plough* [**140** and **141**] is used. In this plane, irons of widths ranging from about $\frac{1}{8}$ in. to $\frac{5}{8}$ in. can be used, according to the width of groove required. These irons can be adjusted to plough to a certain depth and to a certain distance from one side of the wood, the body of the plane acting as a gauge. Irons for planing the tongues are also sometimes used in it, but generally both edges of the boards are grooved and loose tongues put in. Very often when glue is used, the tongue is also nailed into one of the grooves. When a circular saw with a rising table is available, grooves are generally sawn in preference to the use of a plough. Formerly special planes called *match* planes were often used, one to plough a groove, and a companion to it to form a corresponding tongue on the edge of the piece which had to fit it. When such work is done by hand now, ploughs or universal planes are more often employed.

Modifications of the Tongued Joint. The superiority of an edge joint in which the parts overlap and fit into each other is so great that many other forms besides the simple tongue and groove just described are employed. The *double tongue* [**134**] is frequently used for thick joints, or, when machinery is used for cutting them, half a dozen or more grooves and tongues may be made on the edge of a thick board. This latter method is often employed in box-making where thick wood is glued edgewise to make up a given width and afterwards ripped down into a number of thin pieces. There is also the double-tongued joint [**135**] in which both a projection and recess are cut on the same edge of each piece. There is the *bevelled* or *angular tongue* [**136**], in which an easy entrance and close fit are assured by the wedge form of the tongue. Also the *rebated joint* [**137**], in which the edges are cut to form a half lap joint; and there is a modification of this in the *rebated and tongued joint* [**138**]. There is also the *splayed, bevelled,* or *scarfed* joint [**139**], which is more commonly employed for ends than sides of boards, and is then also a *heading joint* All these joints are used for flooring boards and similar work where a number of boards have to be fitted side by side. Where there is no objection to it, a *quirk bead*, as shown in **137**, is employed to make the joint less noticeable if the wood should shrink, and also to improve the appearance.

Rebates are planed with a rebate plane, as shown in **142**. A rebate may be required at an intermediate position as in **142**, or at an end, as in the case of the tongue in **129**. When working across grain it is necessary to run sawcuts to the correct depth before the plane can be used, otherwise the sides of the rebate would be torn and splintered by the plane. If accuracy is desired, the sawcuts are kept to one side of scribed lines, and these are afterwards pared to with a chisel. In planing with the grain, it is not necessary to use a saw, but a strip of wood is generally attached temporarily to the surface to form a guiding edge for the plane. The depth of the rebate is marked with a gauge. A chisel is used for roughing down, and the plane for finishing.

Treatment of Jointed Parts. Unlike exterior surfaces, joints are never finished by glass-papering or other treatment, but are brought to a fit by the cutting tools only, and put together in that state. When properly fitted thus, further work on them would not only be superfluous, but sometimes detrimental, by rendering edges less sharp, and consequently making the lines where surfaces meet more apparent when the parts are together. It is always advisable to have joints a close fit at the exterior, even if this be obtained by undercutting in other parts. A slight amount of undercutting to ensure a close fit at the outside is nearly always permissible, and as a rule is not a weak feature in a joint. Similarly, inner projections, such as dowels and tongues, are invariably kept a little short in their recesses to make sure that they shall not prevent the other parts from coming together as closely as possible. In the tongue, for instance, in **132**, and the other examples that follow it, about $\frac{1}{16}$ in. of space would be allowed between the bottom of the groove and the edge of the tongue. In a rebated joint like **137**, no slackness could be allowed anywhere, unless in cases where one face were hidden and very close joints were required on the other. In thick stuff jointed in this way, slight undercutting might be practised on the edges, but with a beaded edge it would never be necessary.

Parts which have been glued, or otherwise secured together, nearly always require trimming and reducing slightly, to make their surfaces flush, and true with each other. It is simpler to do this after they are united than to attempt to join them absolutely flush, for none of the usual methods of fastening permit of very delicate adjustment of parts. In neat work also, a general cleaning up with a plane is necessary after the parts are together, because surfaces often get bruised and soiled in handling, and pencil-marks, made to show the position of parts in relation to each other, have sometimes to be removed.

ANALYSIS OF COLOUR

Crystallography and its Lessons. Light Waves and Theories Regarding them. The Work of Great Men in the Study of Light Phenomena

Group 24

PHYSICS

27

Continued from page 3731

By Dr. C. W. SALEEBY

Light and Crystals. There is a deeply interesting branch of science which is known as *crystallography*—the study of the form and construction of crystals of all kinds. In the attempt to cover the great fields of physics and chemistry, in this and its companion course, we have been able to spare no space at all for this subject, interesting though it be. But a crystal is made up of molecules, and we cannot question that the shape of the crystal depends, in some way, upon the shape of its molecules. In the course on Chemistry we have had occasion to discuss the work of Pasteur upon the two kinds of tartaric acid, and there we saw how the shape of the molecules must be associated in our minds with their peculiar behaviour in relation to light. We must now study the fashion in which certain crystals act upon a ray of light ; and the point which it is desired to emphasise is that we must not regard the behaviour of solutions of tartaric acid, for instance, upon light, and the behaviour of certain crystals upon light, as unrelated, but must constantly associate them in our minds as various instances of the relations between light and molecules of certain shapes.

Ordinary and Extraordinary Rays. The familiar salt known as calcium carbonate occurs in great quantities in Iceland in the particular form which is known as *calcite* or *Iceland spar*. Portions of this substance can very readily be split or cleaved so as to form a transparent crystal, having the shape of a rhomb. Now, in such a crystal, there is a particular direction which is such that the crystal is symmetrical around it, and this is known as the optic axis of a crystal. This optic axis does not pass through any point in the crystal, but, indeed, there are as many optic axes as molecules, and they are all parallel. This fact alone is proof that the behaviour of a crystal, which we are about to study, is really the behaviour of one and all of its component molecules. Now, if we take such a crystal, and look at any object through it, we shall find that everything is double. [See Plate facing page 1201.] In short, when a ray of light passes through a rhomb of Iceland spar, it is split up into two rays, and these two rays differ from each other in the most remarkable way. One of them is known as the *ordinary* ray ; it passes through the crystal according to the ordinary laws of refraction, and displays no peculiar characters. But the other ray, which is produced by this process of *double refraction*, has some very remarkable properties of its own, and is called the *extraordinary* ray. In the first place, it does not have the ordinary index of refraction, and, in the second place, we shall find that this ray actually turns round when the crystal is turned round, in such a fashion that it always remains in the same plane with the ordinary ray, and with the optic axis of the crystal. Thus, if we look through such a crystal at writing upon a piece of paper, one of the two images of the writing produced by the double refraction actually turns round as the crystal is turned round.

It is essential that the Iceland spar be prepared for this purpose in a fashion which preserves its natural characters. It must be split in its three natural directions. If it be cut, we shall be apt to find that it has no peculiar characters at all and that no double refraction is produced.

The Extraordinary Ray. What we now require is plainly some device which will enable us to study either the ordinary or the extraordinary ray by itself. This can be done by taking a crystal of Iceland spar, cutting it obliquely so as to form two wedges, and then cementing the wedges together with the substance known as Canada balsam. This particular substance is transparent and has a refractive index which is between the refractive index of the ordinary ray and that of the extraordinary ray of Iceland spar. Hence it is an easy matter to adjust the prism—commonly called a "Nicol"—so that the ordinary ray is totally reflected from the Canada balsam (falling upon it at an angle greater than the critical angle), while the extraordinary ray passes on unchecked.

When we come to examine this extraordinary ray, we find the explanation of the fact that one of the images seen through a rhomb of Iceland spar rotates when the crystal is rotated. We find, in short, that this extraordinary ray consists of polarised light—a term which we have had occasion to use more than once already, and which must now be carefully studied.

A Historic Observation. Double refraction had already been studied by Huygens and by Newton. Reference has already been made to Newton's explanation of it, and his question, "Have not the rays of light several sides, imbued with several original properties ?" It was not until 1810, more than a century after Newton's work, that, to quote Professor Tait, "Malus, while engaged on the theory of double refraction, casually examined through a doubly refracting prism of quartz the sunlight *reflected* from the windows of the Luxembourg Palace He was surprised to find that the two rays alternately disappeared as the prism was rotated through successive right angles ; in other words, that the reflected light had acquired properties exactly corresponding to those of the rays transmitted through Iceland spar. Even Malus was so imbued with the corpuscular theory of light that he named this phenomenon polarisation, In what he calls a brief summary of the evidence for the undulatory theory of light, Clerk-Maxwell first of all infers from the fact of interference that "light is not itself a substance. . . . We cannot suppose that two bodies, when put together, can annihilate each other; therefore light cannot be a substance. What we have proved is that one portion of light can be the exact opposite of another portion.

"Among physical quantities," Clerk-Maxwell proceeds, "we find some which are capable of having their signs reversed, and others which are not. Thus, a displacement in one direction is the exact opposite of an equal displacement in the opposite direction. Such quantities are the measures, not of substances, but always of processes taking place in a substance. We therefore conclude that light is not a substance, but a process going on in a substance, the process going on in the first portion of light being always the exact opposite of the process going on in the other at the same instant, so that when the two portions are combined no process goes on at all. . . . We have determined nothing as to the nature of the process. It may be a displacement, or a rotation, or an electrical disturbance—or, indeed, any physical quantity which is capable of assuming negative as well as positive values. Whatever be the nature of the process, if it is capable of being expressed by an equation of this form, the process going on at a fixed point is called a *vibration*. . . . When we contemplate the different parts of the medium as going through the same process in succession, we use the word *undulatory* to denote this character of the process, without in any way restricting its physical nature."

The Nature of a Wave. The reader must pay the utmost attention to the last phrase. It will prepare us for what we are about to see—namely, that our illustration of the rope is only an illustration. As long as our notion of a wave is derived from any of the waves we know, we shall have no choice but to think of a wave of light as a displacement—that is, as a movement of certain parts of the ether. This implies that the ether is discontinuous, and leaves us hopelessly muddled and without any prospect of ever forming a concept of the ether that will satisfy all our requirements.

The original view of the wave theory was that a wave of light consists of a movement of the medium. We must abandon this altogether. Furthermore, we must abandon entirely all our preconceptions as to the meaning of the word *wave*. To define the term somewhat loosely, we must think of a wave as no more than *a recurrent process*. We must cease altogether to think of a wave of light as constituted of something which is moving up and down or from side to side. We are very far from asserting that when we abandon this conception, as we must, we shall be able to replace it by what Descartes would have called a "clear and distinct idea" of a wave of light. But, at any rate, we shall have travelled a little nearer towards the truth.

Clerk-Maxwell points out that Faraday predicted, in a remarkable fashion, the discovery that one and the same medium is concerned in the propagation of light and in electromagnetic phenomena. Faraday, like Clerk-Maxwell himself later, was very much concerned to oppose and disprove the really inconceivable notion of "action at a distance." He found himself compelled to believe, after studying the magnetic force, and the general character of magnetic phenomena, external to the magnet, that the luminiferous ether is involved in the transmission of the magnetic force. "Such an action," he says, "may be a function of the ether, for it is not unlikely that, if there be an ether, it should have other uses than simply the conveyance of radiation." This prediction of Faraday's has been most wonderfully verified, as we shall see.

Faraday's Work. But we have had occasion to refer to few more remarkable men than Faraday, and a brief discussion of his life must be included here. He was born, the son of a blacksmith, in 1791, and died in 1867. When he was twenty-one years of age he went to hear Sir Humphry Davy lecture at the Royal Institution, and the result of sending his notes of these lectures to Davy was that he was appointed laboratory assistant there. He remained and worked in the Royal Institution during the remaining fifty-four years of his life. His first work was mainly chemical and extremely interesting; most notably, however, perhaps, because a new kind of glass, which he then discovered, later enabled him, when he placed it in a magnetic field, to discover the rotation of the plane of polarised light under these conditions. Later, Faraday worked at electromagnetism with the greatest success, and in 1831 he made what Clerk-Maxwell calls the "crowning discovery" of the induction of electric currents.

Magnetism and Polarised Light. Fourteen years later he discovered the effect of magnetism on polarised light. We may quote part of his note on this discovery, especially because the last part of it has been so amazingly verified:

"Heavy glass was experimented with. It gave no effects when the same magnetic poles or the contrary poles were on opposite sides (as regards the course of the polarised ray), nor when the same poles were on the same side, either with the constant or intermitting current. But when contrary magnetic poles were on the same side there was an effect produced on the polarised ray, and thus magnetic force and light were proved to have relations to each other. This fact will most likely prove exceedingly fertile and of great value in the investigation of the conditions of natural force."

Faraday excelled in the presentation of science to people without scientific training, and notably to children. His scientific work shows him to have been possessed, in the highest degree, of the scientific spirit which seeks to follow truth wherever she leads. He was an earnest member of the small Christian sect who are known as Sandemanians.

DRAFTING INFANTS' CLOTHES

Drafting and Cutting out Baby Bodice, Day and Night Gowns, Princess Day Gown, etc. The Short-coating Set and Pelisse

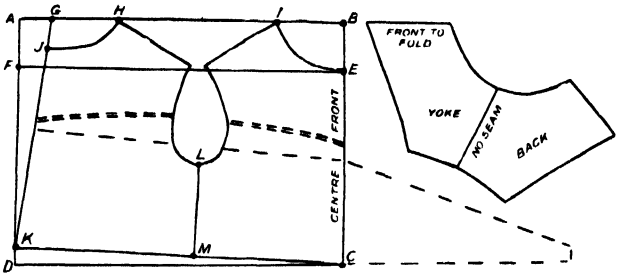
continued from page 3746

By AZÉLINE LEWIS

WE have now to deal with the drafting for the various garments illustrated in the last article. For the first as well as the second, or short-coating set, the following may be taken as good average measurements:

Chest, 20 in. to 22 in.; neck, 10 in. to 10½ in.; wristbands, 6 in. to 7½ in.

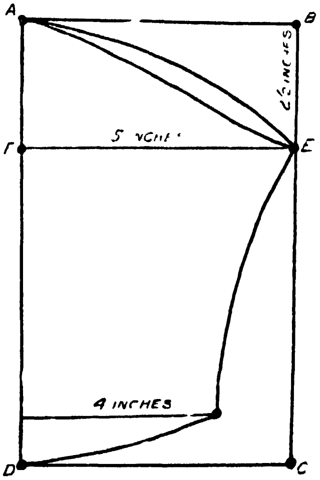
The long clothes should not exceed 30 in. in length, and may with advantage be shorter. No turnings are allowed on the following draftings; 1 in. should therefore be added for hems, ¼ in. to ½ in. for each tuck, if required for ornament, and ⅜ in. at seams and elsewhere. Very much fulness is not advisable for an infant's garment, unless the material be very thin and light.



8. DRAFTING INFANT'S BODICE

An Infant's Bodice. No. 8 gives the drafting of an infant's bodice, which will suffice for that of the long flannel petticoat, robe, and yoke of the day and night gowns [see diagram 1, page 3745]. The single row of broken lines indicates the direction to be followed for the strap bodice of the first long flannel, while the double row shows the method of obtaining the yoke, half of which is shown in the same diagram. [See DRESSMAKING for Blouse Cutting.]

A to B and C to D are 10½ in.; A to D and B to C, 8 in.; B to E and A to F, 1½ in.; B to I, 2½ in.; A to G, 1 in.; G to H, 2¾ in.; G to J, 1 in.; J to K, a little longer than front; L to M, 3 in. Shoulders, 2½ in. These should extend to just above the line F E. If required fuller, simply add on an inch or so to centre front and back. Remember, too, that a healthy baby grows at an extraordinary rate, so that the garments should allow for expansion. The armholes should be quite loose, and *not less* than 9 in. round.



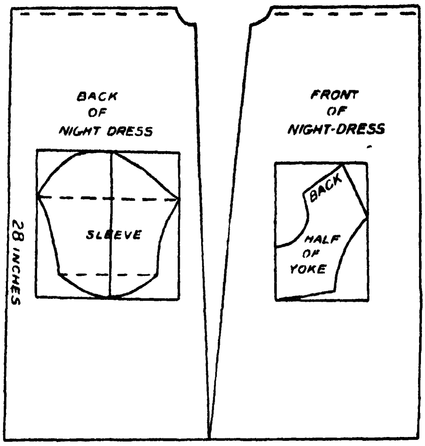
9. BODICE SLEEVE

THE SLEEVE. A to B, and C to D, 5 in.; B to C, and A to D, 10 in.; B to E, 3 in. The under part should only be very slightly sloped out, and, indeed, for an infant, this is scarcely necessary [9].

With the aid of these two patterns, nearly all these little garments can be obtained, the skirt portion in each case consisting of straight, or very moderately sloped, widths from 27 in. to 32 in. in length, the former being quite long enough. For the long flannels, 1½ yd. of flannel, 36 in. wide, should suffice for one garment. This can be taken lengthways, and the 6 in. strip torn off at one side, allowing for the bodice, which should be double flannel. If only 27 in. wide, then 1¾ yd. will be required, two widths being necessary for the skirt, each 27 in. long, the remaining ¼ yd. being for the bodice. The edges may be either hemmed or festooned.

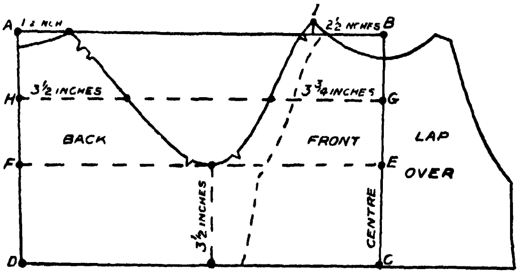
Day and Night Gowns. For the yoke day and night gowns, the front and back skirt widths are shaped as in diagram 10, and sloped out a little for the under part of armhole. For the nightgown, 2 yd. should be enough, of which one width, and a half torn lengthways, are required for the skirt, the remaining half-width sufficing for the yoke (which is double), sleeves, and band. The daygown will require 2¼ yd. to 2½ yd., as this must be fuller and longer, to allow for hem, tucks, and ornamentation. Wide, embroidered, tucked and inserted flouncing can, however, be bought by the yard, which is much used for robes and day gowns, saving much work. If this be employed, 1½ yd. to 2 yd are enough for the skirt portion.

The Empire robe is made either of silk or cambric, and is cut from the bodice and sleeve patterns shown in diagrams 8 and 9, the material being tucked and inserted as required before cutting out. Yokes and bodices can, however, now be bought ready-made. The skirt consists of two or more straight widths, tucked and ornamented as desired—this being baby's smart gown.



10. DAY OR NIGHT GOWN

Slip Skirt and Head Flannel. The slip skirt is made in exactly the same way as the last, without the bodice, ether of cambric, lawn, or silk. It can be trimmed as elaborately as desired, and is secured by a band, whilst two soft ribbon straps pass over the shoulders from the back, to be fastened to the waist in front. This skirt may be made to slip on over the head, but a better way is to make it fasten either at the side with two or more soft satin bows, or to fold it well over at the back without any fastenings at all. The pattern in any case is the same, except that for the last a little more fulness must be allowed when cutting, to allow for folding over.

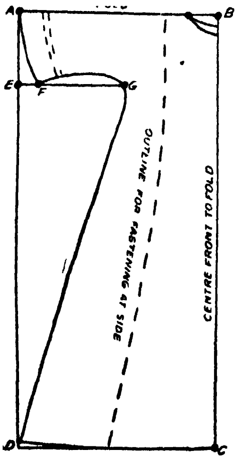


11. DRAFTING LONG FLANNEL

The head flannel has already been mentioned. The best way to make the casing for the ribbon at the head part is by means of the fancy stitches shown in diagram 5.

The succeeding diagrams show how to cut out the hygienic set depicted in diagram 3.

Bodice for Long Flannel. A to B, and C to D, 11¼ in.; B to C, and A to D, 7½ in.; B to E, and A to F, 4 in.; G and H, midway between these last lines. I is ¼ in. above line A B. The other measures are marked in the diagram, and the double front portion is cut as indicated by the broken line, the paper being folded back for the centre line marked B, C, E, and G.



13. NIGHTDRESS

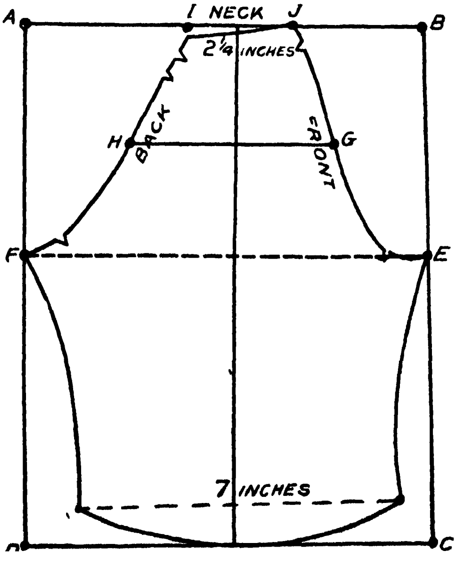
If required without sleeves, the back neck should fasten over the front and the armhole portion must be very neatly bound with soft ribbon [11].

THE SLEEVE. A and B, and C to D, 8½ in.; B to C, and A to D, 11 in.; B to E, and A to F, 5 in.; A to I, 3½ in.; and B to J, 3 in. G and H are midway between last points. The notches correspond with those of bodice and must not be forgotten [12].

The skirt portion is similar to those already mentioned. This pattern will do equally well for a nightdress, with the addition of lace edging and more ornamentation. It may also be made to fasten down the centre of front if preferred.

Nightdress. Diagram 13 is an extremely simple pattern for a nightdress; it is cut all in one piece, and fastens up at the centre-front, or at the side, as wished. A to B, 14 in.; B to C, and A to D, 28 in., or longer if wished. A to E, 5 in.; E to F, 1 in.; F to G, 6 in. The sleeve is curved slightly from F to G, but this is quite optional, as it can be made nearly straight. The neck is from 10 to 12 in. round.

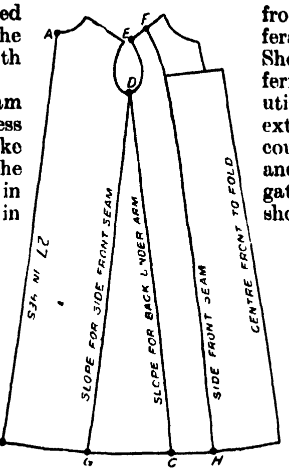
It can also be made double-breasted, as in the diagram; but in this case back and front must be cut separately, the extra portion following the shape of the broken lines. In this last shape the sleeves are better left



12. LONG FLANNEL SLEEVE

open at the top edge and fastened with narrow ribbons, while the edges should be finished off with festooning.

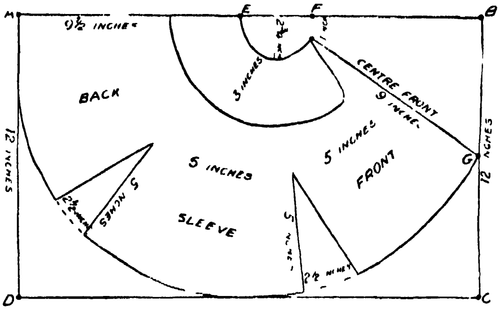
Princess Day Gown. Diagram **14** gives the drafting of the Princess day gown shown in **2**. This, like the former, fastens over at the side, and is put on exactly in the same way. The fastenings in this set should be alternately arranged for right and left. Thus, if the long flannel fastens to the left, the gown should fold over to the right, and vice versâ, a matter which is quite easy to arrange. This frock can be cut from the bodice-pattern [**8**] by sloping out the underarm seams for the necessary width. A, B, C and D represent the back, D, E, F, G and H the side-front, the remainder representing the fulness for front, the yoke of which is cut from the bodice as indicated. Both this and the full front are placed to a fold in the centre. The trimming of this robe is a matter of taste.



14. PRINCESS DAY GOWN

Diagram **15** shows how to cut the square kimono [**4***e*] which is too simple to need further explanation. The ribbons are to tie it round the arms. The neck is a circle about 4 in. in diameter. Diagram **16** illustrates the method of cutting out the circular kimono in **4***d*.

A to B, and C to D are 20 in. in length. A to E, 9½ in.; E to F, 3 in.; B to G, 6 in. The collar is cut from the neck portion three or more inches wide as desired, whilst the remaining measurements are given in diagram.



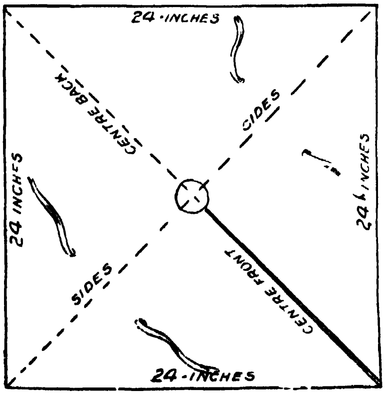
16. CIRCULAR KIMONO

In diagram **17** we have the little tea-jacket or outdoor coat shown in **4***b*, which is cut from the bodice of **11**, being preferable to the round armholes. Should the latter, however, be preferred, the bodice [**8**] can be utilised in the same way by allowing extra fulness at front and side. It could be also made with a yoke, and the lower part pleated or gathered on to it. The broken lines show the way in which the pattern of **11** is to be arranged. The sleeves for both have already been given [**9** and **12**], but in each case they should be much fuller, as this coat is designed to go on over the other garments. The length and trimming are also a matter of taste, about 8 in. being a fair average for the former.

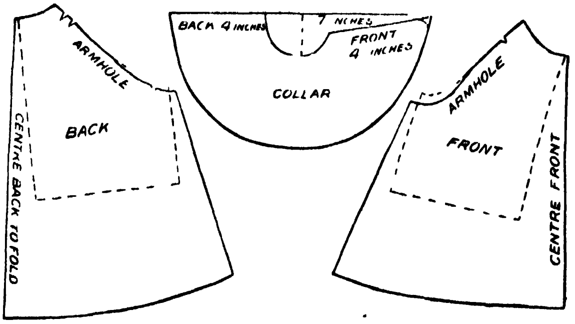
Diagram **18** shows the method of cutting out the cloak in **4**, which is cut on the same lines as the tea-jacket just mentioned, with the wide armholes and sleeves extending to the neck. This shape, however, can easily be formed into an ordinary sleeveless cloak by cutting it with a V at the neck part, as shown by the broken line between the armhole lines. Both capes are shown on the same diagram, but must, of course, be drafted separately.

A to B, and C to D are 41 in.; B to C, and A to D, 38 in.; B to E, and A to F, 20 in. The sleeve opening is 6 in. to 7 in. in depth. For the cape, G to H and I is 20 in., G to J and K, 3 in. Pivot from G to H and I for the outer circle of cape, then cut the neck as shown, and the upper one, or collar, from this. The method of cutting the sleeves is shown in **12**.

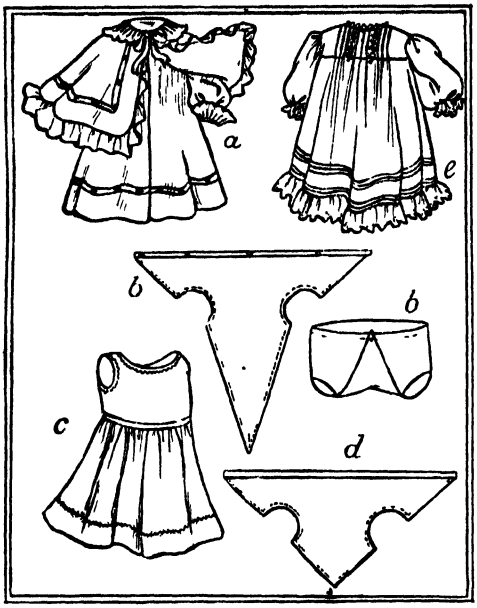
Note that this cloak can be made with a yoke if wished—a little rounded one for preference—which can be cut from **8**. In this case the lower portion is gathered on to the neck, and would not be cut up to it. For this cloak 3½ yd.



15. SQUARE KIMONO



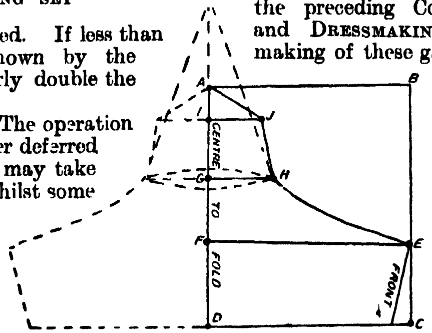
17. TEA-JACKET



19. SHORT-COATING SET

of 44-in. goods are required. If less than 44 in. wide, divide as shown by the broken line, and allow nearly double the quantity of material.

Short-coating Set. The operation of short-coating is now never deferred beyond three months, and may take place before this period, whilst some babies, whose mothers are progressive, have never worn long clothes at all, and have never suffered from the omission.



20. FIRST KNICKERS

The garments themselves differ very little in shape from the long ones except in length and size; the bodices in nearly all cases being larger, which, however, is quite an easy matter to arrange and needs no explanation [19].

Some additions are necessary, however, and these include the pilch, or first drawers, and several dainty pinafores; *b* and *d* show two shapes of pilch; *c* the small petticoat, *a* the pelisse, and *e* the frock.

When the laundry bill is a matter of no concern, pinafores are often never used at all for the first few months, the child always being dressed in fresh, white frocks.

Diagram **20** shows the first drawers, which in the new baby's wardrobe would be of flannel, but in others of cambric or fine longcloth, in each case with the leg-openings bound and trimmed with lace.

To draft the pattern, make A to B, and C to D, 13 in.; B to C, and A to D, 16 in.; C to E, and D to F, 5 in.; F to G, and G to I, 3 in.; G to H, a little more. The broken line on either side of G and H shows the portion to be hollowed out between the legs to give a little more shape here for the next size; but for the very first stage this is not necessary. Half a yard of 36-in. flannel is required. Some people prefer the pilch made with the points extending up to, and fastening to, the waistband. This, however, is a matter of taste, and it is quite easily managed from the same pattern, as shown by the broken lines in the diagram.

A pair of stork pants should also be added to the list. These are much the same as those shown in the diagram, but are made of thin waterproof material.

The Pelisse. The pelisse can be cut from any of the former patterns, and should extend from 1 in. to 3 in. below the feet.

At the crawling stage a pair of loose drawers, or a crawling suit, will be found very useful for keeping the petticoats clean and doing away with frequent changes. The latter is cut somewhat similar to the combination illustrated in the next article, but somewhat fuller in the legs; whilst for the former the drawers portion of the small child's divided garment may be taken as a model, the knee part being gathered into a band instead of left loose, as shown in the sketch.

It is inferred that the reader has followed the preceding Courses on UNDERCLOTHING and DRESSMAKING. Any details in the making of these garments apparently omitted from these lessons will be found to have been previously described. Speaking generally, when once the rudiments of plain needlework and the drafting system have been mastered, it is merely a question of adapting the patterns to the garments required.

18. CLOAK

THE ORGAN

Construction of the Instrument. Pedals, Keyboards, and Stops.
Touch. Fingering. Expression. Church Music. Recitals

Continued from page 3785

By J. CUTHBERT HADDEN

THE organ is known familiarly as the King of Instruments. It deserves the name alike as regards its compass, its powerful dimensions, and the space which it occupies.

Nature of the Instrument. In inception, at least, it is one of the very oldest of musical instruments. Such, too, is the flute, and, as Sir John Stainer has conclusively shown, the history of the organ is nothing more than a narrative of the efforts made by man to bring under the control of one performer a large number of flutes. Not flutes of the modern orchestral type, blown at a hole in the side, but flutes with a mouthpiece, very much like the familiar penny whistle. There is little difference between a penny whistle and an organ pipe, and if you think of the primitive organ as an instrument in which several penny whistles were brought under the control of one performer, you will have a good idea, to start with, of the evolution of the "King of Instruments."

First, they stuck several flutes over a wind-chest supplied by bellows; then, gradually, they added more and more flutes in the form of real organ pipes. A keyboard naturally followed. Before its invention, the pipes (say, the flutes) were "made to speak or be silent at the will of the player by pulling backwards or forwards pieces of wood, the ends of which either closed up the foot of a pipe or allowed the wind to enter it." This was a slow, clumsy business. The first keyboard (about the end of the eleventh century) was not quite so slow, but it was nearly as clumsy. The keys were so long that five of them took up about the space of eight on the modern keyboard, and the player had to hit them with his closed fist or press them down with his elbow, so that he was called not the organist, but the "organ beater." Organists of those days required the muscles of a blacksmith.

Construction. In time the keys were improved until they became practically what they are to-day, except that where the keys are now white they were black, and where they are black they were white. Keys for the hands were subsequently (fifteenth century) followed by keys for the feet, which, in the modern *pedal board*, as it is called, are one of the essential characteristics of the pipe organ. Reed pipes (to be explained later) came also in the fifteenth century, and inventions and improvements went on with the progress of time until now, in the organ of to-day, we have one of the grandest and most complete of all musical instruments—the veritable "King."

To explain the construction of this "instrument of instruments" with any minuteness would occupy a vast amount of space. The student should try to see an organ in actual process of "building." No amount of printed matter can compete with such a lesson as that, and indeed, the modern organ is so complicated a piece of mechanism that it is very difficult to make its details clear on paper. Broadly speaking, these details go into the following divisions: (1) The apparatus for collecting the wind—that is to say, the bellows; (2) the means for distributing the wind—the wind trunk, the wind chest, and the sound-board grooves; (3) the mechanism for playing the instrument—*viz.*, the keyboard and the key movement; and (4) the mechanism for controlling the use of the tiers of pipes—*viz.*, the draw-stop action.

The Mechanism. The bellows requires no explanation. Its primary function is to collect the wind and to send it forward by means of the wind-trunk to the wind-chest, where the wind is directly drawn upon as required. This wind-chest runs the whole length of the sound-board, upon which the various tiers of pipes are stacked; and in it are located the little contrivances called *pallets*, which prevent the wind getting further until they (the pallets) are operated upon from the keyboard. This brings us to the key-action. The pallets are, of course, a long way beyond the player's reach, but they are moved instantly by rods connected with the tail of the key. The action is simple enough in its operation, though it involves the use of three or four separate pieces of mechanism—the *sticker*, the *roller and tracker*, and the *pull-down*, to use the technical terms. By the draw-stop action the player is enabled to bring into use or shut off any particular set of pipes. If it were not for this action, all these sets of pipes would always sound together, just as they do when the organist pulls out every "knob" in his organ. Every separate set of pipes has beneath it what is termed a *slider*. This slider is perforated with holes corresponding with the mouths of the pipes. When the slide is "open" the holes are exactly beneath the mouths of the pipes; when it is shut (by the draw-stop), the wind is cut off, and the pipes are necessarily silent. In short, to quote a musical dictionary maker, "the pulling out of the draw-stop rods in front of the organ so far admits the wind to the pipes that it is only necessary to press down a key, which opens a small valve, to make the pipe connected with it speak; the pushing-back of the register-rod (the whole sweep of the movement is only about an inch) silences the stops." Here, in brief, is the mechanism of the modern organ. But, after all, one feels the explanation to be so sadly futile that he comes back to the originally-suggested advice: see an organ in actual process of construction.

The Piano as a Substitute. Now, there are peculiar difficulties about the study of the organ. You may buy a clarionet or a flute and carry it home in your pocket. A violin easily goes into a portable case. A piano is a recognised piece of household furniture. But you cannot carry about an organ; it cannot readily be set up in an ordinary sized room. You find it in the church only, and you have to make a variety of arrangements before you can enjoy your practice—take lessons from the organist, engage a blower, perhaps bargain with the churchwardens or managers, and so on. Hence it has to be admitted that it is hardly possible to study the organ without calling in the aid of the instructing, living organist. It is only through him, as a rule, that you can get at an organ, though, in London, at least, the student can always command the use of a practice instrument at a moderate fee. Nevertheless, if one is once fairly grounded in the elements of organ-playing he may continue his study unaided as easily as the violinist or the pianist. He may, perhaps, obtain a church appointment where the modest salary is in keeping with his modest abilities. Thus he will have an organ at his sole command, by which he can readily advance to the heights which the great men of the organ world have won and kept.

Then, as already hinted, you may hire an instrument by special agreement. If you do not know of any such instrument, advertise for it. There are churches which hire out their organs to students as a means of reducing a debt that rests on the instrument. Finally, you may have a pedal attachment fixed to your piano. The "foot-keys," remember, are the essential characteristic of the pipe organ. The manual keyboard of the organ is the same as the keyboard of the piano; which means that you can "get up" all your organ music on the piano—except the part for the feet. For this latter you must add to your piano a set of pedal keys. It is a simple matter, though it will cost you a ten-pound note for a good and reliable piece of mechanism. But think what you gain! You can practise your organ studies whenever you like. You do not require to go to the church every time you want to "run through" a Bach fugue or a Mendelssohn sonata. You save the cost of a blower. And—you add to the certainty of your execution; for a mistake on the piano is much more easily detected than a mistake on the organ, and on the piano you must hit a pedal note "clean" or you will know it!

Necessary Preliminary Technique. Whenever possible, get at the organ itself; when that is not possible, the best available substitute is the piano with the pedal attachment. But it is, at best, a makeshift; a supplement, as it were, to work at the keyboard within the church walls. And here another point suggests itself. Keyboard study should never be begun with the organ. It is a waste of time. If you cannot play at all, do not dream of attacking the king of instruments until you can at least play a little. In the words of Sir John Stainer, an organist "should not commence his practice on the king of instruments until he has a thorough knowledge of musical notation, can read fairly at sight, is able to play all his scales evenly and rapidly on the pianoforte, and, above all things, can carry his hand in a good position while playing chords and scales." For giving elasticity of action to the fingers and wrists, for forming the position of the hand, and for training the touch, the piano stands unrivalled. As Stainer insists, all this portion of an organist's work (and it is a most important portion) should be done at the piano. The point must be emphasised. When you have to hire out an instrument, and perhaps to pay for a blower, it is out of the question that you should sit at the organ doing that which you had far better, and with no financial outlay, do at the piano. So, then, do not be in a hurry to get to the organ itself. Learn, first, to play a little on the keyboard—either the keyboard of the piano or the harmonium, the former by decided preference. Then, when you sit down to the organ, instead of having to play scales and finger exercises, and pieces of "absurd simplicity," you will be able to attack at once the peculiar difficulties of the instrument, which consist, essentially, in the combination of playing with hands *and feet*.

Difference in Organs. Having cleared the way of all preliminaries, let us suppose ourselves seated at the organ, ready to begin actual work. With the instrument thus before us, new points for explanation confront the instructor, for an organ is not like a piano. Roughly speaking, there is nothing to explain to the young pianist about his instrument but the keyboard and the loud and soft pedals. There are dozens of things to explain about an organ, to say nothing of the fact that no two organs are alike, as all pianos are essentially alike. For example, we may imagine ourselves seated at an organ with two or three or even four keyboards; with a dozen stops or five dozen stops; with a straight or a radiating, a flat or a concave pedal-board; with a "balanced" swell pedal, or an old-fashioned pedal fixed by a notch. The "action" of one instrument may be tracker, that of another pneumatic, of a third electric, and so on. There is, in fact, no end to the diversities of organs. For the student's purpose, however, it will be enough to take the essentials, and leave the differences for his own individual attention as they present themselves.

In the first instance, then, there are the *manual keyboards*. Organs of two manuals are by far the most common. In these the lower manual represents the *Great Organ*, the upper manual the *Swell*. The names are sufficiently informing. The Great Organ is so called because it includes (or ought to include) all the nobler and more characteristic stops—those of large scale and powerful tone; while the Swell Organ owes its name to the fact that all its pipes are enclosed in a box with a sort of venetian blind front, which can be opened and closed by the foot of the player for the production of *crescendo* and *diminuendo* effects. When there is a third manual it represents the *Choir Organ*, so called because its usual delicate quality of tone was supposed to be specially suitable for the accompanying of voices. A fourth manual is found only in very large instruments, principally in cathedrals and concert halls. It represents the *Solo Organ*, the stops in this case being mostly of an orchestral character, and such as are used for solo purposes.

Pedal Keyboard. So much for the manual keyboards. Next we have the pedal keyboard, an essential feature of every pipe organ. It covers nearly two and a half octaves—from CCC to F, to be precise—and its function is, through its stops, to provide a suitable bass for the manual stops. There are various kinds of pedal-boards, unfortunately. The keys may be perfectly straight, or they may be disposed in radiating form. Either of these, again, may be flat or they may be concave—that is, gradually rise at the extremities. The student will readily adapt himself to whatever kind of pedal-board he has to practise on; but he ought to seek opportunities of playing on pedal-boards of a different pattern, otherwise, if he is being tested for an appointment on an organ whose pedal-board is unlike that to which he has been accustomed, he may easily come to grief. It is a pity that all pedal-boards are not alike, as all manual keyboards are alike; since the divergence exists, the student must make the best of it.

The Stops. Now for another essential feature of the organ—the stops Here, again, there are diversities as regards the nomenclature, but these are to a large extent minimised by the never-failing uniform practice of indicating the pitch of the stop directly below its name. Thus one sees "Bourdon, 16 ft.," "Open Diapason 8 ft.," "Principal, 4 ft.," etc. This requires some explanation, though it is very simple It means that the longest pipe of the particular stop is of the length (in feet) indicated on its stop handle. On the pedal the 16 ft is the groundwork; on the manual the groundwork is the 8 ft., the stops so marked giving exactly the same pitch as that of the pianoforte. Stops marked 4 ft. are, of course, an octave higher; those marked 2 ft., a couple of octaves higher. Thus, to put it in a word, the student will understand that when he pulls a stop marked "8 ft." he is getting the standard pitch; when he pulls one marked "4 ft.," and plays with that alone, he will, in effect, transpose his music an octave higher. The resultant rule is that he must always use the 8-ft. stops as the foundation tone of the manuals; the 16-ft. stops as the foundation tone of the pedal. It is from these "foundations" that he must build up. If he wants to brighten the manual 8-ft. tone he will draw upon the 4-ft. and 2-ft. stops; if to brighten the pedal 16-ft. tone, the 8-ft, and so on.

The Two Classes of Stops. But then there is the question of the individual tone-quality of the various stops. That is best determined by actual experiment. Still, there are certain broad principles which are easily stated. Organ stops are of two main classes—flue stops, so-called, and reed stops. The flue stops include all the open pipes, such as are seen on the front of an organ, in which the tone is produced by a current of air entering the foot of the pipe; while the reed stops owe their tone and their name to the vibration of little metal tongues, as in the harmonium and American organ. The "reeds" are all enclosed in metal tubes; the "flues" may be either of metal or of wood. It would occupy far too much space to give a list, with accompanying tone descriptions, of the multitude of stops found in large organs. Nor is such a description at all necessary in a work of the present kind. What the student has to note at the outset is that he must start with the 8-ft. tone on the manuals and the 16-ft. tone on the pedals. These are his bread and butter of the instrument, to to speak. As he advances, he will want to make experiments for himself—to contrast this stop with that other stop; to balance one stop on the Great with another on the Swell or Choir; to try this or that stop as an accompaniment to the "oboe" or the "clarinet;" to test the "open diapason" on the Great or the "horn" on the Swell as a solo in the tenor octave; to see what can be made of the wood stops and the reeds in combination; and to make a hundred other experiments. This is one of the delights of organ study. The stop combinations and "effects" are endless, and once the young player has surmounted his first technical difficulties he should make constant tone-colour appeals to his ear with every instrument within his reach. Mere book knowledge of organ stops is as useless to the player as a book knowledge of angling is to the man who would catch trout.

Manipulation of the Stops. Well, the stops are there—on the right and left of the keyboard. As a rule, when you want them individually, you must pull them by hand. But it is not always either necessary or possible to pull them by hand, and so certain mechanical contrivances are made for getting them out by the foot. If you look below the lowest manual keyboard, just over the pedals, you will see a set of little irons, technically known as "composition pedals." By means of these you can force out a particular combination of the manual stops (sometimes the pedal is included), the arrangement, as a rule, following in *crescendo* order, from *p* to *ff*. These composition pedals are indispensable for sudden changes in power of tone, and the student should early familiarise himself with their use. But let him always remember that he must never sacrifice the time or rhythm of a passage in an effort to change his stops. "Stops," says an eminent authority, "should on no account be changed, either by composition pedals, pistons, or the hand unless it can be done without breaking the time or disturbing the rhythmical form of the music."

Swell Pedal. As regards the swell pedal, not much need be said at this stage. The management of a *crescendo* and *diminuendo* which the swell pedal puts at the disposal of the player is not a matter for elementary experiment. For one thing, it robs the pedal-board of a foot which the young player can ill spare. He may get a little more expression, indeed, by his use of the swell pedal; but, on the other hand, it is more than likely that he will bungle the performance of a pedal passage. Stainer's rules for the use of the swell *crescendo* and *diminuendo* ought to be impressed on all young players. They are as follow:

"Never use the swell pedal unless the proper expression of the music demands a *crescendo* or *diminuendo.*

"Never sacrifice the proper performance of a pedal passage for the sake of using the swell pedal.

"Be as careful of the way you let the pedal return upwards as of the way you press it down.

"Observe carefully the length of the passage marked *crescendo,* and do not get the swell fully open till the *climax*—unless you are prepared to carry on the *crescendo* by adding stops.

"The swell *crescendo* is the more effective if not used too frequently."

This should be the student's gospel as regards the use of the swell pedal. The bad player never has a leg to spare but he uses it in pumping the swell pedal up and down, often with the most ludicrous and distressing effects.

Position of Player. A word upon another matter. See that you are comfortably seated at the instrument. Occasionally the pedals are fixed too low down for the heels to reach the naturals with ease; sometimes they are set so high that the player's knees knock against the underside of the board on which the manuals rest. There is no remedy for these errors of the organ builder. But very often you will find, when there is any discomfort, that a little adjustment of the height of the organ-stool will put things right. Obviously, a six-foot organist does not want a seat so near the pedal board as a Zaccheus of the keyboard. Stainer's is really the best test of a good position, and it is this:

When seated, lift up both feet and hold them just over the pedals so that they could play, if required, either on the long or short pedal-keys, *at the same time* holding both hands over the manuals, so that they could play, if required, on any of the manuals either separately or in conjunction with the feet.

If the pupil, while in this position, has an uncomfortable sensation that he is likely to knock his nose against the desk, the organ-stool is too far away from the keys or he is sitting too near its edge.

If the pupil cannot move his knees freely to the right and left, the stool is either too near the keys or he is sitting too far on it.

Much has been written about the right sort of footgear for the organist. The matter is entirely one for common-sense. The player's ankles should be quite free; therefore, he should not wear boots. A well-made shoe, not too heavy nor too slim, with solid, broad heel-pieces, and neither too narrow nor too round at the toe, is what experience has pointed out as most suitable. Very thin soles mean an unnecessary strain on the muscles of the foot, and narrow heels (such as ladies wear) can never be quite sure of the key. There are organists who could pedal in Wellington boots, but for the average player there is nothing to beat the shoe as just described.

Practice. Now it seems time to begin actual work. In the way of practice material, it would, we think, be unwise to attempt to give the student anything better or more helpful than the excellent exercises written by men whose names are familiar in every household. Nine-tenths of the organ students of these days begin with Stainer's "Organ Primer" (Novello), and thereafter, if not conjointly, work through the greater part of Rinck's "Practical Organ School," as edited by W. T. Best (Novello). Nothing could be better for the purpose. The Stainer primer begins with a large variety of simple exercises for the feet, following these by exercises for acquiring the characteristic manual touch of the organ; and going on, through graded stages, to the playing of hymn tunes and pieces, and the more elaborate fugues and other work peculiarly associated with the king of instruments. Every student of the organ should found his practice on this excellent manual, supplementing it, perhaps (if he desires to excel in pedal work), by Mr. G. E. Lake's "Pedal Scale Studies," issued by way of supplement to the primer, by the same publishers.

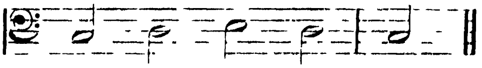
Rinck's "Organ School" is hardly less valuable. Most of our cathedral and other notable organists have been reared on it, and its contents have the recommendation of being at once good technical studies and good music—always useful to the organist in active church work. The "School" is divided into six parts. It will depend on the student's already-acquired facility at the keyboard whether he should work through the preliminary thirty-six exercises in two, three, or four parts, without pedal. These exercises are doubtless useful, but they are not characteristic, and might as well be played on the harmonium or the American organ. We would suggest rather that, assuming a certain technical familiarity with pedal and manual keyboards, a start should be made with the twenty-four preludes in the twelve major and twelve minor keys, following them up with those in the six less usual keys of C♯, G♭, C♭ major, and G♯, D♯, and A♯ minor (Nos. 37 to 66). "In support of my recommendation of such exercises," says Rinck himself, "it may be enough to quote the opinion of my ever dear master, the late Mr. Kittel, organist at Erfurt (the latest living pupil of John Sebastian Bach), who strongly advised practice in all the keys. The same course of study is also enforced by the father of all organ players, the great John Sebastian Bach himself, who, in his 'Forty-Eight Preludes and Fugues,' has given two preludes and two fugues in each and every of the twelve major and minor keys. An organ player should obtain such facility in mastering every key as to overcome every difficulty, however presented." These are valuable words, and the student should weigh them well. When he has conscientiously worked through Rinck's "Thirty Preludes in all the Major and Minor Keys," he will be fit to attack almost anything in the way of ordinary organ music. But first he must go a certain length through the Stainer primer, as is more clearly indicated later.

Playing with the Feet. The prime difficulty with the organ student is that of learning to play with the feet. If he already plays the piano or the harmonium, the manual keyboards of the organ will be perfectly familiar to him. But it is otherwise with the organ pedal-board—the only thing of the kind. That is one of the essential features of the instrument; a feature requiring special study, and better attacked at once before attempting the combination of hands and feet. Turn, therefore, to the Stainer primer, and look at page 37. Stainer's plan with the beginner—and it is a very good plan—is to make him find different notes on the pedals by *feeling with his toes.* This is done by discovering the gaps between the short keys, corresponding to the open spaces at the back of the white keys of a piano between B♭ and C♯, and E♭ and F♯. Just so a blind man learns to play the organ, and because he is debarred from looking at his feet, as most sighted students of the instrument are tempted to do, he acquires a confidence which proves his infirmity a positive advantage.

Stainer indicates the gaps between the short keys (in their order from the lower end) by the letters U, V, W, X, Y, Z. If you thrust your foot into V, the flat of the foot will be over the extreme ends of the keys E and F; if into W, it will be over B and C; and so on. This is what you are to do by way of preliminary practice in "finding" the notes. Having acquired a measure of certainty in locating the keys in these spaces, you go on to find the notes lying near them. For example, you find W with the left foot; then, after feeling the sides of the short keys B♭ and C♯, you draw the foot out and strike B firmly and without hesitation. Stainer gives three whole pages (pp. 38, 39, and 40) of exercises in this finding of individual pedal keys by the "feeling" process. You must work through them, coupling the pedal to one of the manual keyboards, so that the eye may come to the assistance of the ear in determining whether you are perfectly right. Do not get into the habit of peeping down at your feet. That way lies perpetual nervousness as a pedallist.

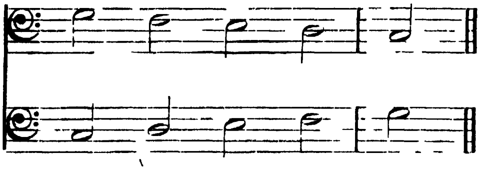
Position on the Organ Stool. These "feeling" exercises mastered, you proceed to the practice of exercises for alternate toes, which, as Stainer remarks, will serve the double purpose of rendering the ankle-joints elastic, and of accustoming you to the measurement of intervals on the pedal-board. The three pages of exercises (41, 42, 43) in this form are made to cover practically the entire range of the foot keys. The student will at first feel himself a little uncomfortable as he works down to the extreme lower notes or up to the higher notes of the pedal-board. He will be tempted to shift his position on the seat to "get nearer them," as students often say. But he must not do this. The legs alone must be made to meet the greater distance either way. You must keep conscious that you are going to the extreme ends, and be continually inclining—but only inclining—your knees and body in that direction. This gradual effort will accomplish it, so that no *sudden* movement in the required direction will then become necessary. You must be particular to observe that you are not assisted in this by the hands, whether by resting on the seat or keyboard frame, or by manual playing, for you must school yourself to accomplish this movement without such extraneous aid. But above all, you must not shift your position on the seat. To do so upsets that subtle process of half-mental, half-mechanical measurement of pedal-board intervals which the organist finds so essential. Fix your position on the seat, and keep to it, no matter what part of the pedal-board is being used.

Pedal Scales. Many organ teachers insist on their pupils practising a complete set of pedal scales at an early stage of their studies. For students who wish to follow that plan there are Lake's "Daily Studies and Complete Scales" (Novello) and Pearce's "Pedal Scales" (Hammond). At this stage, however, Stainer's plan of scale passages seems more practically serviceable. These passages [see pages 51 and 52] he marks for alternate toes, the use of the heel being held over for the present. The student should understand that the system of alternate "toeing" is always to be preferred whenever it can be adopted, as producing a "cleaner" and more certain performance. And he must further note that in this system the right foot has always to be kept well in front of the left, so that the one may pass behind or the other pass in front, as the case may be. Thus, supposing you have this little passage to play:



you will place the left toe well back on the C, the right toe well forward on the D; the left will come up behind the right (the heel of which is raised a little to let it pass comfortably), and strike the E; and so back again to the C. Students often get into the habit of huddling the feet together near the short keys, which always produces a clumsy and uncomfortable performance. In working through the Stainer scale passages, then, let the pupil aim especially at the acquirement of facility in pedalling thus with alternate toes. One must candidly admit that it is somewhat monotonous playing on the pedal-board alone, but the drudgery is inevitable, and must be faced by all serious students of the king of instruments. It is sheer waste of time for the mere beginner to attempt the union of hands and feet while he is still unable to use the feet alone.

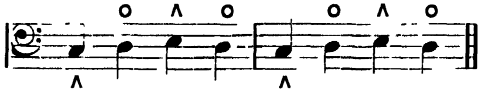
Manual and Pedal Keys. Having gained a certain facility in the use of the foot keys, the next thing is to attempt a combination of manual and pedal keys. This sounds much easier than it usually proves to be. It is a curious fact, which you may readily demonstrate for yourself, that the feet generally want to go the same way as the hands—as the left hand especially. An old master was fond of illustrating this to his pupils by making them write the capital D, with its turn to the left, while the foot was *at the same time* tracing a half-circle in the opposite direction—towards the right. The student may make test of the letter performance, or he may try playing this—the upper part with the left hand on the manual, the lower part on the pedals:



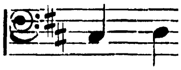
If he does not feel that he would like to have the feet going in the downward direction of the fingers, he may consider himself lucky. In any case, he must aim at complete independence between hands and feet, for which special purpose he will study, as a beginning, the five exercises printed by Stainer on pages 56, 57, and 58. They are called "easy," but the student must not feel discouraged if he finds that they do not answer to this description in his case. To play from three staves, the right hand on one manual, the left hand on another, and the pedal in addition, is by no means "easy" to the beginner at the organ. The best and shortest way of getting over the difficulty is to make sure of the manual parts first; then take the pedal part, first with the right foot alone, and next with the left foot alone. Finally, take all three together. With regard to the manuals, see that you have the tone-quality sufficiently contrasted to make each part stand out distinctly. Thus, if you take the right-hand part on a flute stop in the Great, you might take the left on a reed in the Swell. It is preferable in these exercises to couple the pedal to the Great keyboard.

Touch. At this point it may be well to say something about the manual touch of an organ. This differs from the touch of a piano in several respects. First, as Stainer puts it, an organ key is pressed down, not exactly struck, as on the piano. Next, the loudness or softness of the tone is quite unaffected by the force used by the finger. In some organs (those of older make chiefly) the touch is abnormally "heavy"; in others, it is abnormally light—so light that the weight of a feather will almost make the key sound. Again, there are instruments in which the touch of one manual is different from that of the other manual or manuals. In view of this fact, there is a recognised rule that the player should adjust his touch to the heaviest manual. If he doesn't do this, he is in some risk (when changing from the lighter to the heavier manual) of passing over one or more keys without producing any sound. On the whole, however, the touch of the modern organ is a light touch; and in that respect Stainer's remarks on page 44 are coming to have less and less application in actual practice.

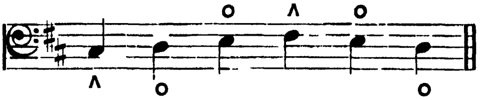
Having mastered the "easy" exercises for producing independence of hands and feet, we are now ready to look at the method of "toeing and heeling" the pedal-board. This method has to be called into use on two accounts. First, the free introduction of the short keys makes it necessary; and, second, there is the frequent withdrawal of the right foot for the manipulation of the swell pedal, making such a use of the heel absolutely imperative. Of course, in many cases it is a question whether toe and heel shall be used, or only alternate toes. Thus, Stainer marks as follows (it is understood that marks *above* the stave mean the right foot and marks [illegible] le left):



But there is no reason why this should not be played by alternate toes, beginning with the left foot. The one method is indeed more comfortable than the other. Take, however, the following:



Though it is quite possible to play this with alternate toes, it is much more easily played with a combination of toe and heel:

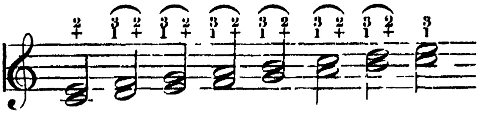


When both feet are free, it is therefore a case of choosing that form of pedalling, as to toe and heel, which is most comfortable and best calculated to produce a smooth and certain performance.

Experience will teach the player many tricks of pedalling—will show him, indeed, many instances in which a passage may be most easily played by ignoring all the rules. For the present he will do well to "stick to Stainer." The toeing and heeling exercises printed on pages 59 and 60 are sufficiently comprehensive, and when the student has completely mastered them he will have laid the foundation of the best possible methods of pedalling. They should be followed up by the five valuable exercises for giving still further independence of movement to hands and feet. These are in two parts only, the left hand being almost solely concerned with the manual part. The series of easy trios numbered 91, 92, and 93 embody the work done up to this point, and will be found an admirable test of the student's progress. These latter may, with eminent advantage, be followed by a careful study of Albrechtsberger's "Twelve Trios," edited by Arthur W. Marchant, and published in Novello's series of Musical Primers. Stainer himself approved of these trios being issued as a supplement to his "Organ Primer."

Fingering. Up to this point nothing has been required to be said about any special method of fingering for the organ. Each hand has had only a single part to deal with, and the fingering has therefore been (as it will be in all such cases) essentially the fingering of the piano. But there is very little organ playing of this kind. It is rarely that the organist has not two parts in each hand, and while the pianist may turn his thumb under the fingers and the fingers over the thumb, the organist has to adopt quite another method. This is known as the *legato* style, and is obtained by changing the fingers on the keys without repeating the sound. The subject is dealt with pretty fully in the Harmonium and American Organ lessons, and to its treatment there the organ student may be referred.

The pianist studying the organ will find it somewhat difficult to acquire the legato style, and will, indeed, often be tempted to ignore altogether this, its most essential characteristic. The disjointed effect produced by fingering the organ by any other method is, however, so intolerable to the ear that no person of real musical taste will ever entirely shirk the very necessary practice of finger substitution. On the piano you may "run up" a scale in thirds without any changing of fingers and yet not outrage the ear; but such a scale can be satisfactorily played on the organ only in some such way as this:



For acquiring this legato style, the peculiar beauty of the organ, there is nothing better than the Stainer Exercises Nos. 94 to 108. No pains should be spared to get them done in the most finished manner possible. It is difficult at first, no doubt, all this finger changing; but the student will find that by-and-by the fingers will shift for themselves without waiting for the direction of the player's will—in other words, they will shift by instinct. It should be added, perhaps, that it is occasionally necessary, in the interests of a very smooth performance, to substitute one foot for another on a pedal key. This is eaily done when the key is a long one; happily, it rarelv needs to be done on a short key, where it is naturally more difficult.

Expression. In all his elementary work at the organ the student will require to think more of "getting the notes right" than of the expression of the music. As he gains facility, however, he will want to acquire the command of such resources as his instrument affords in the matter of expression. These resources, unfortunately, are curiously limited. The organ is admittedly deficient in this respect—namely, that the player cannot influence the intensity of the tone by the character or force of his touch. Stainer mentions four sources of expression as being at the command of the organist: (1) The art of phrasing; (2) the contrast between legato and staccato; (3) the selection of the stops; and (4) the use of the swell pedal.

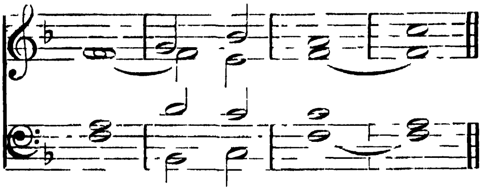
The first two belong, however, rather to advanced musicianship, while as to the third, it can hardly be said to come under the head of expression as generally understood. Practically, expression consists mainly in gradations of the tone intensity, and in that respect the organ player has to depend mainly on the swell pedal. The use of this indispensable piece of mechanism has already been referred to, at a stage at which, however, it would not have been advisable to advocate its employment. Assuming that there is a pedal part to play, it is clear that the young organist cannot effectively control the swell pedal unless he is able to manipulate the pedal-board with the left foot alone. The swell crescendo and diminuendo should therefore be held in abeyance until the student has acquired that expertness in toeing and heeling which the use of one foot implies. Of course, where there is no pedal part, this restriction does not apply.

Church Music. In taking up the study of the organ, most persons have in view the securing of a church appointment, either as amateur or professional. As the basis of an organist's church work is the playing of psalm and hymn tunes and chants, it will be well that the pupil should now address himself to this important branch of study. Simple as it appears, it could not be taken up at an earlier stage—first, because of the pupil's practical unfamiliarity with the pedal-board; and, second, because the legato style of fingering, which is alone used in this sort of work, had not been acquired. Assuming a fair command of the instrument in these respects, the troubles that will present themselves now will be those of "reading" and playing from four parts, and of adapting the system of finger substitution to the rendering of two parts by each separate hand.

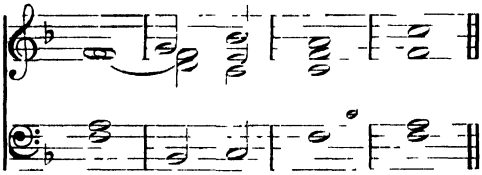
As regards the "reading," very little need be said here. It is chiefly a matter of practice, in which a knowledge of harmony and the general laws regulating part-writing prove of immense assistance. To the pianist or the unpractised organ student it is by no means easy at first for the eye to "take in" four parts at once. But one soon acquires this very necessary facility in reading when the mind is brought to help the eye; for chordal combinations and progressions as seen in hymn tunes are limited, after all, and familiarity comes with continued repetition. It is a good plan for the student to take some popular collection such as "Hymns Ancient and Modern," and work through it entirely as an exercise in reading. He need not waste time at the organ in doing this if he has a keyboard instrument—harmonium, American organ, or piano—in his own rooms.

There is one important point to be observed. Hymn tunes are written for voices—treble, alto, tenor, and bass. In playing them (without pedals) the organist takes the treble and alto with the right hand, the tenor and bass with the left. But the composer does not consider the player's convenience in the "distribution" of his parts, and hence it often happens that a note or notes belonging to the tenor have to be taken by the right hand, and a note or notes belonging to the alto by the left. Stainer illustrates this in the following simple way :

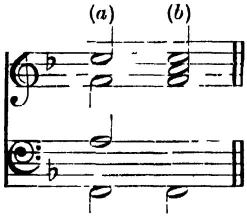
Written



Played



Now and again it happens also that a chord as writen for the voices cannot be played at all as it stands. Thus, as at (*a*) :



In such a case the plan is to transpose the unreachable inner part note an octave higher, always provided it does not, when so transposed, become higher than the treble. Thus the unplayable (*a*) becomes the playable (*b*).

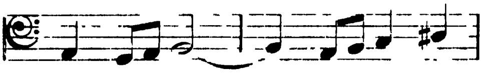
Legato. As regards the system of finger-releasing essential to the legato style, that will be found rather irksome at first when applied to the rendering of four-part harmony. But the difficulty must be got over, and persistent practice is the only "royal road." Let the student keep ever before him this one important rule, that while notes belonging to inner parts (tenor and alto) may be "jumped," every note in an outer part (treble and bass) must have a finger ready for it. Of course, when the pedals are used for playing the bass, the difficulties of finger-releasing are much minimised as regards the left hand, which then (ordinarily) has only the tenor part to play ; but no student should be satisfied with himself unless he can play all four parts with the hands alone in the true legato style, which is the characteristic beauty of the organ. Stainer gives just three exercises toward this end (Exercises 110, 113, 116), but they are sufficient to show the student what is required of him as a preliminary to any satisfactory rendering of psalm and hymn tunes and chants. They should be practised assiduously until they can be played with as much ease as an automaton might play them.

Hymn Tunes. But, of course, the organist does not always want to play his psalm or hymn tunes on the manuals alone. He wants to use the pedals, too ; for if he didn't he might as well be playing a harmonium or an American organ. And this brings us to the various ways in which a hymn tune may be played on the organ, as illustrated by Stainer in Exercises 111, 112, 114, and 115. We may call the playing of the tune on the manuals alone the first way The second way (Exercises 111 and 114) shows the treble and alto assigned, as usual, to the right hand, the tenor to the left, and the bass to the feet. In this manner, great care must be taken, as Stainer observes, to prevent the left hand from doubling the pedal part. It will usually want to do so, especially if the student has been accustomed to play hymn tunes on a manual keyboard alone. In actual church work the bass is often taken by the pedal an octave lower than written, and in that case the left hand takes it as it *is* written, along with the tenor part.

In the third manner (Exercises 112 and 115) we see the treble part played as a solo, with the alto and tenor assigned to the left hand and the bass to the pedals. This is the most difficult of all the three forms, the chief trouble being, alike as regards "reading" and execution, to get the alto and tenor together in one hand. As a matter of fact, the organist has here both to "arrange" his music and to play it. Very often he will find that the left hand is unable to cover the interval between the alto and tenor parts, in which case the two notes "must be inverted, or played in any position most convenient." This "soloing" out of a hymn tune, as it is called, not only gives a pleasing change from the more common methods, but it is useful, in the case of an unfamiliar tune, in so far as it puts the melody prominently before the congregation. In all such cases, it need hardly be said, a stop or stops must be used which will make the melody "stand out" much more clearly than the accompanying parts.

Stop Combinations for Hymns. Thus, you might "give out" a tune on the Swell "Oboe," accompanied by the Great or Choir "Dulciana" or "Stopped Diapason" ; or you might use the Great "Open Diapason," accompanied by the Swell "Oboe" and one of the Diapasons. There are, in fact, endless ways of "giving out" a tune as regards stop combinations. These are for the player himself to discover. Meanwhile, as a student, he will find that it is quite enough to get the notes right in the particular ways indicated by his tutor. He will, of course, work through all the Stainer Exercises (110 to 116) meant to give him command over the various styles of chorale and hymn-tune playing. When he has finished these (which are specially arranged for him), he should attack his ordinary hymnal again, and, selecting, say, a dozen well-known tunes from it, proceed to play them in the various ways which he has just been studying. This is the more advisable, as when actual church work comes to be done, it will be from the hymnal arranged for the voices, and not, as in the case of the tunes in Stainer, for the organ.

It is at this stage that Rinck's "Practical School for the Organ," which has been already referred to, might be taken up with advantage. Many organ teachers *begin* with Rinck, but Rinck assumes, much more than Stainer, that the student can already play on a keyboard instrument. The first section of his "School" includes, indeed, thirty-six "short and easy" exercises in two, three and four parts for the manuals, but these are not fingered and there is nothing to indicate the necessary legato style. The pedal exercises, again, are hardly such as a beginner can benefit by. But, having mastered his Stainer so far, the student would find it of real value to himself to work through the "Thirty Preludes in all the Major and Minor Keys" of Rinck's opening section. It is a pity, perhaps, that the pedal part is left without any indication of toeing and heeling. But the student, from what he has already learnt, can readily add these marks for himself, and thinking them out will do him a world of good. How to pedal this (from No. 37), for example, will lead to some interesting little experiments:



It can be done quite neatly in two or three different ways, and the question for the student will be which way he is to adopt. Hence, perhaps, it was better that Rinck did *not* mark his pedalling. Students who take up Rinck at the beginning generally have his exercises marked for them by a professor. Assuming Stainer beforehand, the student can easily "mark" for himself. At any rate, he should get through these thirty preludes. They are invaluable in many ways, and not least for their covering of all the less familiar keys. Students are apt to stop short at four flats and four sharps, but an organ-player should obtain such facility in all the possible keys as will enable him to overcome every difficulty, however presented.

After these Rinck preludes have been mastered a return might be made to Stainer, taking up the five short pieces (Nos. 120 to 124) intended to represent different styles of organ music and to give the pupil a wider sphere of practice before attacking the classical works of the great masters who have written specially for the instrument. But these should be studied concurrently with the third and fourth parts of Rinck, which embrace a series of thirty postludes, or concluding voluntaries, in the fugue style, all admirably calculated to add to the young organist's facility in the use of the manual and pedal keyboards. Rinck, indeed, though some regard his style as old-fashioned, ought to be the young student's daily bread, so to speak. Stainer's work is a primer, and cannot be expected to exhaust the subject.

A Reliable "School." As a royal road to thorough and "legitimate" organ-playing in all styles, there is no other "school" which will bear comparison with Rinck. A beginner who has been founded on Stainer can follow no better course than go through him slowly, allowing, say, three months for each book. "Rinck's name," wrote the late Sir Herbert Oakeley, Professor of Music in Edinburgh University, "will always live as that of a safe guide towards the formation of a sound and practical organ-player; his works comprise many artistic studies." Again, the illustrious French critic, F. J. Fétis, wrote: "In the composition of music for the organ the talent of Rinck was of a character peculiar to himself. His elegant and simple style was generally noble and dignified. His harmony has much about it that is uncommon and unexpected; his melody is sweet and touching. He did not try to write difficulties: his evident object was to work for provincial organists, to form their tastes, and to perfect their studies." This is no exaggeration, and the words are quoted by way of stimulus to the student who is seeking to acquire a real command of the instrument upon which Rinck himself was so distinguished an executant.

It is possible, of course, that some students who have gone through their Stainer will not care for the rather more severe, ecclesiastical style of Rinck. In that case they might continue their studies by means of Archer's "Organ Book" (Novello), one of the best and most comprehensive manuals of its kind. It continues exhaustively and thoroughly the admirable work which has been outlined in the Primer, so that a student who plods steadily through it feels, after he has done, that very little more can be pointed out to him in the way of instruction. Much of the work must, of necessity, be dry and technical, and as such, may not interest the student. There are, however, many pieces, both short and long, in the work of considerable musical interest, though generally somewhat difficult. There are also Best's two volumes, first-rate both in design and execution; the one for manual work, the other containing an exhaustive set of pedal exercises and studies. On the whole, it will be best for the student who desires to supplement his Stainer to ask at a music-seller's for a sight of the works just named, and choose that which makes the strongest appeal to him. Students are of such different capacities and of such different tastes that it would be foolish to lay down any hard and fast rule in a matter of this kind.

Organ Compositions. But what about "pieces"? it may be asked. For even the most serious student desires occasional relief from exercises and studies, so-called. Well, notwithstanding all that has been written for the instrument, there is nothing better for accompanying the purely technical side of the young organist's training than a course of Henry Smart. Smart's organ compositions are published by Messrs. Novello, in twenty-two numbers. They embrace several styles, and run from easy to very difficult music. The easy pieces can be attacked as soon as the player is familiar with the pedal-board, the fingering of the instrument, and the management of the stops. The same composer's "Organ Student" (Boosey) might also have attention. Smart's "easy" pieces, an authority has rightly said, are specially fitted as studies for students wanting to acquire the true "organ touch" on pedals and manuals. Indeed, a learner who knows his rudiments may find in this master's organ music a progressive school of the very best kind, provided only some judicious friend points out in what order the various pieces should be taken. A beginning should be made with No. 19 of the Novello set, after which might come Nos. 11 and 13; No. 18 is an easy march in G.

The Great Composers for the Organ. Along with these may be named the "Twenty-four Sketches" of Dr. E. T. Chipp; Hesse's "Organ Book," edited by Gladstone; the "Thirty-six Short and Easy Voluntaries," by Dr. C. J. Frost; and the several books of organ pieces by Dr. George Calkin. The latter are very melodious, and many of them are comparatively easy. And then, of course, there is Sebastian Bach. Bach is the king of all writers for the organ. For acquiring technique there is nothing like his preludes and fugues. The "Eight Short Preludes and Fugues" form a kind of school in themselves, though the student had better delay attacking them until they are fairly within the measure of his capacity. They can be suitably followed by some of the large fugues, such as the short E minor and the one in E♭, known as the "St. Ann." As there are many editions of Bach, it is advisable to say that the best is that edited by the late W. T. Best (Augener). Very good, also, though less easy to read, because more crowded on the plates, is the edition of Sir J. F. Bridge and Mr. James Higgs (Novello). Both editions are fingered and marked for pedal where necessary.

After Bach, among the great composers for the organ, comes Mendelssohn, whose little collection of preludes and organ sonatas ought to be on every advanced student's desk. The short movements of the organ sonatas should be taken first, and followed by the Prelude and Fugue in G. The easiest of the sonatas is the one in C minor, which makes a capital study "piece." Among what may be called the minor classics may be recommended the works of Merkel, Guilmant, Wely, Salome, Batiste, and Dubois. Of course, these are merely suggestions for helping the student on his way. A list of "suitable" organ pieces could be made to fill many pages of this work; and, after all, the advanced student is best allowed to consult his own preference, which he can readily do by seeing the music before buying it.

Church Appointments. Ninety-nine out of every hundred students of the organ want to secure a church appointment. This is only natural, for where but in church can the organist make practical application of the art he has attained? There are the big concert halls, of course, but these are among the prizes of the profession, not yet to be thought of by the young player. One great advantage of a church appointment is that the organist secures, as a rule, the full command of an instrument for practice. Indeed, in the vast majority of cases outside the very large towns, this is almost the only way in which a player can get unlimited practice. Even in the large towns it is costly to hire the use of an instrument, and the enthusiast who desires to "get on" will often find it to his advantage to accept a post, when he is competent for it, at a merely nominal salary—nay, at no salary at all—solely for the practice it will bring him.

Generally speaking, the Dissenting churches offer the easier posts for the young organist, the musical services there being so much simpler than in the Church of England. In the village churches the technical requirements are probably about equal, but young players not accustomed to it are apt to find the chanting of the prose psalms and the canticles a difficulty. Still, a Churchman will not readily give up his own "Communion," and after all, granted an adequate competence to begin with, there is much more to advance the player in the Church of England than in the Nonconformist services.

Choir Training. A post in either case is alike in one important particular—namely, that it demands some little ability and experience in choir training. This is a matter which is too often, and very absurdly, taken for granted. It no more follows, of course, that because a man can play the organ he can drill a choir, than it follows that a man who makes billiard balls can play billiards. Every student of the organ who looks forward to a church appointment should make a special point of acquiring a practical knowledge of choir training. It is not a thing that can be gained by reading. The best plan—assuming the student to have a serviceable voice—is to become a member of some church choir directed by an organist who excels in this branch of his art, and watch carefully his methods. The subject of voice production should also be studied, and special attention given to the important side subjects of articulation and expression. A choir *must* be drilled; and the unfortunate thing for the young and inexperienced organist is that the more modest his appointment, the more necessary, as a rule, does this drilling become [see CHOIRS]. Helpful works on "Church Choir Training" and on "The Art of Training Choirboys" are published in Novello's Music Primers series. The student will find it of service to consult also "Common Praise," by F. G. Edwards; "Organs, Organists, and Choirs," by E. Minshall; and "Studies in Worship Music," by J. Spencer Curwen.

A word or two as to the financial side of church appointments. The organist is, as a rule, still miserably paid in England. Especially is this the case in the Church of England, where salaries of £40 a year are common, and salaries of £80 quite uncommon. Often, the sum offered does not exceed £20. In the Scottish Presbyterian churches the salaries are somewhat more in accord with the duties and abilities demanded. Good churches pay from £60 to £80, and salaries running into the three figures are not unknown.

As regards appointments abroad, not much need be said here, because such appointments are generally applied for and obtained by men of experience. South Africa does not offer a very tempting field, unless it be in places of good size, where the English congregate—places like Cape Town, Pretoria, Johannesburg, and Port Elizabeth. The States would seem a better field, for there organists command much higher salaries than the average run in England, though this is largely counterbalanced by the greater expense of living. But the professional can usually take care of himself in these matters. We write chiefly for the amateur, and the amateur organist will probably look rather to the opportunities of his appointment than to its finances.

Service Accompaniment. In the accompaniment of the services, whether simple or ornate, the organist will find plenty of scope for the exercise of his technique and the exhibition of his musical taste. It is hardly possible to teach an organ student to be a really efficient accompanist unless he is endowed with certain gifts in that direction. Much help may be obtained from the works of Messrs. Edwards and Minshall, previously mentioned, and there is also the primer on "Organ Accompaniment," by Sir J. F. Bridge, the organist of Westminster Abbey. In every detail, let the organist remember that the function of his instrument is to accompany, and not to lead, the singing. A player who continually uses the full power of the organ, drowning the voices in a tempest of noise, mistakes entirely the nature of his duties, besides showing a lamentable lack of artistic sense.

Voluntaries. The question of voluntaries is important, not so much from a technical point of view as because of the influence which the voluntary may have in helping or hindering the devotional feelings of the congregation. Broadly speaking, the opening voluntary should be of such a character as will put the people "in tune," as it were, for the service which is to follow. In other words, it ought to be quiet and restrained, without any undue obtrusiveness of technique, without suggestions of secularity. The closing voluntary, on the other hand, may draw upon all the resources of the instrument and all the resources of the player's technique, provided always that it is not in flagrant contradiction to any special character that may have manifested itself in the preceding service Thus, it would be outrageous to follow an appealing discourse on the sufferings and death of our Lord with some piece of "fireworks" drawn from the flimsy French school. Young players seldom "think on these things;" but they may be assured that these things are of essential importance.

In a large majority of cases it will be safe for the organist to fix upon his closing voluntary beforehand. But he ought always to have some pieces of a varied character on the desk for anything special and unexpected that may have come from the pulpit during the service. As Pope said long ago, some to church repair, "not for the doctrine but the music there," and "a song may find him who a sermon flies." Therefore, give special attention to the question of voluntaries.

Postludes. The young organist who has gone so far with us will have little difficulty in selecting a list of suitable voluntaries. The name of such pieces is literally legion. Opening voluntaries are especially plentiful, and not even a tentative list of these need be attempted here. The player should look up the list of 84 pieces printed by Edwards on pages 189–190 of his "Common Praise." Concluding voluntaries are in slightly different case. Young organists often complain that they have trouble in obtaining short, bright postludes. They find the better-known postludes too long, the church being empty before these are half played. The following—among many others—should meet requirements in this direction: Postlude, A. Boyse; Scherzo, A. Boyse; Minuet and Trio, Baptiste Calkin; Festal March, Dr. Bunnett; Minuetto, G. Calkin; Postlude, G. Calkin; Marches Nos. 1, 2, 4, 5, 8, 17, 18, 20, 21, 22, Dr. C. J. Frost; March in C, Lefebvre Wely; Religious March in E♭, Macfarren; Six Marches, Gustav Merkel; Postlude in C, H. J. Stark; Thirty-six Brilliant Postludes, Dr. Volckmar, in three books; Seven Festival Postludes, Dr. Volckmar.

To these might be added: Postlude in D, Merkel; Postlude in D, Berthold Tours; Postlude in A, H. J. Stark; Twelve Postludes, Dr. C. Vincent; Postludes in C minor, Professor Prout; Introduction and Fugue, E. Silas; March in B♭, E. Silas; Offertoire in G minor, Wely; Homage à Mozart, Baptiste Calkin; Postlude in C, Henry Smart. For those who like marches there is the classical "March Album," published by Augener. Much of Rinck's "Organ School" is eminently suitable in this connection, and, of course, Bach must not be forgotten. Players of modest abilities, who want a single collection from which to draw, can hardly do better than with "The Village Organist" (Novello), of which a long and interesting series has now been published.

Extemporisation. The art of extemporisation, of "creating and performing music at one and the same time," is less practised now than it used to be. It is, however, of great value to the church organist, who has frequently to "create" little bits of music to fill up gaps in the service, to extend his voluntaries or "round them off" in the middle, to improvise introductions to anthems, and so on. It is often contended that extemporisation is a gift; but this is only partly true. Fancy, or the power of imagination, as one has said, is undoubtedly a gift, and to this power the player must turn for the *invention* of his original themes and of the phrases and figures that he will need in the development of his movements. But then, beyond the power of imagination, there is the great power of development on which the player must depend to work out *from* this created theme the completely balanced movement. And *that* is an art which may certainly be attained by properly directed study.

We cannot pretend to "teach" extemporisation here—no writer can pretend to teach it anywhere. At most we can only offer a helpful hint. He who would study the subject practically and in all its details can have no safer guide than Dr. Sawyer's "Extemporisation" in Novello's Primers. The subject is there dealt with in two sections—firstly, the extemporisation of the *theme*; and, secondly, the development of the *movement* from such theme. From Dr. Sawyer the player will learn how to extemporise short preludes and long preludes; how to "vary" a given theme; how to extemporise marches, and postludes, and even fugues, the most difficult of all forms to "create" on the spur of the moment. It need be hardly added that extemporisation implies a thorough knowledge of harmony and musical "form." Many young organists who attempt it are without this knowledge, and so ramble on in an incoherent way, without aim or design of any kind, to the pain and disgust of many who are compelled to listen to them. No effort of this nature can be called extemporisation, since it is not music, which alone "attains its power and effect over mankind by the directness and force it contains in the perfection of its rhythm, the even balance of its parts, and the complete connection of its varied sections." Every organist ought to practise extemporisation in private for a long time before attempting it in public.

Organ Recitals. The player who has been fortunate enough to secure an appointment with the command of a fairly good organ will naturally want to give an occasional recital. Here he has something definite to "work up to," and the knowledge that he is to play a selection of pieces to an audience specially assembled to hear him will stimulate to a greater degree of finish than is generally held to be demanded by the ordinary Sunday voluntary. The art of making up a recital programme is not to be taught on paper. The great aim should be to secure as much variety as possible in the character of the pieces chosen. There ought to be a due admixture of loud pieces and soft pieces; the more severe style (say, of Bach) should be contrasted with some lighter style; a good march might be thrown in, and perhaps a piece which affords the player peculiar scope for proving his command of the technique of his instrument. The solo stops will not be neglected. Thus, if the player's instrument boasts a fine "clarinet" or a fine "oboe," he will see to the inclusion of some piece or pieces calculated to show it off, as the saying is.

The recitalist should try to have a fugue by Bach as representing the most solid of all styles of organ music. A Mendelssohn sonata is also considered the right thing by many organists. Some like a Handel concerto, too—the Fifth and Sixth are the easiest, if the player wants to know. Of the more modern German school, Rheinberger and Merkel are specially commended, though Rheinberger is somewhat heavy for the average recital audience. Of the English school, Smart, Lemare, and Hollins, among others, should have attention. The French school may be drawn upon for the light style, though much of the work of Guilmant, Salome, Widor, Dubois, and others answers to something higher. Batiste and Wely are brilliant and showy, and have the advantage of being comparatively easy to play. Of "arrangements," so called, the number is endless. Some purists condemn these entirely, insisting that recital programmes should be made up exclusively of music specially composed for the organ. But the average audience has to be considered, and an effective rendering of, say, "The Better Land" or the Mascagni "Intermezzo" will often give pleasure where a "legitimate" organ solo would fall flat.

Recital Selections. But the young player who has been so far guided entirely by these lessons may rightly ask us to expressly name a list of recital pieces. Bach and Mendelssohn being assumed, take, then, the following: "Occasional" Overture (Handel); Barcarolle (Sterndale Bennett); Priere et Berceuse, Cantilene Pastorale, and Grand Chœur in D (Guilmant); Fantasia in C (Berthold Tours); Postlude in E♭ (Wely); Cantilene in A minor, Pastorale in G, and Offertoire in D♭ (Salome); Andante Grazioso in G, Quasi Pastorale in G, Tenor Song in B♭, and Grand Festive March in D (Smart); Andante and Allegro in D (F. E. Bache); Offertoire in D minor and "The Pilgrim's Song of Hope"—Andante in G—(Batiste); March for a Church Festival (W. T. Best); Fanfare in D, and Triumphal March (Lemmens); Toccata in G (Dubois); Grand Chœur in A (Salome); Evening Bells (Chauvet); Pastorale in E (Lemare); Communion in F (Grison); Overture in E (Morandi). This, it must be insisted again, is the merest apology of a list. The young organist should see as many recital programmes as he can, in search of further hints. A selection is published every month in "Musical Opinion," and every large town has its experienced recitalists whose programmes should never be missed. At the same time it is, of course, advisable that the recitalist should not be always playing the things that other organists are playing. The choice of pieces is extensive enough to enable every player to be original, if he will.

Some Practical Hints. We close with the practical hint that the organist should acquaint himself thoroughly with the mechanism of his instrument, and learn how to tune it and to "regulate" the defects which are almost inevitable in so complicated a machine. These acquirements are specially necessary in small towns and country districts where a professional organ tuner cannot readily be obtained. The more he reads about his instrument and its repertoire, the more intelligently he will play.

Organ concluded

SCIENCE OR MUDDLE IN SOCIETY?

The New Science of Life. The History of the Race is a History of Mistakes. Society will now Develop Scientifically instead of Muddling Through

Group 3
SOCIOLOGY
1
Following on PSYCHOLOGY
from page 3865

By Dr. C. W. SALEEBY

WE turn now, with daring but not without hope, to that great study which is the crown and end and aim and synthesis of all the lower sciences. From a narrower point of view such a description might be applied to the science of medicine in its widest sense, and there is this much of instruction to be gained from the comparison between medicine and sociology—the common explanation of their difficulty. In studying one of the basal sciences, we have no very numerous assumptions. We build our own foundations, and are not at the mercy of criticism from without. On the other hand, there are more complex sciences which depend entirely for their foundations upon the foundational or fundamental sciences. There was no possibility of a rational medicine when chemistry, physiology, and anatomy had no existence; yet medical knowledge was needed, and men had to do their best to acquire it, even though the conditions which made such acquirement possible were unfulfilled.

The New Science of Society. Similarly, the science of society has always been needed by men. Men, as we shall see, is a social animal, and his happiness is gravely affected by the manner of society in which he lives. Thus, as death and disease have always necessitated medicine of sorts, even when the foundations of a rational medicine were non-existent, the needs of human life have always necessitated some kind of sociological practice, even when the foundations for a rational sociology were non-existent, and not even conceived of. Thus, the initial fact, which must surely interest us, is the extreme newness and the very air of novelty which distinguish this science, though the need for it is as old as the human race. Let us first make an inquiry into the history of the word, and then let us consider the foundations and assumptions of the science.

Sociology is a hybrid term, the first part of it derived from the Latin and the second from the Greek. It means simply the *science of society*. Because it is a hybrid, objection has frequently been taken to it; but the word is convenient and intelligible, and has thus come into general usage. It was invented by Auguste Comte, and he had a deliberate intention in compounding it from the languages of Greece and Rome. He tells us that his object was to express the double origin of modern societies, which are, in effect, based upon the practice of the two last and greatest societies of antiquity. The term was accepted in England by John Stuart Mill, who was in some measure a disciple of Comte, and who employs the word in his great "System of Logic" (1843). Subsequently, the term was accepted and popularised by Herbert Spencer, whose work has made it known wherever men think.

Auguste Comte. To the main facts of Herbert Spencer's life we shall devote ourselves in due course. Here our concern is with the idea of sociology as a science; and this is therefore the place in which to make some reference to the philosopher whose name ranks first in this respect. Comte was born in 1798, and early became distinguished for his devotion to learning. When he was still a boy he came under the influence of an extremely remarkable man, Saint-Simon, who was his senior by forty years, and whose relation to Comte cannot better be described than in the words of Mr. John Morley, who is a follower of neither: "The most cursory glance into Saint-Simon's writings is enough to reveal the thread of connection between the ingenious visionary and the systematic thinker. We see the debt, and we also see that, when it is stated at the highest possible, nothing has really been taken from Comte's claims as a powerful original thinker, or from his immeasurable pre-eminence over Saint-Simon in intellectual grasp and vigour."

Saint-Simon had the fundamental idea of applying to social problems the methods of science; but he had not what Comte had in abundance—a remarkably complete and thorough scientific training. This it was which gave Comte the power to carry out the application of what we may call the scientific idea of sociology.

A Philosopher's Religion. We cannot leave this remarkable man, however, without commenting upon the second stage in his history, which dates from the year 1844, when he made the acquaintance of a remarkable woman, who had an amazing effect upon his emotional and moral nature. Says Professor Beesly: "Hitherto, though the ultimate object of his speculations had been to place morality on a firm basis of science, and though, in labouring for that end, he had been animated by a noble, social spirit, he had not professed to be a religious teacher, or to set, in his own person, any special example of a good life. He was simply a philosopher, working out a system which he believed would be of great benefit to the human race, but what he had before recognised as a philosophical truth—that love should be the moving principle of our lives—was now brought home to his heart. And this was fruitful of good."

It was in the second period of his life, thus modified, that he set forth his proposals for the new religion which he called Positivism, and which, though it shows very small signs of converting the world to its views, is yet extremely interesting, and is *unique*, as being an artificial religion constructed, in principles and in details, by a professed philosopher, who was at the same time an adherent of what we may call the scientific school. Comte died in the year 1857, which, by an interesting coincidence, was the very year that saw the introduction by Herbert Spencer of the word *evolution*.

What Makes a Science? Comte made no contributions to the natural sciences. His attempt to make a new religion has been a most conspicuous and significant failure. His name will be permanent, however, in the history of thought because of his establishment of the first principle of sociology, which is that societies and their ways, their origins, characters, and functions are a fit subject for scientific study. Comte's great accomplishment, then, is the application of the scientific idea to the most important realm in which science can conceivably hold its sway. This is not only the first principle of sociology, but is also the most cardinal truth which it reveals to us; and we must consider it carefully.

At this comparatively late stage in our studies we can have little hesitation in answering the question, What constitutes science? When we assert that there is, or may be, a science of anything, we mean much more than that the facts of the subject in question may be arranged in columns or catalogues. We mean not only that there are facts which may be arranged and classified, but that there is a relation between them; we mean, to take an astronomical instance, not only that the movements of the planets may be stated, but also that they may be explained by means of a law which expresses their common cause; or, again, to take a sociological instance, we mean not merely that historians may describe the conditions of various societies in respect of the status of women, and in respect of their relations to war, but also—which is immeasurably more important—that we may establish a relation between the two sets of facts, resulting in the generalisation, so much insisted upon by Herbert Spencer, that "militarism and a low status of women are associated phenomena."

Natural Law in Society. In other words, to assert that there may be a sociology is to assert that cause and effect are as immutably related to one another in the realm of human life as in the realm of mechanics. It is to assert that causation is universal—which, as we have seen, is in a sense the first, the last, and the only assertion of science. Now, to anyone who has had a scientific training the doctrine that causation and the sequence of phenomena are as true of human life as of mechanics is a platitude scarcely worth saying. The idea of the universality of causation has become a necessary condition of all the thinking of such a person. To labour to demonstrate to him that, even though we do not know them, there must be laws of history and social laws in general, as true and comprehensive and as necessary as the law of gravitation, is to waste one's time. It is as if a player of lawn tennis were to spend an afternoon in demonstrating to a cricketer that the amount of moisture in the ground, the presence of wind, and the spin on the ball were factors that had to be taken into account when playing the game. The cricketer might never have heard of lawn tennis, but he would not require to have these things demonstrated to him. He has always known them illustrated in his own game, and he will take them for granted in any other.

The Mistakes of the Human Race. Similarly, the student of physics does not require to be told that social phenomena are caused, and that a given sum of causes will invariably produce a given sum of effects. He who is already familiar with the composition of forces in dynamics is prepared to study the composition of forces in social dynamics. The first assumption of sociology—namely, that there is or may be a science of society, is in no more need of proof for such a student than the first assumption of meteorology, that, appearances notwithstanding, there is or may be a science of the weather.

On the other hand, many persons approach the study of sociology who have by no means had the intellectual preparation of, for instance, the young physicist. In consequence of this simple truth society has again and again been committed, and will again and again be committed, to the most gigantic and disastrous errors. All over the world the greater part of legislation consists of the abrogation of previous legislation. Human history is a history of error. Its successes have been gained, it will appear, by the method which the logicians call the method of trial and error. There having been no scientific sociology, and politicians having been the same quaint and shortsighted creatures in the past as in the present, men have tried every kind of wrong path until at last, no choice whatever being left them, they have entered the right one. Even then they have only too frequently left it; but, on the whole, truth has a way of prevailing, because truth has the superior *survival value*, or value for life, and so progress, though slow, is yet achieved.

"Experience by Experiment." Now, the method of trial and error is satisfactory enough in some cases—as, for instance, when you are faced with a lock and have three keys in your hand. Even in such a case you waste a little time, but that is all. In no conceivable case can waste of time be dissociated from this method, as contrasted with the scientific method. Contrast, for instance, the behaviour of a baby, who does everything by this method, with the behaviour of even the stupidest grown man, who will not put a key into a lock twenty times too big for it, and who, so far at any rate, is scientific. But, as a rule, the method of trial and error is far more disastrous than in this case. Take, for instance, the doctor of old time who had to treat a disease which he did not understand with one or other of three drugs which he understood scarcely better; as Voltaire said, "Pouring drugs of which he knew little into a body of which he knew less." Here the method of trial and error may well result in the death of the patient, even assuming that one of the drugs be as certain a cure as quinine for malaria.

Marriage and Evolution. Now let us turn from mechanical and medical illustrations to a social one. The method of trial and error has been pursued, for instance, in the case of sexual relations. There were no scientific principles on which primitive men could go, or, rather, such men were as ignorant of these principles as are the pestilent fools who, even to-day, raise their witty and worthless voices against the one sexual relation which the method of trial and error has demonstrated to be sound. In the absence of science, then, this method was pursued by primitive men; though, as we shall afterwards see, the superiority of monogamic marriage is so tremendous that our records of other practices are relatively quite scanty—notwithstanding a popular delusion to the contrary. But observe how imperfect the method of trial and error has been in this case. As in every case, it has wasted time—it has delayed progress; but, just as this method in the case of the ignorant doctor killed most of his patients, so in this case it has killed innumerable races and societies. We have the records of peoples who practised other methods of sexual relation than that of marriage; such peoples are no more. Furthermore, history records not merely the fate of obscure tribes, but also the fate of great nations. Historians in the past may have had many virtues, literary and other, but they have scrupulously avoided being scientific. They have their own theories as to the fall of empires; theories as to racial degeneration—which theories biology knows to be an utter myth; theories as to the corroding influence of peace—which, alas! are so plausible as to have deceived even the profound and majestic soul of Wordsworth—recall the phrase in a great sonnet, "When men change swords for ledgers."

Why Rome Fell. But the sociologist—the only historian who has to be reckoned with henceforth—knows that it is the heart at which an empire rots. He knows that peace and prosperity as such have never destroyed any race. He knows that the decline and fall of Rome, for instance—the same being doubtless true in general—were due to the decline and fall of the family, due to error in this fundamental matter of sexual relation, which we must hereafter discuss at some length.

The conclusion which we desire here to insist upon is, firstly, that the method of trial and error—which we may describe as, in general, the method of all societies in the past and present—is unsatisfactory because the price of error is so terribly high. Much more than this, we would insist that the method of trial and error is a failure because even when success is attained by it, it embodies no sure means for ensuring the persistence of that success. The method has taught many races—all the races that have played any real part in the world—that monogamy is the best sexual relation. They have not been taught it consciously, however, or, indeed, taught it at all in any real sense. The method has merely worked. Yet, when adequate temptation arose, the method has been abandoned—and the decline and fall have followed. How different would be the case of a society which based its practice upon sound sociological principles! Such a society would know, from its statesmen downwards—and such a society would, of course, be blest with statesmen—that the decline of marriage and the family must necessarily be followed by a national decline. Such a society would not go into danger with its eyes shut, as all societies in the past have done.

Sociology is a Living Thing. The truth which we desire to demonstrate might well occupy a volume. There will probably not be a paragraph in this all-important course of which the same might not be said. It is the truth that the recognition of a science of society is necessary for any society which, unlike all societies of the past, is to endure. Now, this is an all-important proposition, and it is very generally disbelieved. There is a common and powerful body of opinion which directly controverts this doctrine. The critics have doubtless some excuse for their criticisms—otherwise less would be heard of them. They incline to the view that sociologists are, in general, a bald, bespectacled, withered-up body of folk, old women of both sexes, who meet in small, stuffy rooms well segregated from the life of men, the full-blooded reality of which they carefully avoid studying, and who spend their time in formulating imaginary solutions for imaginary problems. The presumption, then, is that society will get along as well without the advice of these persons as with it. Now it is true that there is a tendency for every science to become academic and cold-blooded—to manufacture a world of its own and to live in it. It is true, also, that sociologists, who profess to study human life, have less excuse than any other body of scientists whatever for such a foolish proceeding. But sociology, at the present day, is very rapidly freeing itself from the reproach for which perhaps Auguste Comte and Positivism are largely responsible. In this course we shall do our utmost to convince the reader that sociology is a living, warm-blooded thing, and is a fit and worthy object for the study of even young and vigorous folk, who take their full share in human life as we know it. We shall try to demonstrate, indeed, that these, and not those others, are the very persons whom sociology needs and who need sociology. Thus, we can hope to dispose of one of the criticisms which say, in effect, that sociology is superfluous.

"Would Sociology have Saved Rome?" But the illustration of sex relations which we have adduced will serve to meet the further criticism that sociology is superfluous on the ground that in point of fact societies have got along without it. The doctrine for which we here contend is that men have certainly "muddled through" without sociology just as they have muddled through in the past without any science; just as monkeys have muddled through, even though they are destitute of anything that we can call intellect. But we submit that the method of muddling through, which is, of course, one and the same with the method of trial and error, cannot be regarded as ideal by any sane person, and that, even though it has achieved, by a purely unreflective and unconscious process, the advance of mankind *thus far*, yet an intelligent method would have achieved infinitely more progress in the same time, and would have averted a sum of human misery which it is indeed well that our imaginations do not permit us to realise. We have chosen a notable illustration, furthermore, which shows the difference in worth between a social practice arrived at empirically—that is to say, by the method of trial and error—and the same practice arrived at scientifically. The mechanical process of natural selection, or trial and error, instituted marriage in Rome; nevertheless, Rome fell. How different would have been the result had the same institution been established, not merely by natural selection, but also by the conscious, scientific, and popular recognition of the place of marriage as a necessary foundation—*the* necessary foundation—of any stable society.

Science versus Muddle. We shall have to write many pages concerning the all-important question of Natural Selection, which pervades the whole of sociology because it pervades the whole of life. We shall have to show that its sway is absolutely omnipresent and ceaseless. Nevertheless, we can here and now justify what we have said as to the value of sociology, even on the principle of natural selection. It is true that natural selection, trial and error, "muddling through," will achieve great things if you give them unlimited time and care nothing for the appalling cost. But after morality itself, incomparably the most valuable thing which natural selection has selected and preserved is the intellect of man, which has been "evolved by and *for* converse with phenomena." This magnificent product of natural selection, enabling us to construct sociology, enabling us, for the matter of that, to make fires, build wheels and houses, sew clothes, prepare food, and so on and so on, is also one of the characters of living men over which its producer—natural selection—holds sway. Thus, of two rival societies, one of which swears by "muddling through" or by the purely mechanical method of natural selection in its social practices, while the other believes in science and in the value of principles, and recognises that the best result of the old method of "muddling through," or mechanical selection, is the emergence of the intellect, which is able utterly to transcend this method—which of these societies do you think that natural selection will select ?

History a Colossal Series of Experiments. Indeed, we may say that the chief value of the age-long method of trial and error in social matters has been the provision for the modern intellect of material from which it may infer the great sociological truths. From this point of view of a subject which may be looked at from an infinite number of points of view, we may—somewhat selfishly, perhaps—regard the whole past history of man as a colossal series of vast experiments, conducted absolutely regardless of cost and without any limitation of time.

If sociology be a science, it must be subject to the methods of the other sciences. It must begin with facts—the facts of observation and experiment. Now, you may make at a cost of a few pence a physical or a chemical experiment which may be crucial and may alter the whole aspect of your science—for instance, Galileo's experiment of dropping two balls of different weights from the leaning tower of Pisa. But the more complex your science the greater the cost of your experiment.

The Great Need of Facts. At this moment medicine could make the most gigantic advances within a few days but for the cost of the experiments that would be necessary. One would need merely half a dozen criminals, and *carte blanche,* to settle once and for all, for instance, the true relations of tuberculosis in man and in the lower animals. But the cost is too high, for it involves the lives of men and a danger to morality.

In sociology, which is immeasurably more complex than even medicine, the cost of the experiments is higher still. The question of the utility of marriage could be settled once and for all by, let us say, abolishing marriage in England for the next generation. But, obviously, the cost of such an experiment in the lives of men and women and children, the cost employed in the destruction of the race, which, after all, is still in the van of progress, would be too high. And yet, since sociology is a science, it is in need of experiment. What we should like to have is an adequate array of facts of observation and facts of experiment. From these, as in any other science, we should proceed by the process of induction to derive certain generalisations or principles or laws.

A Wonderful Thought and a Tremendous Fact. Nowadays the engineer does not build a bridge that he thinks should be strong enough, and then run a train across it and make a note in his pocket-book that the bridge cracked or did not crack. The engineer is a trained physicist. He has principles on which to work, and he knows that, under given conditions, a bridge of a given structure will be necessary. If those conditions persist, the bridge which he builds does not crack. This is evidently a highly satisfactory result of science. If, then, we were able to derive sociological principles from sociological experiment, as the physicist derives physical principles from physical experiment, then the statesman and the social reformer would be able to build sound social structures at the minimum cost in time and life, just as the engineer is able to build sound bridges without first of all constructing a dozen bridges that crack and throw trainloads of men and women into the water. If only, then, we could make the necessary experiments!

But the tremendous fact is that all the important experiments have already been made. It is one of the greatest achievements of sociology to have made this discovery.

BOOTS AND SHOES

The Evolution of Leather Footwear. Varieties of Boots and Shoes. The Materials and Tools of the Shoemaker

Group 20
LEATHER
8

Continued from page 3716

By W. S. MURPHY

EVER since mankind began to live in settled communities the shoemaker has been recognised as a craftsman whose skill was an asset of the commonwealth. The reason is plain. Men may play or hunt with naked feet, but without shoes they cannot do constant labour or endure the life of the town. Wherever there are cities, there you see some sort of foot covering. Out in the wilds of Nature, amid rocks and thorns and storms, the foot needs no covering; it adjusts itself to environment like other organs, and even develops to fine perfection in the process. Civilisation, however, brings conditions too insidious to be resisted by mere strength of muscle or vitality of blood; the dust of the street pollutes where the soil of the valley falls away innocuous; the regular tread of industry wears the feet

The first form of foot-covering was a sole fastened by thongs round the toes and the ankle. The sole is the foundation and yet remains the most important part of the boot. Climate and other circumstances determined the materials and shapes of soles in early civilisations. The bark of trees, plaited reeds, raw hides of animals, and flat pieces of wood, have been used in the making of soles. Some specimens of those early foot-covers have survived in Egypt, and are to be seen in many museums Egyptian sandals are composed of plaited straws of papyrus, and very neat the work of those ancient craftsmen is.

Beginning of the Craft. The bare sole was not a very efficient protector to the feet; sand and grit got between the foot and the sole, and made things rather uncomfortable for the wearer, so a ridge was run round the sides of the sole. This was the real beginning of the shoemaker's craft. Another step in the development of the shoe was the padding of the sandal heel. Some very ancient sandals show the heel fixed on the flat sole, and others have sides without heels. These facts prove that the Egyptian shoe was a natural development, growing up irregularly, as natural growths do. One sandal-maker would think that a heel pad was required to make the sole last longer and be more comfortable to the wearer; another sewed a protecting ridge round the heel and along the sides of the foot, to keep out sand and small stones. Perhaps for a century or two the heels and the sides were distinctive marks of two kinds of sandals worn by different classes of people. At a period in the misty regions of conjecture, the two features were combined, and a sandal that was almost a shoe evolved.

In the earliest record of human life we possess the shoe appears as a finished piece of craftsmanship, not as the production of amateur labour. Historians of the trade never fail to refer to a remarkable painting, said to date from 1495 B.C., on the walls of Thebes, in which shoemakers are depicted at work, with their tools on the space beside them. It is very remarkable that in this painting the awl, the bodkin, the wax and the thread are represented. Even at that early time the shoemaker chose and formed his tools; how well he chose, the fine efficiency of the awl bears witness.

Footwear in Olden Days. The warm climate of the East renders the higher quality of boot unnecessary. A shoe, very little in advance of that worn thousands of years ago, is still worn by Eastern nations. Slippers and even sandals are the fashion among populations which can hardly be described as either poor or barbaric. It is to the Northern peoples, who work hard and build great cities amid changes of climate too severe for the naked feet, that we must look for the evolution of the leather boot and shoe. The Greeks made shoes which came well up the sides of the feet, and were fastened by numerous thongs. But it was when the Romans began their conquests in the North that strong boots covering the whole foot came into use

For marching in the wild forests over rocky ground, the Romans devised a boot, called the *calceus*, and studded the sole with flat-headed nails. Our present-day Army boot is not far from a likeness to that boot. The Goths and Celts, whom the Romans conquered, had already evolved a kind of hide foot-covering with a sort of legging strapped on their lower limbs. Under Roman rule the Saxons, Franks, and Britons learned to make shoes, and some of the products of those ancient craftsmen show a talent quite artistic. The shoemaker became a fixed institution in all the villages of England, and when the governing powers had settled who had the strongest right to rule over the country, we find him everywhere, from the Tees to Southampton Water, plying his craft.

To the shoemaker the age of chivalry, so-called, was an era of queer boots. No more fantastic collection of footwear could be imagined than the boots and shoes of that period. Boots of steel plates, boots of chain mail, long-pointed boots, gold-mounted bell-girdled boots, boots and shoes made of leather, cloth, and all sorts of materials—every variety conceivable were made and worn.

The Evolution of the Boot. About the end of the fourteenth century, boot fashions began to evolve somewhat in the direction of rationality and uniformity, and gradually the long-legged boot, extending to the thigh, came to be the fashionable footwear for outdoors. This was the real boot; the articles we now call boots would hardly have been dignified by that name by the original bootmakers. The sea-boots worn by old-fashioned fishermen are the sole surviving specimens of the great boots. Step by step the boots were modified, and the jack boots, a refined model of which is worn by the Household Cavalry of the British Army, came into vogue. About the middle of the eighteenth century the heavy heels and strong leather tops hampering the knees went out of fashion with English gentlemen, and the form now called top-boots, and worn by postilions, footmen, and liveried coachmen, was adopted. Gay boots they were, with yellow tops and lacquered legs and fronts.

Wellingtons. The great Duke of Wellington, with his stern practical sense, ordered his boots to be made short in the leg and fit to be worn under his trousers. The great leader's idea at once caught on, and everybody adopted the Wellington boot. Up till this time knee-breeches were the dress for men; but trousers became the common vogue, and with that came a modification of boots. With trousers the long leg of the boot was unnecessary. Ladies continued through all that long period wearing shoes, sometimes with high heels, sometimes with pointed toes, at one time plain and at another extravagantly ornamented, the uppers of a variety of different materials, but always with leather for the soles.

Dress Boots. At home, in the dining-room or in the parlour, the gentlemen also wore fine shoes, of light leather, with buckles of fantastic shapes and styles. When the military and hunting professions of gentlemen ceased to be of so much importance, and peaceable pursuits brought wealth, the shoe took the place of the boot, and from about the middle of the eighteenth century on to the middle of the nineteenth the buckled shoe gradually drove the boot out of fashion. With the advent of the trousers, as we have hinted, the shoe gave place to the boot, and even on the shoe the buckle was superseded by the tie or lace latch.

Working-men's Footwear. While these changes were going on in fashionable circles, the footwear of the working classes also was altering. Large sections of the poorer people never wore boots except on Sundays, and then it was a pair of large jacks or tops handed along from one member of the family to the other, or a single pair was got by a man when he was full-grown by scraping pence together, and made to serve his lifetime. In some districts, clogs—shoes with thick wooden soles—were worn, and as money became more plentiful among artisans they sought to imitate their social superiors by patronising the shoemaker, who made them an inferior kind of buckled shoe. On the other hand, in some districts the fashion of wearing boots of a good quality never went out, because the shoemaker rose or fell in status with his fellows of the town or village.

Changes in Fashion. During the latter half of the nineteenth century successive waves of change swept over the boot trade, effecting a complete revolution, which, because gradual, was scarcely noted outside the trade itself. The Wellington, the Blucher, and other forms of long-legged boot went out of fashion, and for a time the shoe, the lacing boot, and the elastic-sided boot struggled for the market. The elastic-sided boot was a solid upper coming well above the ankle, sections of elastic cloth being let into the side to give the boot grip on the foot. By the year 1880 the battle had been decided wholly in favour of the lacing boot—that is, a boot with open front, closed over the foot by drawing a lace of leather or silk or cotton through ringed holes along the edge of the two sides of the opening, the top coming over the ankle.

Enlargement of the Boot Market. Contributory to the success of the lacing boot was the advent of boot-making machinery. Before looking at that tremendous event, however, we shall glance at the social factors which helped the change. Within the last thirty years of the nineteenth century the mass of the British people became a boot-wearing population. Previous to that time, country people seldom wore boots in the summer, and children, in the North especially, ran about barefooted till well on in the autumn. At the beginning of the twentieth century all this had changed. Except among the poorest, every man, woman, and child adopted the habit of wearing boots winter and summer, and generally had one kind of boot for each season. Industrial conditions made boots absolutely necessary. Town life further increased the need for boots—boots strong and serviceable, easily put off and on.

Customer and Shop Boots. With the increase of wealth in the country the standard of life rose all round, and the result was an increase in the demand for boots among the working class. To meet this large and not too critical mass of custom, the ready-made boot trade sprang up. For a time it seemed as though our craft was to be split in two; a great cleavage seemed imminent between what we call the bespoke and the shop trades. In the bespoke trade, the boot buyer comes in and gets his foot measured, and the boot is made up exactly to the size and shape desired; for the shop trade, the boots are made up into sizes, and the customer buys the boot of the size and pattern that fits or otherwise suits. But the cleavage has not taken place. The ready-made boots have improved in quality and gradation; the bespoke trade can be done in the factory. The handicraftsman has been almost put out of existence.

Division of Labour. Among the millions of boots worn to-day, scarcely one pair in a thousand has been made by hand; the great boot producer is the factory. The division-of-labour principle has gone through all productive industries, dividing up trades into parts, and setting separate groups of workmen to each detail. In shoemaking, the preliminary step was accomplished a good while before the factory was thought of. Very often two partners or brothers, or father and son, or husband and wife, divided the making of the boot between them — the younger or more refined taking in hand the top or upper, while the other sewed in the sole and finished the boot. It is easy to see how this could be extended and the partner become employee. The shoemaker supplies the leather, all cut, to the upper-closer, and pays him so much for the work. As his trade grows he employs another bootmaker and another topmaker, and soon the workshop grows into a factory. The cutting of the boot tops is given over to a workman, called a *clicker*, who does nothing but cut tops and linings; the linings are given to one worker, generally a woman, and the leather fronts to another; they are separately sewn, and to one worker is given the duty of putting them together or *joining*. Similarly, the laying of the insole and the sewing of the sole are separated. Then came the sewing machine.

Boot Factory. The advent of the sewing machine marked the beginning of a new order in the bootmaking trade. The handicraft had been broken up into small details, to each a separate workman or group of workmen; but as yet the whole process was carried through by hand. But by quickening production in the top department, the sewing machine set the pace for the whole factory. Bootmaking by machinery was bound to come. How it came we shall see

Making Boots by Hand. Bootmakers have been blamed for making boots that cramped the feet, deformed the toes, raised bunions, and even reduced the mental energy of the unhappy wearers. We emphatically deny that the blame for unhealthy shapes of boot can be laid wholly on the shoemaker. We are the servants of the public, and if the people have a craze for pretending to each other that their feet are more slender or smaller than they are, boots must be made according to the dictates of that craze. Many a man has lost a good customer because he has tried to resist the foolish desire for what a perverted taste calls neat feet. No shoemaker with a proper respect for his honourable craft will blindly copy the models set by ignorant fashion. He has, however, to make his living in a world where nothing is perfect, and meet, if possible, the wishes of his customers. The desire to have a neat foot and a graceful carriage is as natural and right as the love of beauty itself. Boot reformers are apt to forget that grace is also worth considering; a healthy boot need not be also an ugly boot. The three leading qualities of a boot are these: (1) It clings to the foot without cramping it; (2) it wears well in all parts; (3) it is graceful in appearance and shapely.

Structure of the Foot. The bootmaker should never forget that the foot is a living organ he is commissioned to cover. If the trade was thoroughly organised, no man would be allowed to make boots or shoes unless he had passed an examination showing that he possessed a good knowledge of the anatomy and structure of the human foot. The boot is made for the foot, not the foot for the boot. Knowledge of the foot would tend to induce a proper reverence for it. No more wonderful structure has been created. It is impossible in this work to give an exhaustive description of the foot, detailing all the bones, muscles, blood-vessels, and nerves of the organ. A standard work on anatomy must be consulted by the student.

Bony Structure. The structure of the foot is composed of 26 bones, so disposed as to form an arch, the back pillar of which is the heel bone, and the front is supported by the toe-joints. Above the heel bone is the bone called *astragalus*, which is the key bone of the foot. It fits into the bottom socket of the leg bone, puts the pressure of the body on the heel, and at the same time distributes the force forward on to the arch bones, and thence to the toes. The central arch bone, named the *scaphoid*, is connected with the heel bone by an elastic ligament, and is touching the key bone, while connected forward with the three bones from which the toes spring. The toes come out from the metatarsal bones, the large toe having two phlanges, the other toes three.

Muscles. Very important is the strong muscle extending from the inner extremity of the heel bone to the five metatarsal bones, forming a kind of tie beam to the arch of the foot, and bracing the structure together. The structure is further held and strengthened by the muscles coming down from the leg and ending on the bones which form the joints.

As we have seen, the astragalus forms with the tibia and fibula the ankle joint, the inner joint with the heel bone, and the forward joint with the arch bones in front. This gives flexibility to the foot. There are three sets of muscles of prime importance: (1) The muscles of the calf, attached above to the bones of the thigh and the leg, and below by the Achilles tendon to the heel bone; (2) muscles coming from the tibia to the main-arch bone; (3) the muscles from the fibula to the outer frontal bone of the foot. By means of these muscles the main movements of the foot are energised and controlled.

The Fitting of Boots. The other and smaller muscles, the blood-vessels and nerves, have also to be considered by the bootmaker; but detailed study must be carried on further in other ways. Enough has been shown to indicate clearly the main structure of the foot. It is obvious that respect must be had to bones, joints, and muscles here indicated by the maker of boots. To make an arch to the instep too high, pleasing to vanity as it may be, is to injure the great muscle upon which the whole grace of the foot depends; to narrow the boot across the instep is to squeeze together the lower bones of the arch and reduce the foot to the condition of a club. We insist upon it, that all those efforts after grace which limit the free play of the foot in all its parts defeat themselves.

Tools and Materials. A shoemaker's equipment [29] is not small. In these days of continual effort after improvement there have not been wanting temptations to the shoemaker to abandon the time-honoured tools of his craft for new, and perhaps handier instruments. We prefer to stick by the old range of tools, because they are the foundation of all departures, which are various. In one town or district one kind of new tool is taken, and in other places another set of improved tools are accepted.

The Bench. The two most conspicuous pieces of furniture in the shoemaker's shop are the bench and cutting-board. In construction the bench is a box 4 ft. long, 2 ft. by 2 ft. the top and inside divided into two sections. One half is covered by a padded leather seat, and the other is compartmented into boxes, in which are kept wax, tacks, sprigs, and various kinds of smallware. In the vertical division of the bench to the right of the shoemaker as he sits we find two drawers, the top one of which contains balls of flax or hemp thread, and in the lower one measures and notes on customers' boots.

Places of Tools. The division under the seat is usually occupied by tools not in immediate use, and small pieces of leather which may come in handy for packing. Along the wall behind the bench is a rack holding in leather sheaths the range of awls and knives constantly required in work. To the left is an iron table, with smooth top, and on the bars under it are several lapstones. On a rack in the middle of the floor hang over a hundred lasts of sizes ranging from the child's to the full-grown man's foot. Beside the last-rack stand thick logs of various lengths, in the top end of which are stuck what look like iron feet.

Awls. This is a general view; but we must look closer and learn the character of the tools we have to handle. Some of the awls [29, A to F] have long handles shaped for grasping; but look at the blades. They are of the finest steel, and curve curiously to the double-edged points Straight at the handle, the curve of the steel aids the thrust of the worker as he sends it through the hard leather. Other awls are straight and flat on the head; these are meant to be driven direct through the leather by the stroke of the hammer.

Punches. Next are short-bladed piercers with stout handles, for making the holes into which the sprigs or tacks are driven. Three pairs of punches, one with a needle-like point, one larger in diameter, and the third larger still, hang ready to make the holes in the boot-tops for lacing rings or ornamental patterns on the toecaps.

Setting Irons. While we think of ornament, the setting irons [29N] are to be noted—curious steel blocks, one side with edged ridge, and set in strong handles. Along with them we find what look like spur rowels stuck in handles, little wheels that impress the leather with a pattern—some a line of points, others wavy lines, and named *stitch-prickers.*

Knives. Then there are the knives, a perfect arsenal of blades. One broad piece of steel has a point curving out from the face of the blade; another, shaped like a crescent with a handle coming from the inner centre of the curve, is the skiving knife; and others of various sizes are straight, business-looking cutters. All are kept sharp as razors by the stones near at hand. The catalogue is long, but the shoemaker's tools are many. In addition to these, he has hand mittens, knee belts, waxes (yellow, brown, and white), emery-cloth, sandpaper, rasps of different degrees of sharpness and size, bristles that make needles for his threads, polishing-black bottle, and polishing shaft.

The Topmaker's Tools. Where the shoemaker has an upper or boot-top sewer in partnership with him, they hold the most of the tools in common; but the sewer has his or her bench, and a set of fine awls, fine threads, a closing clamp or board that holds the top in its jaws while the sewer works, and, in newer shops, a sewing machine for linings and light leather.

Materials. Our materials are not so numerous as the tools; but they are sufficiently varied to confuse the beginner, unless he has some warning of what to expect.

Sole Leather. Sole leather is thick, hard, heavy, and very stiff. It comes to us in hides, and may vary a good deal in weight and quality. Before the clever chemists came to teach the tanner how to play upon the hides, it was comparatively easy to tell the different qualities. The best qualities had a buff colour, and could be worked to the hardness of iron without fear; the lower qualities tended to red in colour, and kept soft in spite of all the hammering in the world. Leather may now be of perfect colour, and send flakes and splinters from under the beater before the sole has been shaped; red leather may turn out quite good.

Tests. Adulteration of leather has been very common of late years, weighting of the hide with glucose or sulphate of baryta, a kind of earth, being the most frequent For discovering the latter, you have only to draw your knife sharply through the edge of the leather and the earth will rasp on the edge like sandstone. Glucose can be detected by laying two pieces of the leather in a damp cloth and leaving them overnight. If the pieces are sticking together with a soft, syrupy substance between them, glucose is present. There are other ways of faking leather, but if you buy from a good tanner, and there are many, you are sure to get a fair quality for a fair price.

Top Leather. Next in importance is the stock of top leathers. These vary in thickness from the heavy hide for making the uppers of stout working boots, boots for hunting, deer-stalking, mountaineering, and the like, down to light calfskins or glacé kids, for fancy boots or ladies' wear. Then there are a good many patterns — plain, grained, pebble - grained, diamond-grained, or pigskin-grained [see plate facing 3217]. Patent leathers—morocco, russia, and roans—have to be stocked for fine edgings of high-class boots and shoes, toecaps, or fronts of ladies' slippers. Going on from heavy to light, we come to wash leathers, split sheep, calf and goat skins, for linings and bindings. Light pieces of hide called offal by the tanner are needed for insoles and packing.

Fine Leather. Experience alone can teach a man how to be independent of the honesty of the leather merchant in dealing with those top, fine, and fancy leathers. Of course, he must learn, and that very quickly, to tell the difference between a pebble-grain and a box-grain, or a roan and a russia leather; but that is not a difficult matter to an intelligent person.

Various Materials. The independent shoemaker has to stock a good deal of ironmongery and drapery, which must be judiciously and carefully stored. Linings of cotton, linen, canvas, felt, and cloth, straps of mohair, flax, and cotton; soles of felt, cork, canvas, and pasteboard fill up a good many shelves and drawers. Wood pegs, brass and iron rivets, sprigs, sparables, hobs, heel-plates, toe-plates, boot-protectors, rubber heel-plates, eyelets, buttons, and patent fasteners of many kinds—all these fill up the drawers and stock boxes of our workshop, and absorb a lot of capital.

Our inventory of bootmaking materials is general; there are many things used by specialists we have barely noticed. The things enumerated are common to the whole trade, and should be known to every craftsman. We hold strongly to the opinion that the beginner ought to be taken through the stock-room and shown every tool and material of his craft, with explanations of their uses. This is the main intention of the present section of our course.

CYCLOPÆDIA OF SHOPKEEPING

MOTOR-CAR DEALERS. Prospects of the Business. The Garage and its Requirements. Prices and Profits. Motor-car Repairs

MUSICAL INSTRUMENT DEALERS. Training. The Importance of Tuning. Buying and Selling. The Hire-purchase System

MOTOR-CAR DEALERS.

The time when the selling of motor-cars can fairly be included under the term shopkeeping has not yet arrived, but something of the possibilities of the business may be discussed, if only in the light of intelligent anticipation. The difficulty does not lie in the actual selling, but in the circumstances attending the newest of our industries. The fact is that the manufacturers of motor-cars are not anxious to enlist the services of the middle-man at present. The public is in no mood to purchase otherwise than direct from the manufacturers, or, if the car be of Continental make, from the first-hand agent in this country, or of the importing firms.

Cycles and Tricars. This statement, however, hardly applies to tricars, and certainly not to motor cycles. The latter have already been reduced in price to reasonable figures—there are now good machines to be retailed at about £30—and many agents have done well by investing in a single machine, by riding and showing which they have been able to dispose of others in large enough numbers to make a success of the business. A good many riders prefer to buy a machine which has been "tuned up," and it is certainly a promising risk to buy a motor cycle on the chance of disposing of it in due course. Practically this way of doing the business is the only likely one at present.

Motor cycles and the profits which they carry are discussed on page 2094. The profits on motor-cars are not as satisfactory upon a percentage basis as are those of the motor cycle. On tricars, which are made by cycle manufacturing firms, the inducement is fairly good, being up to £25 profit per car, and occasionally more, but on the heavier vehicles the prospect is less enticing. Ten per cent. commission, and sometimes 15 per cent., is as much as motor-car manufacturers will allow to the agent. If business can be done without holding stock, and if the customer pays cash, orders are, however, well worth seeking.

There are good profits on accessories, some of which are subject to 30 per cent. or more discount.

Small Cars. The three-wheeler, or tricar, holds the field at present, but sooner or later it seems destined to be displaced by the car on four wheels. At from £65 to £105 the tricar is dear, and in the matter of maintenance is not so economical as a four-wheeled vehicle. Already there are a few of the latter type to carry two persons purchasable at or about £100, and it is safe to predict that five years hence buyers will find a choice between half a score at or below that figure. When that time comes the agent in a small way will get his chance. With more competition the makers will be keener to have his co-operation.

The present system of deferred payments will be modified so as to enable agents to profit by introduced sales. As things go now, commission on deferred sales is rather grudgingly accorded because they are rare; for, as we have seen, the buyer goes direct to the maker.

Prospects. At present high-power cars are very expensive, and, indeed, unreasonably so compared with other work involving the same class of workmanship and similar materials. The makers, of course, have a good case in the argument that the initial expenses have been enormous, and therefore that the whole of these high profits must be secured to themselves at present. Later on this cry will no longer be tenable, and then all will be altered—motor-driven vehicles will be designed for the lightest classes of business, and a big industry on sound business lines will be developed. This will displace the present necessary but not altogether desirable system, which has opened the door for a whole round of commissions to the friends of buyers, who are not always disinterested in tendering advice. Moreover, as things stand, "oiling" the drivers is alleged to be inevitable, and thus the agent is not unnaturally a little shy of the whole business, which, under any conditions, involves the investment of considerable capital.

The Garage. Still, something can be done. As we have already shown, business is possible in small cars and motor cycles, and there are openings in many towns for the starting of garages where cars can be stored, accumulators charged, repairs undertaken and accessories retailed. Of course, in every such establishment motor spirit and suitable lubricating oils must be stocked, and although the profits on these are low, and the conditions under which the former is stocked are somewhat onerous, these commodities bring other business, and cannot be ignored.

The first provision of a garage is an inspection-pit, which must be brick-lined. The best dimensions for this are 42 in. width and 54 in. depth. The length of the pit depends on the building, but it should be not less than 6 ft. The brickwork round the top edge should be rebated, to afford a 2 in. bearing for a 1½ in. wood cover. If expense be not a serious item, steps at one end are well worth including in the scheme, and drainage of some sort will be necessary. If there happen to be any difficulty about making connection with a drain, as might be the case in a country district, a hole 3 ft. deep at one corner, half-filled with shingle and coke, and covered with an iron cover, may answer, although obviously such a plan will involve periodical cleansing and renewals of the coke, etc.

Garage Equipment. The usual precaution of not having a naked light in the motor-house must be stringently observed in respect to the pit. If the electric light is not available, only a Davy lamp should be permitted in the place.

The agent who undertakes repairs and does them in his garage will have to face the problem of heating the building in winter. The ideal plan is to sink a small boiler-house or lean-to outside the main building, and to install pipes or radiators inside the garage. The absolute necessity of some such provision will be appreciated after a sudden drop in the temperature during the night, resulting in a cracked water-jacket in a customer's car.

Another special apparatus necessary will be the vulcaniser. This device for repairing cuts and bad places in the tyres will cost the agent from £3 upwards. There are several patterns on the market. Most of them depend for heat upon steam, generated by a gas jet, or a blow lamp; but in one at least the heated surface is derived from iron blocks which can be made hot in a forge.

The third essential feature in the agent's garage will be the provision of means of re-charging accumulators for customers. The agent who can command the use of current from electric mains will do so. The cost in that case will not be serious, for a charging board is not an expensive affair. If the district is outside the area of any of the electric supply companies, a primary battery and resistance board will have to be installed.

Repairs. The would-be dealer in cars and motor cycles must cultivate the repairing business. First, if he be a fitter or mechanic he might get employment in a garage, where he would have opportunities of learning something of the mechanism of various cars. With the knowledge thus acquired, and if he can command the use of £100 or £200, he can take premises, build his own pit, put down a lathe, grinding machine, drill, electric charging and vulcanising plant. There is available to the man who wishes to perfect himself in the knowledge of motor-car details a considerable volume of literature which is by no means expensive. Mr. Worby Beaumont's book on the subject is, of course, the classic, but as it costs about two guineas it will not be within the reach of the individuals we have in mind. However, from the list which follows he will be able to select suitable and helpful books. Mr. Douglas Leechman's "Autocar Handbook" (215 pp., 102 illustrations), costing only 1s. 6d., contains plenty of elementary information about the motor, and something about the châssis and gears. It is published by Iliffe & Sons, Ltd., of Coventry and 20, Tudor Street, E.C., which company also publishes a capital handbook on "Motor-Car Repairs," at 2s. 6d., and a third publication, "Useful Hints and Tips for Automobilists." The last is a collection of more than 500 hints reprinted from "The Autocar," which is the leading weekly (3d.) connected with the sport and industry. A more expensive book is W. Poynter Adams's "Motor-Car Mechanism and Management" (174 pp., 22 diagrams). Only one part, dealing with the petrol car, has been issued up to the present, but others, treating of the electrical car and the steam carriage are promised. Each part costs 5s., C. Griffin & Co. being the publishers. On the very intricate subject of ignition, the Cycle Trade Publishing Co. have published T. H. Hawley's "Motor Ignition Appliances" (137 pp., 43 drawings). It is an exasperating book to read, owing to the long and involved sentences affected by the author, who, however, covers the ground well, and gives the purchaser a generous half-crown's worth.

Finally, we may mention "Petrol Motors and Motor-Cars," by T. Hyler White (187 pp., 44 diagrams). Longmans, Green & Co. publish this at 4s. 6d., and it may best be described as the handbook of the designer and draughtsman. The principles underlying construction, with the formulæ for determining the correct proportion of the engine details, brakes, transmission gear, etc., are discussed in this eminently practical volume.

With a moderate capital, some experience, and a determination to master the principles upon which a car works, a start could be made which might be expected to provide a moderate living at once, and to furnish the basis on which to build up a successful business in the near future. What we wish to point out is that the practical man has a better chance of making a success than his fellow who has been engaged only in buying and selling, and whose early training has been along commercial, rather than mechanical lines.

MUSICAL INSTRUMENT DEALERS

Under this heading is comprised the shopkeeper who deals not only in musical instruments and their accessories, but also in sheet music.

Many a now profitable music business has originated in a private house. The reason for this is that the first essential for success in this special sphere of commercial activity is a practical knowledge of the business. The second desideratum is care in bookkeeping. A good accountant has often succeeded where the purely practical man has become bankrupt. In Great Britain a beginner with small capital should avoid attempting to startle his neighbourhood at the outset. The tyro has not much choice as regards a site if he purchases the connection and goodwill of a going concern.

Apprenticeship. There is no type of business misunderstood more often than is that of the music-dealer. If a young man, or a young woman, show musical aptitude nowadays, and be a failure in a professional sense, he or she is considered qualified to open a music-shop. Such establishments are soon closed. The best recipe against shipwreck is to be the son of a successful music-dealer and to have profited by his experiences. But, for those unable to select the occupation of their parents, the best way to ensure success is to have the training of a piano-tuner and be possessed of good credentials from a firm of standing. In old-established London factories to-day lads are indentured as apprentices for tuning at the age of fourteen. The apprenticeship period lasts from five to seven years. The usual procedure is for a lad to go to a recognised firm and offer his services in return for tuition in piano-tuning. In some factories a small remuneration is offered to the apprentices, but in the majority of cases the beginner works for no pecuniary reward. An apprenticeship in a piano factory is desirable for learning piano-tuning properly, not so much because the lad gets to know the internal mechanism of different types of pianos but he has constant practice in actual tuning all the time. Some historic makers charge premiums for apprentices, and if the youth's parents can afford it, the expense is justified by the experience gained.

Assistantship. Apprenticeship over, the next step for the youth is to get a position in a retail music shop as an improver. There (where probably he will be paid £1 a week) he will have old pianos as well as new ones to tune, and he will learn from the old instruments many matters he has no opportunity of discovering at the factory. Moreover, he gains experience of retail business methods, and after two years should be competent to serve as what is known as an "outdoor tuner." When such skill is attained, the next move is to get the employer to send him out to tune the pianos of customers. It is understood that the shop selected for the improver is one in which not only pianos but musical instruments of all kinds are sold, and sheet music as well, so that, while advancing in piano-tuning—which, after all, is the main thing—he is also learning other necessary departments.

The prices and profits secured for and by the sale of all kinds of instruments, sheet music, and musical adjuncts, and the general principles of business have to be diligently acquired during this period. To excel as a tuner it is not necessary to be what is known as musical. Some of the best tuners are not pianists. There is no greater mistake than to imagine that the child with a good "ear for music" will make a successful tuner. An apprentice who is ambitious, nevertheless, will always learn sufficient of the art to enable him to play with facility arpeggios and chords so as to "try" the tone of any instrument.

Opening a Shop. Before deciding to start in the music business, it is very advisable to have a tuning connection as a basis. This is an important point, for experience has proved that man cannot live by music selling alone. Practical men who have gone through the mill know that the beginner should have a connection of at least 300 tunings per annum, and one-third of that number should be regular contract tunings. The usual charge for tuning a piano is 3s. 6d., and five pianos per day is an average day's work.

Although, in the music trade, connection is of greater value than mere advertisement, the latter should not be altogether neglected. One prominent music-dealer whom we have in mind advertised in a manner which gave the maximum result at a minimum cost. All he inserted in the local newspaper was, the first week, "Wanted, 1,000 pianos to tune." Then followed his name and address. Next week the wording was changed to "Wanted, 995 pianos to tune." The figures gradually diminished in this way, and the impression given was that the newcomer had succeeded in getting considerable business.

The Window. One of the cheapest advertisements for the music-dealer is to have his shop-front dressed as attractively as possible. In quiet country towns the magnetic qualities of a well-arranged window are much undervalued. It is a mistake to show the same goods continually. The windows should be kept scrupulously clean and not overcrowded. Effective displays need not entail expense. The most useful class of passers-by can be attracted by photographs of musical celebrities. For violins or brass instruments, a plush curtain forms a good background. Musical accessories, such as gramophones, metronomes, and glass insulators for the piano, can be grouped artistically. Frontispieces of new music are supplied by publishers for window display so as not to soil the music sold. But such title-pages should be always up to date. It is seldom that a beginner in the music trade has room to show pianos in his window. Should he be fortunate in this respect, care should be taken to have a blind ready to be lowered so as to secure temporary privacy when the instrument is tried.

Advertising Materials. The retailer should take full advantage of all help in advertising he can get from the makers of instruments he particularly represents. Some firms of enterprise are generous in this respect by (1) supplying well-framed and artistic showcards; (2) defraying the cost of decorating the window with enamelled letters and coats of arms illustrative of Royal appointments they hold—but in this case there must not be too much display of lettering on the front of the shop; (3) supplying music wrappers with appropriate advertisements; (4) and various stationery, such as letter paper and bill-heads bearing the dealer's address as well as an advertisement of the particular agency. Intelligent use of all such matter effects not only a considerable saving annually for the beginner, but stimulates business.

The Shop and Fittings. The foundation for the stock required in a music shop is often laid by the wide-awake young tuner while living at home. In the course of his vocation he has the opportunity to acquire cheaply second-hand pianos from customers who wish, for a variety of reasons, to dispose of them. In the course of a year or two he may thus become the owner of several pianos, which he can keep in his private house until he finds it desirable to start a shop. The neighbourhood should be carefully selected, and should be as near as possible to the centre of the district where his tuning connection lies. The shop must of necessity be fairly good, well decorated and attractive. The fittings required are merely the usual counter, one or two glass cases, and lettered cardboard portfolios for music, all of which should cost not more than £10.

Stock. Owing to unchecked piracy in sheet music, there is at present no profit in it in Great Britain. Yet it is useful in keeping together a connection, or for attracting fresh customers. The typical music-shop is stocked with medium-priced and cheap pianos, American organs, self-players and phonographs, violins, mandolines, and other stringed instruments, military wind instruments, besides the "cheap lines," such as melodeons, whistles, mouth-organs, fiddle-strings, and various accessories. There is no need, at first, to tie up capital by keeping all such goods in stock. Pianos, and, in fact, nearly all musical instruments, may be obtained from the wholesale houses or factories on sale or return. They seldom need to be paid for until actually sold. Of course, if the beginner has a capital of £100 or £200 to expend, it is advisable to pay for as much of his stock as he can, so that he may be independent of trade creditors. With a few second-hand pianos acquired before starting, the beginner has already a show. He may then order half a dozen new pianos of various prices, and two American organs on approval. Then he can order, in the same way, or paying cash for the "small goods," three or four violins and three or four mandolines, and a judicious selection of accordeons, concertinas, autoharps, flageolets, whistles, mouth organs, jaws harps, music desks, fiddle and mandoline strings and fittings. A sum of £20 should suffice to make a good display and give a varied stock of these goods. Another £20 would be expended on sheet music, carefully selected and varied to suit all tastes. The selection or particular kind of stock necessary can be gauged only by carefully anticipating the needs of the neighbourhood, and it is here that the judgment and foresight of the beginner must be intelligently exercised. The large houses issue well-illustrated and comprehensive catalogues showing exactly every detail of articles wanted. The scope in small merchandise should not be overlooked by a beginner, as it is often relatively more profitable than the high-class trade.

Sole Agencies. To prevent underselling, manufacturers of standing, with but few exceptions, nowadays appoint a sole agent for each district or town. He has the right to arrange sub-agencies. But there is little profit derivable from a secondary appointment. The beginner will have no difficulty in ascertaining the names of the sole agencies held by established rivals in his locality. There are so many makers of repute that it should be easy to add another name to the list. A glance at the advertisements in the "Music Trades Review" or the "Musical Opinion" will enable the new-comer to approach those houses most likely to be useful to him. It is desirable to acquire the sole right to sell, within his town and the area covered by his tuning connection, one high-class make of piano and one medium class. At the annual Music Trades' Exhibition, if he has an opportunity of visiting London, he will be able to arrange for a cheap line and be sure of getting value for his money. The point is to see that such instruments stand in tune. Touch and tone-quality are secondary considerations, although they rank first with high-class makes. On the choice of the cheap line will most likely depend the success or failure of the new business. To every expensive instrument sold, probably a dozen cheap pianos will be disposed of. As the price is cut as finely as possible, and such instruments may be obtained wholesale from £10 apiece, the dealer is expected to pay promptly for them.

Hire System. When instruments are sold retail on the instalment plan, the profit on them furnishes the dealer's main source of income. But if this capital be small, the rock on which the practical man usually comes to grief is selling too many instruments on the hire system. Sometimes, even in cheap lines, manufacturers, eager to do trade, hold out the inducement of extended credit, and accept bills. When such bills become due, it is difficult to renew them. To give acceptance for goods received is always dangerous. Unable to find the necessary money, owing to the pianos received having been sent out on the hire-purchase system, the dealer is at the mercy of his wholesale "friends." He is fortunate if they take over his business, retaining him as manager. In that case, he will get a small salary and a commission on sales, so that, however hard he may work, a third party, unknown to his neighbourhood, pockets the harvest which should otherwise have been his. Many prosperous music-dealers owe their financial success to observance of the rule never to sign a bill.

Making a Connection. As regards the medium and high-class makes, these give the new business its reputation and furnish the connection with its best customers. Whenever an instrument of 50 guineas or upwards is sold, the dealer will have little trouble in arranging to tune the instrument periodically by yearly contract. According to the distance, so the price for four quarterly visits ranges from 12s. to 42s. per annum, a reduction being made for a second piano in the same house; and the tuner, after he has done his work, gets the contract-card signed, as a proof that the instrument has been duly attended. This is valuable to refer to when disputes arise after Christmas, before bills are paid. The new-comer will find that two sole agencies are sufficient for him. He should concentrate his energies on selling those instruments, but, before doing so, should be careful that the agreement he enters into with makers is so worded that, directly a demand is created, the agency may not be taken away from him and put into other hands.

Commissions. It is in the sale of the higher class instruments that the question of commission arises. The music teacher, who has been the means of bringing an order for a piano to the dealer, naturally expects to be reimbursed for the time and trouble he has taken in the matter. But since the London Co-operative Stores, by giving wholesale orders, have been able to buy in bulk at dealers' prices, and have sold musical instruments to the public for cash, on terms formerly reserved for members of the musical profession, profits on cash transactions have greatly diminished. As the amateur purchaser receives stores prices, the margin left is nominal. Yet the intermediary is not likely to go out of his way to influence business if he does not receive back his expenses. What the Law, in recent enactments regarding secret commissions, stipulates is that an intermediary may act either on behalf of the seller or on behalf of the buyer, but he cannot represent both parties. Obviously, the music teacher, when he chooses a piano, and stands sponsor for it, endeavours to select the best instrument he can to help on the studies of his pupil. Therefore, as he is acting on behalf of the purchaser rather than the seller, it is becoming the rule of the professor to tell the parents the professional price, and add to it a reasonable fee for his services in that matter. Under such circumstances, no subsequent claim is made on the dealer.

Three Years' Agreement. Before supplying any musical instrument on the system of hire-purchase extending over one, two, or three years, the dealer should be careful to get a legal form signed and witnessed. It should bear a sixpenny stamp, fully describing the piano or organ supplied, and state the amount of the instalments and the dates when they become due. But the main object of the document is to make clear that until the instrument is paid for it remains the property of the dealer, and cannot be distrained for rent by a landlord, and that, in the event of its being destroyed by fire, the hirer agrees to continue to repay its value. In the event of the instalments falling into arrears, the owner also has the right to recover the instrument. Legally-worded forms are obtainable from the office of the "Music Trades Review." In exceptional cases, dealers have been unduly hard in resuming possession of a piano when almost all the instalments have been met. Sharp practice of that kind is, however, rare. It does not pay. What does pay is to hire out instruments on this system to customers whose instalments are received punctually, so that the dealer can not only meet his obligations to the manufacturer, but give the latter fresh orders. Care, therefore, should be exercised, in the first instance, to insure that the customer is honest, and a couple of references should be required.

Exchanges. Naturally, the first endeavour of the music dealer must be not only to supply what is wanted, but to make each transaction yield a profit. This is a difficult matter when orders for new instruments involve taking back old ones. People attached to old pianos fail to understand that modern improvements have rendered them out of date and commercially worthless. The outside may be "as good as new," and the original cost £150, but the twenty-year old grand is probably not worth £5. Nevertheless, the dealer may be obliged to offer £10, and his only way to dispose of it will probably be to get a traveller to take it off his hands, at the best price possible, conditionally on his giving the latter an order.

Ordering Music. Travellers' terms for music are more tempting than those offered by the publisher direct. The latter, when he brings out a new song or piano piece which he believes will become popular, speculates by printing a considerable number, and offers exceptionally liberal terms through his traveller to induce the dealer to share the risk with him. But the beginner cannot take risks. His music shelves, bearing the words "Songs," "Dance Music," "Piano Solos," "Piano Duets," etc., are mostly often dummies. It would not pay him to keep in stock the entire repertoire of the average professional or amateur musician. Instead, he orders single pieces of music by post direct from London through some friendly publisher who acts as collector for him. Some dealers make up such a list of music wanted twice a week on order sheets. In any case, a music-dealer should never depute an underling, however honest he or she may be, to give orders to travellers. A case occurred a few years since where a lady assistant was entrusted to order sheet music from samples. Instead of distributing such orders impartially to the different representatives who called, she put all her eggs gradually into one basket. The result was that when, at the end of the year, the proprietor came to take stock, he found his shelves loaded with ephemeral songs and dance music bearing the same imprint and worth the price of wastepaper. A golden rule is always to have the hands clean when showing sheet music. Once soiled, it becomes unsaleable. If possible, it should be put away into its case, if not wanted, before the customer leaves the shop. If there is small profit on sheet music, a better investment is to be found in albums of standard songs, pianoforte sonatas and oratorios. These do not spoil by keeping, nor get out of date like comic songs, ballads, and dance music. Some houses have an ingenious plan of furnishing entire libraries of classical music, indispensable to teachers, on favourable terms, provided that such stock is insured against fire or other damage, and the music-seller immediately orders a fresh piece to supply any piece sold.

Looking after the Shop. Better have no shop at all than not look after it properly. To many a beginner in the music trade, how to be in two places at once is a troublesome problem. His main source of income may depend, at first, on his tuning connection. That cannot be neglected. Prospective purchasers have to be waited upon at their residences with catalogues, etc. During such visits, a customer, who should receive special attention, may call at the shop.

It is here that the intelligent co-operation of a sister or wife has often been the making of a young man. Ladies have more patience with callers whose visits are unprofitable. It is unnecessary to have served a long tuning apprenticeship to be able to waste half a day exchanging sheet music or selling fiddle strings. Yet this has to be done. The young dealer should arrange his work so as to be in charge of the shop on such days which are busiest in the week. In country towns, this is generally when market is held and people make their purchases for the ensuing week. It is suicidal, however, for the beginner to neglect his tuning connection for the sake of the shop. If he is not in the happy position of having a wife or a sister to look after the place in his absence, he should engage an alert lady assistant at a cost of 15s. to £1 a week. Some tuners teach piano playing, and it may possibly pay to engage a lady teacher to play and teach in the shop, looking after the retail business in the meanwhile. The fee usually paid to a professional in such a case would be £1 a week with a commission on the teaching.

Repairs. The practical tuner, on his rounds, frequently has to attend to minor repairs. A keyboard instrument, unlike a violin—although that often requires seeing to—has much mechanism which wears out after a certain time. To repair a piano thoroughly, the shop must be provided with an apartment containing a bench, a hammer-covering machine, and other appliances. To fetch the instruments, a van will have to be hired, or, if that is not obtainable, a cart, should it have no springs, must be lined with straw. The repairs will probably occupy two months, and another instrument has to be supplied meanwhile, its use being included in the estimate given. For re-covering hammers, the usual charge is from £3 to £5, while a thorough repair, according to the work necessary, may be from £10 to £30. Where the workshop is not fully equipped, it is best for the dealer to send the number and other particulars to the maker, get an estimate, and then forward the instrument to headquarters. It is advisable at first to send as many of the small repairs as possible to a factory, for such work must be completed without delay, and the tuner's time can be better employed.

Taking Stock. The practice of shutting up during the afternoon on the now customary "Early Closing day" gives the beginner a weekly opportunty to make up his books, attend to repairs and other matters of importance without being interrupted by visitors. A man who has been trained as a practical tuner and not as a clerk often finds the clerical work irksome at first, but if he does not master the rudiments of bookkeeping he cannot hope to be successful financially. A good check on each day's takings is an automatic cash register. All items should be entered in a day book and transferred into a ledger. A diary, in which is recorded the dates of tuning visits due, should always be kept up, and customers informed by postcard before each visit. But a very important matter is not to neglect taking stock. This should be done once a month, and most carefully at the end of the year. It may involve considerable work to go through a quantity of sheet music and musical accessories which have accumulated. It is better to sacrifice profit and get rid of them, because a "sale" may attract new customers, and space is always of value. The main point is that the dealer should balance up his books periodically so that he may know how he stands financially, and reduce expenses in certain ways if he finds his liabilities increase unduly.

Aids to Business. The tuner who is also a good musician may perhaps increase his success in the neighbourhood by organising at-homes, concerts, and so forth, and by playing in private houses. The usual fee for such service is from 10s. 6d. to £1 1s. per night, but it is fatiguing work, and ruinous to health if kept up for any length of time. Although a matter of £20 to £30 a year extra may be made in this manner, and it may be helpful as an advertisement in the district, it should be discontinued as soon as possible.

Hiring out pianos to concert halls and to parties is another way of making an additional income, and an able man is always ready to supply orchestras, etc., for evening parties, all of which should bring profit in the way of commissions. But these things are subsidiary to tuning, which should be sedulously nurtured.

The Question of Profits. The average percentage of profit on the sale of music is a small one. It must not be forgotten that the articles sold are, in a sense, luxuries, unlike the necessities of life supplied by a grocer, butcher, or similar shopkeeper. The average of profit on the direct turnover should actually realise from 30 per cent. to 40 per cent. Sheet music of the cheaper sort bears a big profit usually —a sixpenny song will cost less than threepence —but the higher-priced music, that marked 4s., but actually selling at 1s. 4d., costs about 1s 2d. wholesale, and sometimes more. There is therefore no profit in selling the dearer music under present conditions; but there is a big future for cheap music, provided the cutting of price is effectually prevented. It is not only that the depredations of the "music pirates" are to be deplored, but that the suicidal undercutting of prices between one dealer and another in the trade prevents a living profit being obtained for everyone. The music trade has its possibilities for the intelligent dealer, and particularly for the careful, efficient and well-trained tuner. There are so many imperfectly-trained and incompetent "tuners" at work that the energies of competent and careful men, if properly directed, reap a rich reward.

ENGINEERS' COPPERSMITHING

Brazing Materials and Practice. Copper Pipes and Spheres. Templets, Bends, Tees, Branches, Joints, and Flanges

By JOSEPH G. HORNER

ENGINEERS' coppersmithing is a special branch of work done by men who have usually been trained in engineers' works, and have therefore had no experience as braziers or artisans in cooking utensils. It includes the work of the marine and locomotive shops, of brewing utensils, sugar-pans, and some pump parts. The principal kinds of articles treated are pipes, bends, tees, with their flanges or other fittings, steam-dome coverings, safety-valve covers, coppers, pans, etc. The shops are larger than those of the ordinary brazier's, and the appliances are larger, and some are of a special character. The work of the engineers' coppersmith has been invaded in one direction by the manufacture of seamless pipes and tubes, and by those that are produced electrolytically—developments due to the risks of using brazed pipes for the high steam pressures now common. Much bending of pipes is also done by means of rollers instead of by hand.

The Shop. The engineers' coppersmiths' shop is, as a rule, larger than that of the ordinary brazier's, because the mass of work done is larger. It is also more lofty, so as to permit of the handling of pipes, which form the largest section of the work done. The pipes and other articles are hung from a hook on one end of a chain, which runs over a pulley suspended from another pulley, or *traveller*, that runs along a rail below the roof. There are hooks in the walls, to which the free end of the chain is attached when work is slung over the forge fires for brazing. The shop also contains a mandrel-block [325], with holes to receive numerous mandrels for bending pipes and other articles on; also a bending-block [331], a floor-block [326], with holes for various stakes; forges; vice-benches with drawers; pits, 5ft or 6 ft. deep to receive pipes, and having a blast-pipe for brazing; fires for melting resin and lead for pipe filling; trestles for carrying work upon, and some other common appliances; and a stock of tools, as stakes, hammers, cods; also bins for coke, boxes of spelter solder, borax, etc.

Pipe Work. Straight copper piping is now seldom made by bending and brazing, but the same methods are often employed in other work, and in odd sizes and shapes of pipe. Bending is done round mandrels, and the joints are made either by thinning or cramping [327]. Thinning alone is suitable for heavy material, but cramping is nearly invariably necessary with the lighter, because it strengthens the joint materially. Notches are cut along one edge at a bevel, at intervals of from about 1 in. to 3 in., dependent on the size of the work, and the metal is bent to right and left alternately. The other edge is thinned and inserted between the cramp, as shown to the left in 327, so that alternate cramps come on opposite faces of the thinned edge. The pipe is bound with wire [328], and the joint closed with a mallet or hammer round a mandrel. It is then *chattered*, or *jarred*, to cause the parts to open slightly, so as to permit of the spelter solder flowing between the adjacent overlapping portions.

Brazing Materials. The methods of brazing are all essentially alike in principle, but details differ with the character of the work. Sometimes the borax and spelter are charged separately, but it is better to mix them in equal proportions with water, and preferably a day or two before use. The mixture must be laid evenly along the joint, and the pipe or other article placed in a clear coke fire, of which the temperature is regulated until the borax fuses and *drops*, and the spelter begins to melt and run, as indicated by the blue fumes of the zinc. It may be necessary to add more borax finely powdered, and the pipe may be tapped lightly to assist the running of the solder in the joint. Spelter solders are composed of various alloys of copper and zinc. The strongest, for copper, comprises 3 of copper and 1 of zinc. A weaker is 16 of copper to 12 of zinc. Another is 8 parts of brass tubes to 1 of zinc, and for brazing brass, 1 of copper to 1 of zinc. Joints to be brazed are cleaned by covering the parts with a strong brine made of salt and water, then heating to a cherry red, and quenching in clear water—which also has the effect of annealing the copper—followed by scouring with clean water and sand applied with a wad of tow.

Brazing Practice. A piece of pipe must be laid horizontally for a seam joint, and if the joint be long, runners should be provided on stands outside the forge to allow of ready and easy movement of the pipe through the fire. If joints have to be made in pipe lengths, they must be suspended vertically, and the joints are those suitable for pipe, being either flush [329] or socketed [330]. The first retains the external diameter, but reduces the bore; the second retains the bore, but enlarges the external diameter. A flange, A, is laid off on the socketed portion to retain the solder and to prevent it from running away outside the pipe. This is filed off subsequently. Such joints are made either by soldering or by hard brazing. If the former, both internal and external pipes must be tinned. Heat is applied to the pipes for soldering and brazing by means of fire-pots. In small pipes sufficient heat may be obtained by a pair of red-hot tongs. Large pipes may be soft-soldered by hanging a pot of burning charcoal inside. But in other cases a fire-pot encircles the pipe, and the latter is held with screw clamps in suspension within the pot, the height being

adjusted with one of the sling chains, to which a weight is added on the slack side to counterbalance the weight of the pipe, or the chain may be fastened to the wall. The fire-box rests upon a clamp which is made to grip the pipe. It is filled with charcoal and coke broken small, and is fitted with a blast-pipe and holes arranged round an annular ring, much resembling the arrangement in the annular wind-chest of a cupola furnace. Care must be taken that the solder does not run away at the bottom of the joint. Lampblack and gold size may be rubbed round the bottom, or moist clay. Or, if the joint be tinned, the tinning must stop short of the end. As soon as the spelter has run, it is skimmed off flush with the top of the socket, and salt is strewn on to kill the borax, which would otherwise leave a hard surface to interfere with subsequent filing.

Pipe Bending. There is a good deal of pipe bending done. In the absence of special machines, simple leverage is the method adopted, and a *bending-block* [**331**, A] is fixed in the floor of the shop for the purpose. It is of cast iron, about 14 in. or 15 in. square, and pipes up to 5 in. can be bent on it by hand. It is shouldered, or rebated, round the top to receive an iron strap, B, by which a *lead piece*, C, is secured on the block. This lead piece has a hole to take the pipe to be bent without bruising it. The leverage is taken against a back plate, D, that fits by pins edgewise on the bending block. When the lead piece is not used, a pin, E, is dropped into a hole on the top of the block, and the pull taken between this and the back plate. The pipe is pulled round by a lever, F, secured thereto with a loop of rope or a copper band. Bruising is prevented by packings of lead or soft wood at all localities where pressure is made against the pipe.

Two preliminaries are essential to bending pipes and tubes—filling the pipe with lead or resin to prevent puckering, and annealing the part to be bent, the remainder to be left hard. For small curves, soft lead is better; for long ones, resin. The straight part is not filled, but the progress of the lead or resin is arrested where required by rolling up a hard ball of paper and thrusting it in. The lead or resin are melted out subsequently to the bending.

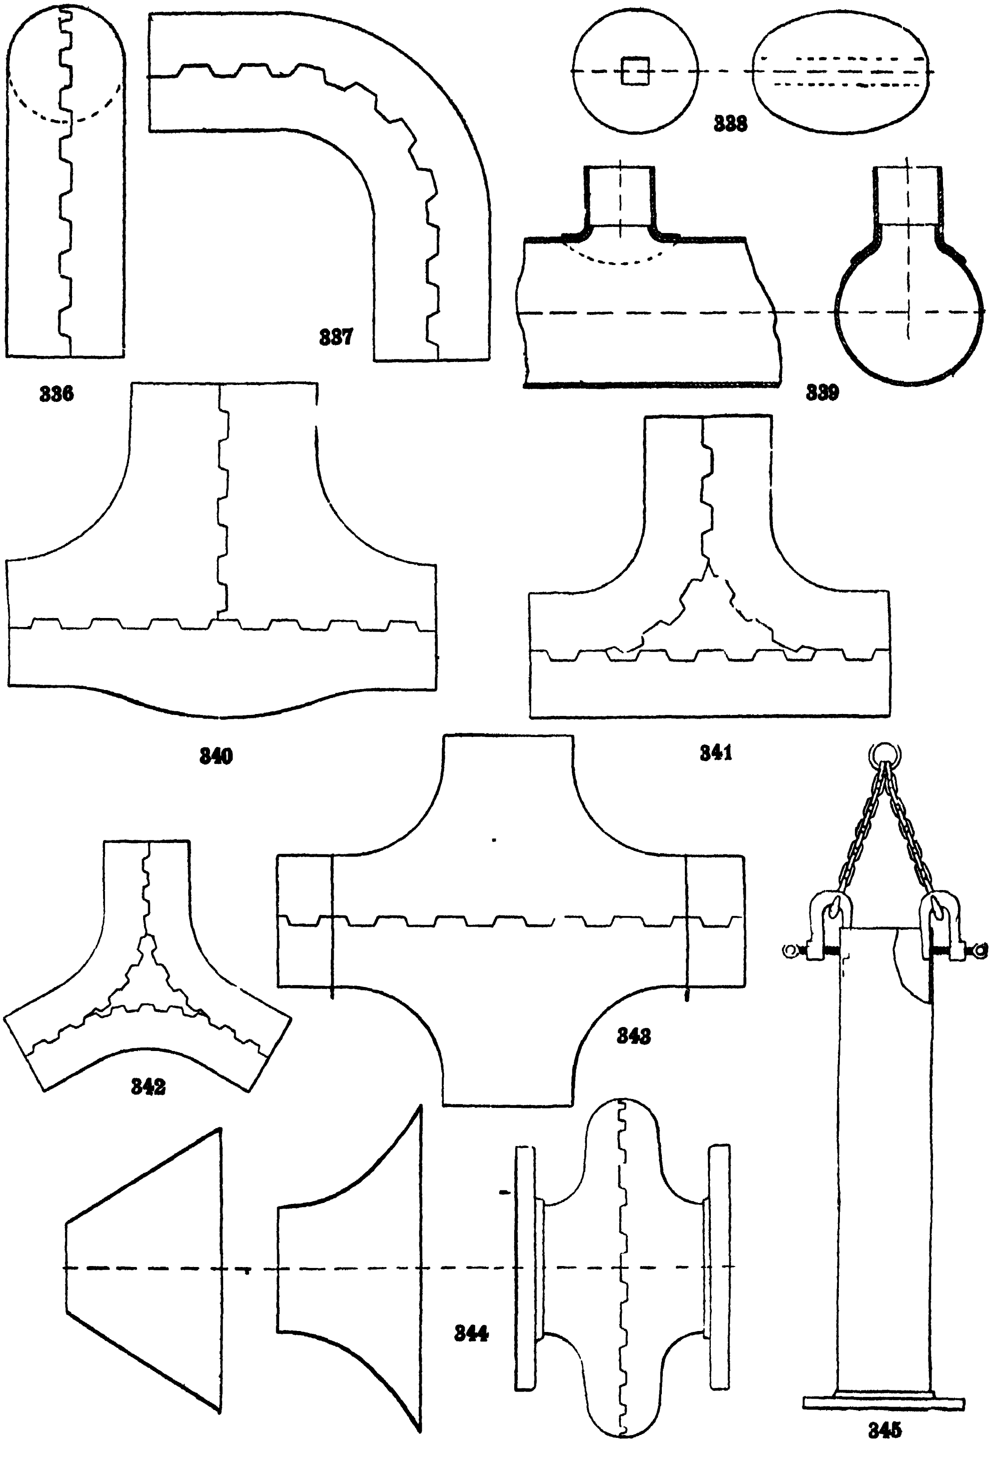
Templets. Pipes are generally tested during bending by templets of iron rod of from ¼ in. to ¾ in. diameter in smaller and larger templets [**332**]. The rod must be sufficiently stiff to retain its shape while being handled. The curves correspond with the centre of the pipe being bent, and the templet is laid upon the pipe from time to time as the bending proceeds. Templets of wood [**333** and **334**] are frequently made by the pattern-makers or carpenters. The outlines of these correspond with the external edges of the pipe. They are of deal, about ¼ in. or ½ in. thick. If flanges are required, these are indicated by flanges nailed on the ends of the board and secured with brackets, as shown.

There is a different kind of templet, termed the *templet board* [**335**], which is not used to give the curve of the bends, but their lengths. Its purpose is to fix the exact positions which the flanges have to occupy in the marine engine or locomotive, so that they go into place without any tentative fitting. In repetitive work a model of the part in which the pipes have to fit is kept. Thus the steam pipes for locomotive smoke-boxes are fitted in a model box, and go into the engine only when the work is finished. The templet board [**335**] comprises two boards, hinged so that they can be set to right or other angles, with wing or quadrant pieces, and clamped, and the faces of the flanges are fitted against them at the lengths required. They are most useful for repair work, since a broken pipe can be pieced up and repaired to correct lengths by first fixing the templet board correctly, and marking the positions of the flanges on the board.

Made Bends. The term *made bends* signifies bends that are not bent from straight pipe, but are made in halves from copper sheet, which is hollowed to the forms required in *hollowing blocks* and over *tee stakes*. The halves may be joined at the sides [**336**] or along the interior and exterior radii, *throat* and *back* [**337**]. This is more difficult work than mere bending of pipes, because the metal has to be upset on the shorter radii, and drawn on the larger, and wrinkles will form which will have to be worked out over the tee stake. The joints are made by cramping, and closing over a *cod* [**338**] on a mandrel standing out from the mandrel block. Allowances have to be made for the bending and puckering which takes place, and much practice is necessary to ensure good results. In manipulating large bends for brazing, the halves are pulled together with an encircling chain and bolt slung suitably over the fire, so that they can be readily manipulated without crushing the fire.

Tees and Branches. These are attached to pipes by soldering or brazing, though in some cases they are cut from the solid sheet. When fitted, the end next the pipe is bell-mouthed and flanged slightly, and the flange is fitted to the curve of the main pipe [**339**]. A hole is cut in the latter, smaller than that in the branch, to allow metal for turning outwards to enter the *flaring* portion of the branch. The burred edge is made to fit neatly within, and the flange on the outlet to fit the pipe body neatly. The joint is then ready for securing. If it be soft-soldered, the joint faces are now thinned; if to be brazed, the flange of the branch is coated with spelter solder. The spelter is strewn on the face and melted, and spread evenly over it. It is then placed on the pipe and secured with binding wire, and the pipe laid on the forge. Spelter and borax are strewn on flange and pipe adjacent, and the parts are heated up slowly at first, and more rapidly as the heat increases, until the spelter runs through the joint.

Made Tees. Large numbers of *tee-pieces*, or three-way [**340** to **342**], and *four-way*, or *cross-pieces* [**343**], are made from copper sheet, which is cut, cramped, and brazed. There are different ways of jointing adopted—in the plane common to the branches, in saddles or throats, or at right angles therewith, with gussets [**341** and **342**] or without gussets [**340**]. Large bends are better made with the joint in the throat and back (*saddle*



ENGINEERS' COPPERSMITH WORK

336 and **337.** Made bends **338.** Cod **339.** Branch fitting **340-342.** Tee-pieces **343.** Cross-piece **344.** Expansion joint **345.** Pipe suspended for brazing a flange on and *back*) than in the other direction, though many are made in the latter way. Fig. 348 shows a tee piece, but the jointing may be done in alternative ways, as in bends.

Expansion Joints. Expansion joints [344] are in frequent use, and are made by two conic frusta in the first place, with cramped seams, which, after being drawn out round the edges by hammering, are cramped in the central plane of the expansion piece and brazed. The brazing may be done from inside or outside. The figures to the left show one coned piece, and the same when drawn out or bell-mouthed,

Flanges. Large numbers of flanges are brazed on copper pipes. The pipes are slung vertically with flanges lowermost [345]. A little clearance is allowed for the spelter to run in. The hole is slightly tapered, and, properly, the end of the pipe should be. The flange bore is countersunk on the face side, and the pipe very slightly opened out [see also 346]. The countersink is filled with fine soft clay, to prevent the spelter from running away. Sometimes the heat has to be prevented from going up the pipe by filling it up with a plug of wood or cotton-waste, or, in large pipes, with an iron disc luted with fine clay.

COPPERSMITH WORK AND TOOLS

346. Steam-pipe with flange and cone **347.** Hollowing a hemisphere **348.** Steam-dome covering **349.** Hammers **350.** Stakes

Fig. 346 shows the internal steam-pipe of a locomotive that runs from the tube plate to the regulator. It has a flange brazed at one end, as in 345, and a cone at the other. Both are bored to fit the pipe, and brazed when in a vertical position. The countersunk or burring over at the flange end will be noticed, and the recess in the top of the cone piece to receive the solder. The cone is covered with fireclay and plumbago during the brazing.

All flanges to braze to copper pipe must be of pure copper, or of *brazing metal*, 98 of copper to 2 of tin; or a mixture of 1 lb. of old copper to 1 lb. of brass tubes. If flanges are supplied of ordinary gunmetal they will melt before the spelter fuses. In such a case the melting point of the spelter must be lowered with slight additions of zinc.

Hollow Spheres. Hollow spheres [347] are produced by hollowing in halves, which are brazed together. The diameter of the disc to form, when raised, the half of a sphere is obtained by the well-known property of the sphere—namely, that its surface is equal to that of its circumscribed cylinder, or equal to that of four discs of the same diameter as that of the sphere. So that the surface of each disc would be equal in area to that of two discs of the same diameter as the sphere, to which allowance must be added for seams. Hollow spheres are made in solid halves, or in halves as a frustum of a cone, and a bottom or *pan* cramped and brazed in; the latter being sometimes more convenient than having to find metal for large discs. If a disc

351. COPPERSMITHS' SHOP (Isaac Storey & Sons, Limited, Manchester)

be used, a circle is struck from the centre having a diameter equal to half the diameter of the disc to serve as a guide for *wrinkling* into cup or pan form first. Next, the wrinkles are worked out with the hammer over a stake and smoothed, which is the stage in **347**. Annealing follows, and the wrinkling is repeated in courses. Then the *lag*, or angle between the sides and bottom, is hammered out on a stake, and the curve of the side and bottom produced. After annealing, cleaning, and planishing, the halves are ready to go together. If the halves are produced each by cramping a bottom in a conic frustum, the conic frustum is formed by a cramped* and brazed joint, and the bottom cramped and brazed in. Afterwards the spherical form is imparted by hammering.

Dome Coverings. Dome coverings [**348**] are made in sheet brass in two pieces, a cylinder and a crown, brazed with cramped joints. The diagram shows the operations clearly, The foot is worked round by hammering, and the top or crown in a hollowing block, or at the mandrel block in courses, annealing being done between the courses. After smoothing, it is cramped and brazed, being slung on the traveller chain. The brazing is done in detail, one cramp at a time. The cover shown has a hole in the top. When this is not the case the cap piece may be cupped out in the solid, or it may be made with a hole as shown, and a crown piece cramped on and brazed.

Fig. **349** shows a few only of the principal hammers which have been referred to in this article. They are the *hollowing* (A), the *planishing* (B), the *razing* (C), the *creasing* (D), and the *riveting* (E). Fig. **350** shows some of the stakes, A and B being bullet stakes, straight and cranked, C a horse with stake inserted in the end, the angling of the horse being done to enable awkward work to be tackled.

Fig. **351** illustrates the coppersmithing shop of Messrs Isaac Storey & Sons, Ltd., at Manchester. Instead of the traveller chains, it is fitted with swinging jib cranes and an overhead traveller. Two pans are seen in the foreground, one to the right cramped ready for brazing, and one to the left already brazed. The brazing hearth stands just behind.

Behind the hearth the workman has a bend pipe suspended over a mandrel sticking out from the mandrel block. At the extreme left-hand lower corner a hemispherical piece is having its wrinkles taken out by planishing. At the extreme right lower corner a condenser is being fitted up. Various templets will be seen hanging on the right-hand wall.

FOOD FOR DAIRY STOCK

Being a Brief Enumeration of the Various Grasses, Forage and Leguminous Crops, and Concentrated Dry Foods suitable for Dairy Cattle

By Professor JAMES LONG

Value of the Grasses. In supplying food to the cow it is more advantageous, because more economical, to provide a mixed ration, where the animals are stall-fed, than food of one particular kind. Thus, during the grazing season a cow obtains upon the pastures, unless they be very inferior, a mixture of grasses, clovers, and other herbage which not only belong to different natural orders but which are differently composed. Grass is the most important food of the cow, and it is important in proportion to its quality and variety. Grass, however, is a term applied to the herbage growing in pastures and meadows, and is, therefore, as already observed, a mixture of many plants. Both pasture and meadow under careful cultivation for hay provide a minimum number of inferior grasses and weeds and a maximum number of superior grasses and plants of the clover tribe, which, flowering at different periods, provide a succession of growths, and maintain, therefore, a sufficient bite for grazing stock. Although cows may graze during a large part of the year, the herbage is more or less abundant only between May and October, and unless the land be overstocked it is during this period that they improve in condition and yield the largest quantity of milk. Mature grass, partly owing to the fact that it contains more fibre than young grass, is of less value as a food. When young and succulent it is more nourishing and digestible, and when cut and dried it produces the best hay. There is no greater mistake than that usually made by those who leave grass crops intended for hay until they have passed maturity in the hope of obtaining a larger crop. The weight of hay gained may be greater, but quality is sacrificed. The value of grass, like hay, depends largely upon its richness in digestible albuminoids, and the proportion of these materials present in a sample is greater when the grass is young.

The Foods that Should Supplement Grass. Where soil is in poor condition the grasses are not only inferior in quality but in variety, nor do they grow so luxuriantly. The result is that it becomes necessary to supply the cows either with green forage crops to supplement grass or with meal or cake in order to make up for its deficiency in nutritive matter, and especially in the albuminoids. Where grass is luxuriant but deficient in clover herbage, an addition of a nitrogenous cake or meal is desirable [see page 2704], the clovers being the richest in nitrogenous matter among the cultivated pasture plants. The rainfall is also an important factor, and it is for this reason that corn-growing is common in the Eastern and grass in the Western counties. The systematic supply of manure, or the feeding of the cows upon cake, is followed by an increase in the clover herbage, especially in white clover, and where a pasture or meadow is well stocked with clover and perennial ryegrass—the latter a rich and important plant—its feeding value is considerable.

Varieties of Grasses. The farmer should make himself acquainted not only with the clovers and trefoils but with the superior and inferior grasses [see pages 872 and 940]. Among the former are foxtail, cocksfoot, perennial ryegrass, catstail or timothy, hard fescue, tall fescue, meadow fescue, and smooth-stalked meadow grass; while among the latter are red fescue, sheep's fescue, the brome grasses, fiorin or creeping bent, Yorkshire fog, and tall oatgrass. There are, however, many others of doubtful quality. Among the weeds, yarrow or milfoil, plantain, and burnet are sometimes classed, but these and other plants which belong to neither the grass nor the clover families and which are commonly found in pastures and meadows are in many cases relished by stock. The provision of liquid manure, which sometimes enables the scythe to cut four crops of grass in a season, as employed in Scotland and Switzerland with great advantage, very largely increases the weight of the crop; and this remark applies equally to the employment of farm sewage. This manure, chiefly the urine of the cattle, is distributed over the land immediately after the cut grass has been removed. It may be remarked that its influence is not only owing to its marked superiority over solid manure but to its liquid character, gratifying to plants at a time in which the soil is dry. The extra labour involved is more than repaid by the largely increased crop.

Feeding in Hot Weather. Cows are frequently fed on ryegrass manured with liquid, or upon forage crops of other varieties, lucerne, vetches, clover, sainfoin, maize, green rye, and cabbage, which are cut, and carried either to a dry pasture or to the stall in which they are tethered during the hot days of summer. Extra labour is involved in the cutting and carting; but, on the other hand, labour is saved in the better condition of the ditches and hedges, in the driving of the cows to and from the fields, in the prevention of their excited and roving habits owing to the heat and to flies, with the result that they do not break into the cornfields of neighbours, involving damage and unfriendliness. In the Channel Islands and in some parts of the Continent, especially in France and Denmark, cows are frequently tethered upon grass, a stake, to which a rope or chain is attached, being driven into the ground, and a limited supply allotted to each animal.

Hay. In many parts of England hay forms the principal part of the winter ration. As we have seen, it varies in quality with the age and character of the grasses from which it is made. If the grasses were old before cutting, the stems may be chiefly composed of useless fibre, the nutritious portion of the plant having passed into the seed, which, where cutting is too long delayed, is often shed upon the ground. In such a case hay is of but little value. Inferior hay contains a much smaller quantity of feeding matter than good hay. It may, nevertheless, be utilised if the feeding matter which has been lost be added in the form of cake or meal. Where hay is employed as a leading food a cow may receive from 10lb. to 25 lb. daily in accordance with what is supplied in the ration in addition. First-rate hay is usually too valuable to employ with freedom for milk production, especially when prices are high and when other foods costing less will secure an equally good result. Good hay is the best balanced of all dry foods. Owing to its fragrance and sweetness it is agreeable to stock, and from this point of view cannot be replaced, but for the production of butter and cheese it is inferior to grass. Early cut grass, which contains more moisture, demands greater care in making and stacking.

Forage Crops. The forage crops are chiefly grown for the dairy herd on the arable farm, but the grass farmer is wise in planting a small area, though succulent food may be employed during the months of July and August, when the pastures are frequently bare. Forage crops, without exception, are less well-balanced than grass, and therefore less useful when supplied alone. Unless they be mixed, as where oats or rye are grown with vetches, they should be supplemented with cake or meal to prevent loss by waste. Foods like lucerne, vetches, and clover, which are exceptionally rich in albuminoids, should be supplemented by a dry food rich in carbohydrates, while foods like green maize, rye, and cabbage, should in their turn be supplemented with a rich albuminous food like cotton-seed meal, bean-meal or pea-meal [see Table, page 2704]. If there be no addition the excess of albuminoids in one food is not utilised, while the excess of the carbohydrates is similarly lost in another.

The remarks upon foods which follow supplement those already made on pages 2702-6 and 2904-9, and refer to the special feeding of milking cows.

Leguminous Crops. Among the leguminous crops which are most suitable are lucerne, sainfoin, vetches and the clovers. *Lucerne* [page 1197] should, however, be given with food rich in starch. *Sainfoin* yields 15 tons to 17 tons per acre, and is twice cut. Like lucerne, it makes superb hay, and is suitable for cows, especially when rice-meal or maize-meal are added. *Vetches* or *Tares* are only once cut, although, when cut early a small growth follows. The winter vetch seed mixed with oats or rye provides a more suitable food for cows, coming early in spring, when they may be followed by spring vetches which are good in late summer and autumn. Like all similar succulent forage plants, the vetch should be cut a day before using. If supplied to the cows quite fresh, it may cause hoven, or distention of the abdomen, which is sometimes followed by death. The *Clovers* [pages 940-1] include the broad red, crimson and white trifolium, incarnatum, alsike, and trefoil, which are the most suitable as cow foods. They should, however, to be perfectly suitable, be mixed with grasses or fed on the pastures, or, if in stalls, supplied in conjunction with meal rich in starch, as already shown. Cows may be tethered on either the red or alsike variety, after becoming accustomed to the process. Where clovers are grown with ryegrass or catstail they provide a better balanced food.

Various Forage. *Cabbage* is grown on many soils and to great weights per acre. By the aid of cabbage, forage crops and roots, cows may be fed through the entire year on natural succulent rations. *Kale*, a variety of the cabbage tribe, may be cut twice. *Rye* [page 874] is perhaps the earliest of all spring green crops. The average yield is from five to six tons per acre, but owing to its early harvest its value is out of proportion to its small yield. *Maize* [page 1198] is essentially carbonaceous. Owing to its sweetness it is relished by cows, and produces no waste.

Roots and Tubers. The plants supplying these foods are costly in cultivation, but they have a double value inasmuch as they enable a farmer to clean his land, which they occupy with advantage in his rotation.

The *Mangel* [page 942] is the most important, although, owing to climate, it is generally supplemented by the swede in North Britain. It is harvested in October, clamped, or pitted, and usually supplied to cows from January forwards, keeping until after midsummer, although, owing to chemical changes, its feeding value, like its weight, is diminished. Since certain varieties are much richer in nutritive matter than others, while other varieties are greater croppers, the grower should endeavour to fix upon the variety which returns him the greatest weight of digestible matter per acre. From 20 lb. to 50 lb. daily may be supplied to each cow. The yellow tankards and globes are preferable to the long reds.

Swedes and *Turnips* are commonly used for dairy stock. The approximate percentage of dry matter in sugar in the various bulbs referred to is shown by the following figures, the result of the work of the late Sir Joseph Gilbert.

Roots.	Dry matter per cent.	Sugar per cent.	
		In fresh roots.	In dry matter.
White turnips ..	8·0	3¼ to 4½	44 to 56
Yellow turnips..	9·0	4 to 5	44 to 56
Swedes	11·0	6 to 7	55 to 64
Mangels	12·5	7½ to 8½	60 to 68

Swedes and turnips may be pulped, sliced, or cooked for mixing with the cow's ration of chaff, greens, and meal.

Kohl-rabi is but little used by the dairy farmer, although those who grow it for cows speak of it in high terms and in some cases prefer it to any similar food. Kohl-rabi keeps well throughout the winter, and communicates no ill flavour to the milk.

Probably owing to its sweetness, the *Carrot* is much relished by milking cows. Owing to the richness of the carrot in carbohydrates, it should be supplemented, when supplied in large quantities, by foods, such as cotton-cake, which are rich in albuminoids. The crop, when carefully stored, keeps well through the winter. The leaves may be fed with advantage.

The *Parsnip* [page 945] provides 12½ per cent. of digestible dry matter in its roots, 11½ per cent. in its leaves, of which in each case about 10 per cent. are carbohydrates and 1¼ per cent. albuminoids. It flourishes on a similar soil to the carrot, keeps well, but is not so much relished. The best field cropper is the Jersey hollow crown.

The *Potato* crop, when abundant and cheap, is frequently employed either cooked or raw.

Concentrated Dry Foods. These foods are chiefly the by-products of the milling of grain, of the processes of oil extraction from seeds, and of the manufacture of sugar, starch, and alcoholic drinks.

Linseed Cake [page 2907] is more useful for mixing with *cotton cake* than for employment alone in a ration. It should not be too hard, containing not less than 10 per cent. of oil, 28 per cent. of digestible carbohydrates, and 23 per cent. of digestible albuminoids. It is of high value in the rearing of young dairy stock. When broken it weighs 43 lb. to the bushel. The product of the cotton seed is used in three forms for cows—as meal, decorticated cake, and the common, or undecorticated, cake. The last-named is highly fibrous, and if less costly, is much less economical, as reference to the composition tables on page 2907 will show. The meal and the best cake are highly relished by cows, are of great value for milk and butter production, and are believed to make butter firmer than any other food.

Rape Cake possesses a disagreeable flavour, although it is very rich in feeding matter, and is consequently used in various patent foods. Owing to the small demand its price is low; but when used for cows patience must be exercised in inducing them to eat it readily. Another useful food, but little used in this country, is *Palmnut Cake*, which is readily eaten by cows. It is extremely rich in oil, and, when obtainable at £5 a ton, it is most economical. *Bean-meal* is highly nutritious, and weighs 50 lb. to the bushel. It is useful for employment with roots, cabbage, straw, inferior hay, rice or maize-meal. *Pea-meal* is richer than bean-meal, and may be similarly employed. English peas, however, like English beans, are usually too costly for cows; hence, imported pulse is employed. *Lentils* are frequently placed on the market, and if poor in oil, are rich in the other feeding constituents. Lentils weigh 63 lb. to the bushel. *Rice-meal* is extremely rich in starch and should be used on that basis alone. It should never be used without analysis. *Gluten Meal* is a residue in the manufacture of starch from maize. This is an American product of high value, when it is pure; but it is only in its experimental stage in this country. *Bran* [8] is a most valuable addition to the ration of the cow. Bran weighs 17 lb. to the bushel. *Sharps* or *coarse pollards*, like *middlings*, which are still finer, but richer in starch, are both useful foods when prices are low, and although less laxative, they are as rich and as sweet as bran. *Maize-meal*, which weighs 47 lb. to the bushel, is a highly concentrated and valuable food, largely used when the price is low. Compared with the oat, it contains 50 per cent. more feeding matter, weight for weight, when prices are identical. Maize-meal is especially valuable when cows are fed upon hay, herbage, or forage crops unusually rich in albuminoids. *Maize Germ Meal* is a comparatively new food, is rich in all the feeding constituents, and when pure and costing £4 to £4 10s. a ton, is a very useful addition to the ration of the cow; it is, however, frequently adulterated.

Oats [page 873], although a costly food, owing to its low weight, its price per bushel, and the proportion of husk or fibre, is one of the most valuable for milk production. A good oat, weighing 40 lb. to the bushel, and costing 20s. per quarter of eight bushels, provides 177 lb. of digestible feeding matter at a cost of about 11s. 6d. per 100 lb. A quarter of maize weighing 60 lb. to the bushel, and purchased at a similar price per quarter, produces 340 lb. of digestible feeding matter at a cost of about 5s. 9d. per 100 lb. Thus, in purchasing foods it is essential to consider not only the price per quarter or per 100 lb, but the actual cost of the feeding matter which each food contains [see page 2705]. Some allowance, however, may be made, as in this case, owing to the mechanical superiority and better balance of the oats as compared with maize.

Grains are obtained from distillers and brewers in a wet, and from merchants in a dry, or desiccated, form. They mix well with chaff and other foods. *Dried grains* may be used with confidence and success if the water be carefully added a day before they are to be used. They weigh 20 lb. per bushel. Brewers' grains are richer in phosphoric acid and lime than the barley from which they are produced. *Malt Culms*, *Germs*, or *Sprouts*, are the small dead radicles, or rootlets, of barley which has been malted. They are sweet, of agreeable flavour and odour, and well adapted for mixing with chaff and pulped roots.

The *straws* of cereals and pulse are of high value inasmuch as they provide the padding which is so essential in the feeding of an animal with such a capacious belly as the cow. The best straws are oat and pea, but wheat, bean and vetch straw are sometimes used. Al straws are preferably chaffed, or chopped, for mixing with rations. The chief feeding con

stituents are the carbohydrates and the cellulose, of which about one-half are digestible in the cereals and slightly more in the pulses. The pulse straws not only provide more feeding matter, but they are richer in albuminoids.

Adulteration. In the course of these lessons we have often referred to the adulterations to which dry foods are subjected, and the analyses undertaken by specialists and others holding appointments under the various county councils and agricultural societies. In the detection of adulteration the microscope is of the greatest use, for it is frequently only by it that admixture of foreign substances can be found out. Many vegetable substances, when viewed under it, exhibit characteristic markings or general appearances which serve to identify them and to indicate their presence; whereas, the differences of chemical composition as set out in the figures of an analysis would not be sufficient in themselves to indicate this. We give on this page an interesting series of microphotographs taken by Dr. J. Augustus Voelcker, Chemist to the Royal Agricultural Society. These show how the presence of certain forms of adulterants can be detected. In the top row are given the microscopic appearances of bran [8], coffee husk [9], and a sample of bran adulterated with coffee husk [10]. The cross-linear markings of the coffee husk are very clearly indicated.

In the second row are shown the appearances of linseed [11], corn-cockle seed [12], and of a sample of linseed cake containing these two mixed [13] Rape [14] and spurry [16] are other seeds that frequently occur as adulterants of linseed in linseed cakes. They each exhibit characteristic markings when viewed under the microscope. Fig. 15 shows the occurrence of rape with linseed in a sample of linseed cake

Oscillations and Waves. Coherers and Other Detectors. Transatlantic Wireless Telegraphy

By Professor SILVANUS P. THOMPSON

Oscillations and Waves. In the preceding article [page 3747] it was explained how electric oscillations can be set up in electric circuits in which there is a spark-gap; and the dependence of the frequency of the oscillations upon the capacity and self-induction of the circuit was described. We have now to deal with the relation between such oscillations and the electric waves to which they give rise, and further to explain how such electric waves are made use of for signalling, without wires, from one place to another.

Electric and Magnetic Fields. The first point is to get a clear notion of the *fields* that are set up in space by electric currents and charges. On page 562 it was explained how a current, even in a straight conductor, sets up an invisible magnetic field in the space surrounding it. In that case the field consists of magnetic lines that surround the conductor. Now consider the state of the space that lies between any surface that is charged with a positive charge and a neighbouring surface that is charged with a negative charge. This is the case within the layer of glass, or of air, that is acting as a condenser charged as explained on page 3580. The dielectric, whether air or glass, between the two charged surfaces is, as was there described, in a state of electric strain, there being electric lines of force through it from positive to negative, and these constitute an electric field. Now let us see how these things will be in the case of an oscillating circuit.

An Oscillating Circuit. Fig. 231 represents a simple condenser made of two flat metal plates with a layer of air between them. They are joined by a simple circuit made of bent brass rods, ending in polished balls, with a spark-gap between them, so as to be able to start oscillations, as described in the last article, by connecting them to a suitable source such as an induction coil. Just before a spark passes, one of the metal plates is highly positive, and the other highly negative, and then there will be an electric field across the air space between them. When the spark occurs, the positive charge rushes round the circuit into the plate that was negative, and then surges back again with incredible rapidity, oscillating along the conducting circuit. Each such rush constitutes a current, and as the successive rushes are in opposite directions the conducting wires or rods become the seat of an alternating current of high frequency. Consequently, in the space surrounding the bent wire there will be set up an alternating magnetic field. This magnetic field surrounding the wire will be strongest when the rushing current is at its strongest, and this occurs precisely at the moment when the condenser has been emptied, and before it is charged up again the other way by the continuance of the rush. But the electric field, which will also be alternating, and which lies in the crevasse between the metal plates, will be at its strongest at the moment when the rush either way is completed and the charge in the condenser is at its highest. So we see that with such an arrangement the electric field and the magnetic field occur in different places, and have their maxima at different times. Under these circumstances there will be no electric waves emitted.

Hertz's Oscillator. Suppose now that we open out our condenser into the form shown in 232, where the two metal plates, W W, are extended out like wings, and the communicating conductor, with spark-gap A in the middle, is made straight. The two plates can still act toward each other like the two coatings of a Leyden jar, the surrounding air being still the dielectric. When they are charged there will be an electric field extending from one to the other, as in 233. If a current were rushing up or down the conductor, it would make a magnetic field around the conductor as in 234. And if now a spark is made to pass, setting up a series of oscillations, the electric field between the wings will extend, as the dotted lines show, right across the space where the magnetic field will occur during the rushes of current up and down the rod. The electric field will not have died away before the magnetic field has begun to grow, and vice versâ; so that both kinds of fields can be present in the same space at the same time, and while the electric lines will be mainly parallel to the conductor, the magnetic lines will be transverse whirls surrounding the conductor. *For the production of electric waves it is necessary that there should be both an electric field and a magnetic field at the same point of space and at the same time.* This simple apparatus is capable, then, of throwing off into the space surrounding it an electric wave at each oscillation. Such waves do not return back into the system, but go travelling off into space with the speed of light, following one another as in 235. The more the metal plates present of free surface, the more freely do they radiate off electric waves. If they are of flat metal, the electric waves radiate off more freely from their flat faces than from their ends or edges. If set vertical, they radiate out mainly in front and behind; but they may be set horizontally at the ends of the system. The late Professor Hertz devised this simple apparatus in 1887 for the manufacture of electric waves. It is known as a *Hertz's oscillator*.

Hertz's Detector. To observe the waves thrown off from the oscillator, Hertz employed detectors which we should now think very inferior and insensitive; but they enabled him to detect the presence of electric waves in other parts of the large room where he was working. He employed a very simple device—namely, another circuit with a very minute gap in it, across which sedentary sparks could be seen to pass. Suppose we make a second piece of apparatus exactly like the first, with two metal plates, as wings, joined together by a rod, but with a minute gap, B, at the middle. The gap must be minute—about $\frac{1}{1000}$ of an inch—otherwise the induced electromotive forces may not be able to make the electricity jump across as a visible spark. Let these two pieces of apparatus, the oscillator and the detector, be set up, as in **236**, a few feet apart from one another in a big room. Let an induction coil or an influence machine be used to excite the oscillator and cause sparks to occur at A, then each such spark sets up oscillation in the metal of the oscillator, and each oscillation sets up a wave in the space around it. These waves spread invisibly through the room, and some of them, of course, fall upon the extended wings of the detector; each wave as it reaches the detector sets up an electromotive force in it, tending to move electricity from one wing to the other and back again, with the result that a new actual oscillation is produced in the metal of the detector, and if the stimulus so received be sufficient, there will be minute sparks seen—a spark at B every time there is a spark made at A. Hertz used principally a detector of even simpler form—namely, a mere ring of wire, or a plain rectangle of wire (as is shown in **237**) having a minute spark-gap in it. When once the sparks have been seen with the two pieces of apparatus a few feet apart, and the apparatus is in proper adjustment, it is easy to detect them when the distance between the oscillator and the detector is increased. Hertz was able to show that these electric waves could be reflected from a large sheet of metal, or collected by a parabolic mirror, or refracted through a prism of pitch; in fact, that they behaved like waves of light, but were quite invisible.

Other Detectors. Very soon other and more sensitive detectors were devised. Righi proposed to lay a long strip of metal foil on glass, and divide it across the middle with a knife, to form a minute spark-gap. M. Branly discovered that a heap of metal filings possesses the very curious property that, though it is usually a very bad conductor for electric currents because of the innumerable imperfect contacts between its particles, it yet becomes a much better conductor when an electric spark is made anywhere near it. Lodge and Fitzgerald found the imperfect contact made by a pointed wire resting against a metal plate to be sensitive to the action of an electric wave. Such imperfect conductors he called *coherers*, because the action of the waves was apparently to make their particles come into better contact. Taking advantage of Branly's observation he constructed *coherers* of metal filings enclosed in a small glass tube between metal rods inserted at the ends; and these proved very sensitive. He found that they required to be tapped after each operation to cause the filings to decohere; and proposed methods of automatic tapping. Fig. **238** illustrates Lodge's filings-coherer.

Coherer as Receiver. The method in which the coherer was used to receive or detect the electric signals is as follows: The coherer is connected to one voltaic cell and to a suitable galvanometer, all included in a simple circuit, as in **239**. The coherer has so poor a conductivity that practically no current passes. Directly an electric wave, however, falls upon the coherer, or upon the wires attached to it, it sets up oscillations, and probably also sets up minute sparks in the gaps between the filings. Whether this be so or not, it makes the coherer conduct better, so that the single cell of battery can send a current through the galvanometer, which thus signals the reception of the wave. The coherer must then be tapped, when the galvanometer deflection at once disappears in readiness for receiving the next signal. Lodge found considerable advantage in fastening on to the end of the coherer an extended piece of wire projecting out as an *antenna* to receive the wave. In some of his early experiments he enclosed the whole of the receiving apparatus in a tight metal case to exclude the effects of any stray waves, the only thing that projected out from the box being the receiving antenna. As such coherers are far more sensitive than Hertz's spark detector the distance between sender and receiver may be increased up to two miles or more, depending on the power of the transmitting apparatus.

Other Oscillators. Various other forms of oscillators were proposed by various experimenters. Lodge found that an exceedingly powerful emitter was made by a single polished metal ball between two smaller balls, as in **240**. Righi proposed two metal balls immersed in oil, and also an arrangement [**241**] of two large metal balls placed between two smaller balls which sparked into them. Marconi patented the combination of a particular kind of receiver with a transmitter having one end of its sparking appliance connected to earth and the other to an insulated conductor. In practice he adopted the device of a tall mast, with a spark-gap between two metal balls, one of which was joined to the mast and the other to the earth. Jervis-Smith found better oscillations if the sparks were made in compressed air.

Waves Emitted by Oscillators. In a simple upright Hertz oscillator such as **235** or **242** the two capacity-areas or plates at the top and bottom ends of the oscillator are the places which become most highly charged, the middle part of the connecting system being, as it were, a node in the potential wave. The same would be true of the same apparatus if used as a detector; the ends are the places which receive the maximum changes of potential. The middle part, on the other hand, is the seat of the strongest currents. But this is no longer the case if the oscillator (or the receiver) is earthed as to the lower half; for then the earth takes the place of the lower half, and the node in the potential wave occurs just above the earth, and half-waves [**244**] are sent out.

"We thus," says Professor Fleming, "arrive at the conclusion that if a vertical rod is set up in the air, and at its lower end there is a spark-ball in opposition to another spark-ball connected to an earth plate, that this arrangement constitutes electrically one-half of a Hertz oscillator; and the system of electric and magnetic force created, when oscillations are set up in the rod by charging it and discharging it across the spark-gap, is the same as that on one-half of a Hertz linear oscillator."

Earthed and Non-earthed Oscillators. Imagine a Hertz oscillator, entirely insulated, 200 ft. high, with its node at the middle as in **242**. Cut off its lower half just below the spark-gap and plant it in the earth: it will then act with the same frequency as before, but will send out waves of a different type—that is, half-waves, with the node at the bottom, as in **243**. Since, in *this* case, the earth takes an essential part in the transmission of the waves, as in **244**, it must be of good conductivity, wet soil, or sea. Earthed apparatus does not work well over a dry desert. The movement of the half-loops of electric force outward from an earthed oscillator—that is, a "Marconi aerial," as distinguished from the non-earthed oscillators used by Hertz, Lodge, and others—is hindered by bad conductivity on the surface of the earth, but is helped by a fairly good conducting surface such as that of the ocean. On the other hand, for non-earthed oscillators emitting whole loops of waves as in **235**, the action of the conducting surface of the earth is no help, or is even detrimental.

As the frequency of the oscillations is determined by the capacity and self-induction of the apparatus, it will clearly depend on the length from the node to the ends, and on the surface it presents; also, any coils introduced into it will increase its self-induction and lengthen the waves. Any oscillator which, like Lodge's polished ball, has relatively large surface and small self-induction, will radiate so freely that the wave-train will die out after very few oscillations. If the wave-train is thus very short, the detector cannot be tuned to it with any accuracy, and any untuned detector within range will pick up the waves.

Early Wireless Signalling. Apart from the researches of Hertz, the earliest exhibition of wireless telegraphing was that of Sir Oliver Lodge, who in 1894 sent wireless signals through stone walls and from one building to another, using as detector a filings coherer as described above, the system being untuned.

There are several modes of using coherers in the receiving circuit. (1) The coherer may be connected in series with a single cell and a galvanometer, or a direct telegraphic instrument, such as a siphon-recorder. This is Lodge's plan. (2) The coherer may be put to earth in circuit with a single cell and a sensitive telegraphic relay, which in turn actuates an ordinary Morse instrument, printing dots and dashes. This is Signor Marconi's method. (3) The coherer may be placed in circuit with a single cell and an ordinary telephone receiver. Thus, at the instant when the coherer changes its conductivity, a click is heard in the telephone. This is the method of Jervis-Smith and Castelli. For use with his method Marconi adopted a coherer consisting of metal filings in a V-shaped gap between two metal plugs in a glass tube, as **245**. For the third method, Castelli used a coherer with two drops of mercury between plugs of iron and carbon [**246**]. More recently, Lodge has adopted as a self-restoring coherer a small revolving steel wheel, slightly oiled, dipping into a drop of mercury [**247**].

Using a Righi oscillator, and a filings coherer with a relay, Marconi was able, in 1896-7, to send wireless signals 250 yards across the Thames; and with the help of the Post Office engineers he sent signals several miles. To extend the range he then adopted the plan, now claimed as essential to his system, of using a tall mast like a lightning conductor one end of which is in good connection with the earth, and called an "aerial wire," or "antenna," or "earthed vertical oscillator." Using masts of 120 ft. or more high, he had, by the end of 1898, been able to signal from 12 to 20 miles.

The Jigger, or Oscillation Transformer. Owing to the circumstance that the simple Marconi aerial resembles the Hertz oscillator in possessing a large radiation decrement, it cannot send out such trains of waves as would be required for syntonic working. In none of these early operations could tuning be secured, and they were liable to interference from stray disturbances in the atmosphere. If a source of persistent oscillations could be applied, the receiving apparatus could then be tuned to the sending apparatus, and the whole system would thereby be rendered far more sensitive for long-distance work. To accomplish this, the sending apparatus must in some way be linked up with an oscillation-circuit, such as was described on page 3749, and the distant receiving apparatus should similarly be provided with an oscillation circuit; then the two can be tuned together to the same frequency of oscillation. There are more ways than one of associating the wave apparatus with an oscillation circuit. The most usual one is by means of an oscillation transformer, called in telegraphic slang a *jigger*, and is due to Sir Oliver Lodge. This induction transformer is a simple arrangement for a primary coil of one or two open turns, surrounding or surrounded by a secondary coil of a larger number of turns.

Increasing the Range. A simple form of Lodge's device is illustrated in **248** and **249**, in the former of which a jigger is arranged for transmitting, while in the latter it is for receiving. J is the jigger, represented by two separate spirals; K is the condenser; A the spark-gap; E the cell; C the coherer; G the siphon-recorder or galvanometer. Apart from the advantage of tuning, there is another advantage in putting an oscillation transformer into the receiving circuit. For at the node of the receiving circuit the potential is a minimum, and the current a maximum ; therefore, as a coherer depends on the potential, and not on the current, the node is a bad place in which to insert the coherer, as was done in the early operations. By placing in the node the primary of the transformer, and inserting the coherer in the secondary, the increased voltage so applied to the coherer was found to increase its sensitiveness vastly, and therefore greatly extended the range of working. Marconi, being desirous of working over still greater distances than those already covered in 1899, adopted the jigger into his receiving arrangements, and was able thereby to extend his range to 85 miles, without even tuning. For transmitting oscillations the transformer was constructed as follows : It consisted of a square wooden frame, wound over with a number of lengths of highly insulated, stranded, copper cable, joined in parallel so as to make a primary circuit of one turn. In some cases, two or more turns may be employed. Over this was wound a secondary of five to ten turns. The oscillation transformer was usually immersed in oil.

Magnetic Detectors. Rutherford, now of Montreal, discovered in 1895 that electric waves can exercise a demagnetising influence upon a highly magnetised small steel needle ; and he made a magnetic detector of waves on this principle. He was thus able to detect the waves of a Hertz oscillator half a mile away across the town of Cambridge. The waves produced an oscillatory current, which was carried through a small copper wire coil around the magnetised needle. Seven years later, Marconi described a modified form of magnetic detector, in which an endless band of thin iron wires moving past a fixed magnet becomes magnetised, and is subjected to the demagnetising action of an oscillation coil connected to the receiving circuit. The inductive action sets up sounds in a telephone. Other magnetic detectors have been devised by Wilson and by Fleming.

Transatlantic Wireless Telegraphy. Determined to succeed in sending electric waves across the Atlantic, Signor Marconi, aided by Professor Fleming, constructed a powerful transmitting station at Poldhu, in Cornwall, and has since erected similar stations in Italy and at Cape Cod and Cape Breton. These stations have each four tall lattice towers between which is suspended a conical web of aerial wires. In a power-house an alternator generates powerful alternating currents, which in turn act on spark-gaps, producing oscillations of tremendous energy. From the station at Poldhu signals can be sent from 2,000 to 3,000 miles over the ocean, and have even been detected in the Mediterranean and at the Russian end of the Baltic. The Atlantic liners can be signalled to at any point of their journey, though the apparatus they may carry may not be powerful enough to signal back more than 200 or 300 miles.

German Developments. Professor Slaby, of Berlin, in association with Count Arco, and with the Allgemeine Company, has developed another system. In this an oscillation circuit is associated with the antenna in a way different from Lodge's. Slaby uses a second and horizontal antenna branching off from the vertical antenna near the ground. In this auxiliary antenna the spark-gap can be inserted at a place near the node ; and the oscillations set up in the horizontal branch set up a similar set in the vertical one. For receiving, the coherer is inserted in the branch antenna, not near the node but at the other end, between the branch and the earth. For syntonic working, oscillation transformers are introduced between the branch antenna and the spark-gap or the coherer as the case may be.

Professor F. Braun independently developed special arrangements for the inductive coupling of a closed oscillation circuit with an oscillation circuit suitable to emit electric waves. As condensers he used glass tubes partially covered inside and outside with a silver coating.

The devices of Slaby, Arco, and Braun have been taken over by a single interest and operated under the name of the Telefunken system. The name Telefunken signifies distant sparking

American Developments. In the United States several inventors, De Forest, Fessenden, Stone, and Shoemaker, have devised particular methods of wireless telegraphy, all of them claiming certain advantages. De Forest has produced several forms of detector which do not depend on the coherence between metallic powders or imperfect contact, but upon electrolytic phenomena. It was previously known that a film of moisture between two strips of tinfoil on a glass plate would act as a detector, and required no tapping. De Forest has used two small electrodes in water, in circuit with a telephone. Like Marconi he employs a tall mast. Fessenden has devised a detector consisting of a very thin platinum wire sealed into a glass bulb. The feeble oscillations which are set up in the receiver, passing through this wire, heat it, momentarily increasing its resistance. This device he calls a *barretter*, and it is included in a local circuit with a single cell and a telephone. He has found that a liquid barretter can be made with an electrolyte in a glass tube of extremely fine bore. This acts in the opposite way by decreasing its resistance.

Present Position of Wireless Telegraphy. Briefly, the present position is this : For the Atlantic service, the Marconi Company stand alone, and they have equipped the principal passenger ships of the Cunard and other companies. A much greater number of stations (over 400 altogether) in various parts of the world have, however, been equipped with a different system, that of the Telefunken Company. For overland service, on account of its not using any earth connections, and for its great perfection in working, the Lodge-Muirhead system is distinctly ahead.

AUSTRALIA & NEW ZEALAND

South Australia. West Australia. Tasmania. Physical Features, Products and Towns of New Zealand. The Pacific Islands

Group 13
GEOGRAPHY
27

Continued from page 3702

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

SOUTH AUSTRALIA

SOUTH AUSTRALIA was first settled, as the name suggests, round the inlets of the south coast. It now stretches across the continent and covers 903,700 sq. miles, the northern part forming the Northern Territory [185, page 3699]. Settlement is at present mainly confined to the south.

The colony, as a whole, is flat, though in the centre the Macdonnell and James Ranges reach 5,000 ft. In the south the Flinders Range rises west of the Murray, and is continued by the Mount Lofty Range, overlooking Adelaide. Much of the southern part is a region of lakes, some, like Lakes Eyre and Torrens, being large, but varying greatly in size at different seasons, others being mere chains of lagoons and holes. All are salt and low lying, Lake Eyre being probably below sea-level. The only river of importance is the Murray, which enters the sea through Lake Alexandrina.

Climate and Resources. The Northern Territory lies in tropical latitudes and has a heavy summer rainfall along the coast in the monsoon region. Both summer and winter temperatures are high. There are tropical forests along the coast, which is fringed with mangroves, while there are dense thickets of paper-bark tree along the rivers. The centre is dry, and passes into desert. As the south coast is approached, the salt bush appears, forming a poor pastoral region on which one sheep per ten or more acres is the utmost that can be supported. The rainfall of Adelaide is about that of the drier parts of England, and falls chiefly in winter. Long spells of drought are very common, and seem to recur periodically.

Much of the Northern Territory will never be anything but desert, but if underground water could be tapped by artesian wells, large tracts might be made available for pastoral and agricultural settlement. In the southern part of the colony sheep farming is by far the most profitable employment, but agriculture is spreading in the Murray Flats, and may develop with irrigation. A considerable acreage is under wheat, but though the quality is very fine, the yield is extremely scanty. Soil and climate are suitable for fruit growing, and the vine, fig and olive do well. The mineral wealth is chiefly in copper. [See AGRICULTURE, page 3236.]

Towns. The towns of South Australia are generally small townships of a few hundred inhabitants. Adelaide, the capital, is finely situated on the Torrens, near the base of Mount Lofty. The city has fine streets and buildings, and is surrounded by a broad belt of parks. Mount Gambier, in the extreme south-east, near the Victorian boundary, is the centre of a fertile district. Gawler, north of Adelaide, is in a wheat growing district. The richest copper mines are at Wallaroo, on Spencer Gulf, and at Moonta, a few miles inland. In the Northern Territory is Palmerston, overlooking the fine harbour of Port Darwin.

WEST AUSTRALIA

West Australia (975,000 sq. miles) is the largest of the Australian colonies. The greater part of the interior consists of a waterless plateau, dotted with lakes, which, in the dry season, are glittering surfaces of dry salt and mud, and filled with brackish water after the infrequent rains. This plateau comes down to the sea on the south coast, forming the harbourless cliffs of the Great Bight. Along the west coast its higher margin rises above the coastal plain, which is of varying width. In the Stirling Mountains, which rise behind Albany, these marginal heights reach 3,500 ft. in the extreme south ; but in the Darling Range, which runs north for 300 miles, they do not exceed 1,500 ft. Further north, the plateau margin recedes 200 or 300 miles from the west coast, rising in the Kimberley region in the north to 2,300 ft. [185, page 3699.]

The rivers are confined to the western coastal region, rising in the highlands already mentioned. As the interior is extremely dry, many of them are mere empty watercourses, except after rain. The Swan, at the mouth of which Fremantle has been constructed, is the most important.

Varieties of Climate. The climate of West Australia is tropical in the north, with a summer rainy season. This forms the Kimberley region, the coastal portion of which bears tropical forests, and permits of stock-keeping in the river valleys. Among the stock are camels, introduced from India and South Australia for transport in the desert interior. Away from the coast, the climate rapidly becomes extremely dry, and the greater part of the colony is stony or sandy desert, bearing little vegetation but the dreaded spinifex. A tongue of desert, marked in maps as the Eighty Mile Beach, extends to the coast north of the De Grey River, separating the Kimberley region from the more temperate portions of the colony. In the latter the summers are cooler, and the rainfall along the coast moderate in quantity. The most thickly settled portion is the coastal strip from Geraldton to Albany. Most of this region has a Mediterranean climate with winter rains, and can raise cereals and fruits, the vine and orange doing especially well. The forests of the south-west contain magnificent timber, including the gigantic jarrah and karri eucalyptus. Away from the coast the plateau is extremely dry, and the population has not penetrated more than 500 miles inland, attracted by the sensational discoveries of gold. [See AGRICULTURE, page 3235.]

The Rush to the Goldfields. A solid belt of auriferous country, only interrupted by the Eighty Mile Beach, appears to stretch along the edge of the plateau from north to south. The tropical goldfields are difficult to develop, owing to the exhausting nature of the labour, which in these latitudes cannot be done by white men.

In 1891, the population of the whole colony was under 50,000, but the discoveries of 1892 in the Coolgardie region immediately led to an inrush of population. "The track, which ran eastwards through the primeval bush, was a curious sight in those days. Heavy waggons, laden with flour, chaff, and whisky, lumbered axle-deep through the mud, drawn each by its team of a dozen great horses in single file, for 1893 was a wet season." Now, a railway from Perth runs to Coolgardie and the surrounding goldfields, the richest of which is Kalgoorlie, some twenty miles beyond Coolgardie, in the desert. To drive the engines and fill the sluices of the Kalgoorlie mines, water is pumped for more than 200 miles through steel pipes from reservoirs near the coast. At Kalgoorlie is the famous Golden Mile, containing half a dozen of the richest mines known. Other well-known fields are the Murchison, the Yalgee, the Yilgarn, the Mount Margaret, and the Dundas, and many rich goldfields are doubtless waiting discovery. The pioneer prospector in these waterless regions takes his life in his hands, and should he be successful, and return safely to civilisation, the almost prohibitive difficulties of transport and water supply have yet to be overcome. The cost of living on the goldfields is extremely high, and since the inrush the colony is unable to raise food enough for its population. The total value of the gold obtained in West Australia in 1903 was approximately £8,770,000.

Towns. Perth, the capital, is situated on the Swan River, some ten miles from Fremantle at its mouth, the chief port of the colony. Geraldton, the most important town north of Fremantle, is the port for the Murchison district, which, in addition to gold and minerals, produces wool. Cue, the chief town of the Murchison Goldfields, is some 300 miles inland. Coolgardie and Kalgoorlie are both connected with the capital by rail. The chief town in the south is Albany, on King George's Sound, a coaling station for the British Navy, and a place of call for many steamers.

TASMANIA

Tasmania (26,000 sq. miles) is somewhat smaller than Scotland, which it rather resembles in scenery. The interior consists of a plateau, cut by the valleys of the rivers, and rising, in Ben Lomond in the north-east and Mount Cradle in the north-west, to over 5,000 ft. [137].

The picturesque lake, river, and mountain scenery make Tasmania a favourite summer resort for Australians. Lying in the track of the westerly winds, it has an equable climate, not unlike that of Southern England, and rain at all seasons. At the time of its discovery it was covered with forests, which have been partly cleared for agriculture and sheep farming. They still provide valuable timber, including eucalyptus of giant size. In addition to sheep farming, much attention is paid to fruit growing, and Tasmanian apples are largely exported. Hops are also grown, and the usual temperate cereals.

The capital is Hobart, at the base of Mount Wellington, on the Derwent, which flows to the dangerous but picturesque Storm Bay. Launceston, on the Tamar, is the chief port in the north.

NEW ZEALAND

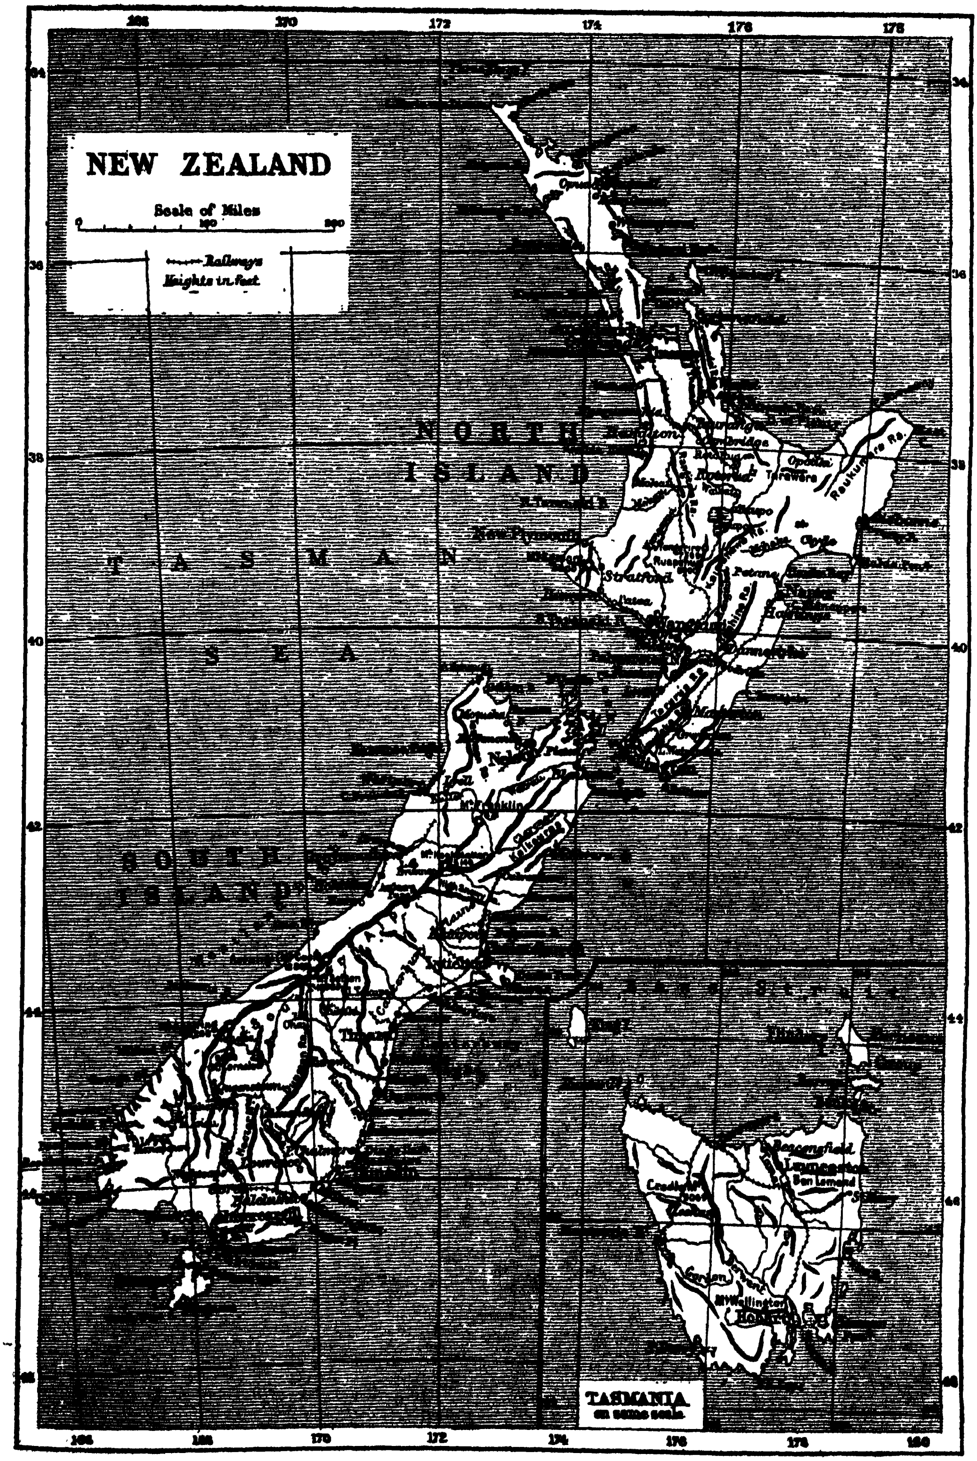
New Zealand (104,750 sq. miles) consists of the large islands of North Island (44,500 sq. miles), South Island (58,500 sq. miles), Stewart Island (665 sq. miles), and many smaller islands.

New Zealand turns, as it were, its back to Australia. The west coast of South Island is deeply cut by magnificent fiords, but these give access only to lofty and inaccessible mountains, whose glaciers descend to within 1,000 ft. of the sea. The west coast of North Island, though lower, has no good harbours, and access is from the east, where all the important harbours are situated. Cook Strait, which separates North and South Islands by thirteen miles of sea, has good harbours on both shores.

Mountains and Rivers. The west coast of New Zealand is almost everywhere high. In South Island it is bordered by the Australian Southern Alps, rising to the height of the Bernese Oberland in Mount Aorangi or Cook (12,300 ft.). The New Zealand Alps contain fine glaciers, and their scenery is of true Alpine character. They are continued to the south by the mountains of Stewart Island, and to the north by the western mountains of North Island, which reach 5,600 ft. West of these western mountains of North Island, and quite independent of them, rise three volcanic cones. Ruapehu (9,000 ft.) and Tongariro (7,500 ft.), with its triple summit are still active, but Egmont (8,200 ft.), rivalling Fujiyama in its faultless symmetry, is extinct. The surrounding region, with its geysers and hot lakes, is one of the most interesting volcanic districts in the world. The famous pink and white terraces were destroyed by the eruption of Tarawera in 1886. The Western Highlands give rise to many rivers, which flow east following the slope of the country. They are of no great use for navigation, being either too swift or too shallow. The lower eastern half of New Zealand is the settled portion.

Climate. The climate of North Island is considerably warmer than our own, the summers averaging from 65 degrees to 68 degrees, the winters from 48 degrees to 55 degrees. The climate of South Island is not very different from that of Southern England. The islands lie in the path of the west winds, and their western coasts receive heavy rains. East of the mountains the rainfall is lower, but sufficient for agricultural purposes.

Vegetation, Resources and Occupations. The wetter parts of New Zealand are densely forested, evergreen pines and beeches predominating. One of the finest trees is the kauri pine of North Island, which yields



187. NEW ZEALAND AND TASMANIA

magnificent timber and a valuable gum. Large quantities of this in a fossil state are obtained.

The drier eastern regions are grass lands, originally covered with fern or coarse grass. Much is now sown with European grasses. On these grass lands are grazed enormous numbers of sheep, bred for meat as well as wool. A large trade is carried on in frozen mutton, which is exported in steamers fitted with special refrigerating chambers. Cattle are also bred, especially in the west, and the dairy industries are rapidly growing. Much frozen butter is exported. Other occupations depending on the pastoral industry are wool-washing, bone-crushing, boiling down, tanning, and such manufactures as boots and shoes and woollens.

Agriculture is increasing in importance. Oats are the principal cereal, and wheat, which has a much heavier yield than in Australia, is grown in the Canterbury Plains. Potatoes are an important crop. Fruit growing is not yet important, but might easily become so. [See AGRICULTURE, page 3466.]

New Zealand has valuable minerals. In 1903 the output of gold exceeded £2,000,000, chiefly from the Thames basin in North Island, the north-west of South Island, and the river sands of the south-east of South Island. Coal is mined in several places, but much has to be imported.

Seaports. The capital is Wellington, on Cook Strait in North Island, but the most important town is Auckland, on a narrow isthmus, with a harbour on either side. Thames, Napier and New Plymouth are smaller North Island ports. In South Island, Lyttelton is the port of Christchurch, on the Canterbury Plains, which have a southern port in Oamaru. Dunedin, and Port Chalmers on Otago Harbour, and Invercargill, on Foveaux Strait, are the chief southern, and Hokitika and Westport the western ports.

THE PACIFIC ISLANDS

The Pacific is studded with island groups of which the most important south of the Equator are the Solomon Islands (British), the New Hebrides (under British and French protection), Fiji and Tonga (British), Samoa (United States and Germany), Society and Marquesas (French). North of the Equator are the Marianne and Caroline Islands (German), and Hawaii (United States). All are either highly volcanic, densely forested islands, or low coral islands with little vegetation but coconut palms. Economically, the most important are Fiji, Samoa, and Hawaii. Rice, cotton and sugar are grown in Fiji and Hawaii, and all the islands supply more or less copra, the dried flesh of the coconut. The chief centres are Honolulu on Hawaii, Apia on German Samoa, the United States naval harbour of Tutuila on Samoa, and Levuka and Suva in Fiji. The French island of New Caledonia (8,000 sq. miles), between New Guinea and New Zealand, is a penal settlement. It has great mineral wealth and is the chief source of nickel ore.

AUTOMOBILES

Goods Vehicles. The Commercial Motor Body. Metal Construction and Weight Cutting. Pleasure Vehicle Design. Coachbuilders' Machinery

By H. J. BUTLER

OUR railway trains run on fixed highways, and therein lies one of their greatest drawbacks. Most railway companies look to the carriage of goods as the chief source of income, and there are instances where it has been the sole object for which the railway was formed. In the United Kingdom there are about ten times more goods railway vehicles than passenger vehicles, and one-eighth more receipts from the former traffic.

Flexibility of the Motor-car Service. The motor-car is not confined to a set of iron rails, and it may be loaded up at the warehouse and despatched direct to the customer without the expense of any intermediate handling. We may therefore look forward to the development of the commercial motor in the near future, and probably it will benefit commerce as the railway has so magnificently done. By the adoption of motors we do away with the dangers of two-wheeled vehicles and falling horses.

For carrying the mails, the Government are adopting the new traction in many types, from the tricycle carrier up to the large mail van. The market gardener brings his fruit and vegetables quickly to Covent Garden or other distributing centres without delay and in safety. Very often he has been glad to accept the new state of affairs, owing to the behaviour of the railway companies in charging rates that are very high in comparison with the charges made for transport from the Continent and America. Those who have many calls to make—as commercial travellers or carmen—find that they cover more ground in a day by the use of a motor-car.

Goods vehicles are not only in the majority on the railway, but horsed vehicles are also used chiefly for commercial purposes. Therefore it is seen that vehicles are designed principally for the distribution of goods.

The Commercial Motor Body. As Motor Engineering is discussed elsewhere in this EDUCATOR, the bearing that mechanical improvement will have on the development of the transport of goods by motor will not be dealt with here. Still, the question of the bodywork, so often ignored, is worthy of attention.

Frequently we see bolted to the châssis a mere box, often badly finished and designed. Sometimes the body is projected too far over the hind wheels, which not only looks bad, but is a continual source of skidding. The motor-car manufacturer often makes his commercial châssis sizes without consulting the coachbuilder, and he absolutely refuses to alter them until he is compelled either by losing the support of his customers, or by his rivals designing more useful frames. No doubt, a short and narrow châssis is desirable where possible, but a little more width and more regard for a useful length of châssis behind the dashboard is essential, if serviceable bodies are to be designed.

The Engineer's Shortsightedness. Another cause of unsatisfactory bodies is the fact that the body is often entrusted to the motor engineer, or to his specifications. He generally has little respect for the superstructure, considering it a mere item of the whole. In many cases he insists on the lowest possible price, and binds the coachbuilder to delivery in so short a time that good workmanship is impossible. Nevertheless, the motor-car engineer grumbles just as if every advantage had been given to ensure a highly finished useful body. One cannot expect the body-builder to spend any time in evolving fresh designs, or taking particular care in little details and the general effect, if every inch of stuff and every minute of time must be considered. Let the body-builder have a fair price and time to do his work.

Design for the Laundryman. This trade requires a van designed to facilitate distribution of the hampers of clean linen. When collecting the soiled linen, no special arrangement facility is necessary, but much time will be saved if the van may be unloaded from a side divided into shelves, so that one hamper may be removed without disturbing the others. The safety of the contents will be increased if the floor slopes a little to the centre. Most châssis are built lower on the ground than the horsed type, and this is a great advantage, as the hampers are more easily handled. The whole may be roofed over, and to the roof a luggage rail may be attached for taking extra hampers, especially empty ones. From the edges of the wooden canopy, waterproof side curtains, which may be drawn out of the way in fine weather, should be attached.

Ice Motor Waggons. In the distribution of ice to fishmongers, hotels, and other establishments, we see a very useful application of the motor. We can understand why ice should reach the customer without delay. The vehicle body should be isolated from the heat of the engine, and the space between its double panels packed with a non-conducting material, such as felt. Improvements in draining the body are certainly wanting in some of the horse-drawn types, where the results of melting are allowed to drip all over the undercarriage. The quicker the interior of the body gets rid of its superfluous moisture, the longer the ice will keep. The inside might be lined with zinc, while the ice blocks in their encircling blanket stand on narrow wooden laths, the water running down to a metal floor, which, for preference, should be drained towards the centre and to the rear. Railway waggon floors are drained in this manner.

Fruit Motor Waggons. The carriage of fruit also demands care and promptitude in its despatch. Lately, we have been confronted with the large supplies of bananas that reach these shores. The Great Western Railway has done signal service in bringing the supplies promptly to town, and when punctually met at the station by the road van, their deposit at the wholesale fruiterers in a perfect condition is ensured. Fruit often requires to be protected from extreme cold or heat, and contact should be prevented as much as possible. Properly ventilated vehicles arranged either to accommodate hanging bunches or to take on its shelves and partitions small baskets, is the most serviceable design.

Mail Conveyance by Motor. The remarks concerning the design of the laundry van might be applied with advantage to the construction of the vehicles carrying the parcel hampers and letter-bags, although extra means for safeguarding the load must be provided. This side method of loading is certainly useful for emptying quickly, which is necessary with postal work, and we may note a passenger parallel in the method of seating the firemen on the manual or steamer. We cannot fancy our friends in the brass helmets sitting face to face in a waggonette and descending calmly one by one from a narrow downway to a narrower step and finally to the ground. No, they jump in a group before a door handle could be turned.

Commercial Travellers' Motor-cars. There have been many attempts to provide a useful vehicle for the traveller. It is necessary that he should get into his car easily, and not be perched aloft as in some undesirable patterns. If he can take hold of a box of samples before he leaves the car and without going to the back, so much the better. He should therefore sit facing towards the side of the car a little so that the opening immediately behind his seat may allow him to enter the body proper, where there is just room for him to turn round with all his boxes arranged on shelves around him. The interior may be lighted by a small skylight or a neat electric lamp.

Doctors' Motor-cars. A doctor should keep to the old order of things unless he can afford a small medium-powered single landaulette with roof extension to the dash with the chauffeur seated on a single central seat. He has few things to take with him, and this type of vehicle is at once dignified and suitable for all weathers. Why a rabbit-hutch contrivance in which both the professional man and his chauffeur are boxed should be considered desirable is a matter requiring much reflection. The landaulette need not be made wide enough for two between the standing pillars if it be necessary to reduce weight to a minimum. A width of 2 ft. 9 in. allows of a comfortable seat and room for a bag and books of reference.

Cars for Heavy and Light Bulky Loads. Hitherto when transporting heavy material such as boilers and machinery, it has been found most economical to use ordinary horse-drawn vehicles coupled to a small traction engine. Most of the heavy motor lorries are quite as high as the horse-drawn types. With mechanical improvements we shall probably have cranked bodies as we have seen in pleasure car châssis, such as the Darracq and Talbot. Bulky loads, such as farm produce, and empties are often carried by means of trailers.

Front-driving Motors. A motor coupled up to the front wheels, such as the "Latil," is useful when desiring a motor van to carry theatrical scenery or long lengths of timber. The transmission of the power to the far away hind wheels would mean great loss of power and entail an amount of heavy shafting, etc. This type of motor might be made useful for the transport of other light bulky loads besides scenery.

Motor Omnibuses. Perhaps the chief way in which the utility of the motor-car is impressed upon the general public, especially those who cannot afford to possess one, is by means of the public service vehicle.

The electric tramcar partakes of both the railway and the motor-car, but the "'bus," be it single or double decker, is an automobile proper. Rather than see how many passengers we can crowd on a certain châssis, it would be far better if each passenger were allowed a little more room, even at the expense of reducing the carrying capacity by three or four. It is the untiring effort on the part of the different companies to wedge their customers into the smallest possible legal space, and this is the reason why the corridor carriage is not yet more generally adopted on our railways. Motor 'bus promoters, who grumble so much at tramcars, will do well to copy some of the interior comforts of the latter.
